FROM the eighth century to the time of the Reformation the history of education in England, France, and Germany was in many respects similar. The one champion of learning was the Church; and in the religious house we find an organised and established system of education of which not only the lower rank of people, who could not pay for their learning, but noblemen and gentlemen's sons might take advantage. In England the system was particularly successful; as early as the year 1201 there is said to have been more than 3000 scholars at the University of Oxford, and Roger Bacon tells us that the never had been so great an appearance of learning as so great an application to study as at that time, when schools were erected in every city, town, and borough. The learning of Englishmen compared favourably at the early date with that of scholars on the Continent. We are told that in 1169 there was a "colony" of English students at the University of Paris, belonging to the faculty of arts of which it is said that they "in particular were numerous that they occupied several schools or colleges, and made so distinguished a figure by their genius and learning, as well as by their generous manner of living, that they attracted the notice of all strangers."

Against the Church, in this matter of education, was arrayed both the general opinion of the aristocratic class and also the power of the law. Not all the sons of gentle-

1 From a paper read at the North of England Education Conference, Leeds, on January 8, by Otto Siepmann.

men were left in utter ignorance. Younger sons gave themselves with increasing frequency to the studies of good learning, though those who inherited their fathers' estates were usually of the familiar type. The daughters of the upper classes were not infrequently educated by the Church, but the fact remains that the provision made for education in religious houses, and in the grammar schools that were founded in the twelfth century, was in the main intended for the poor citizen's and ploughman's children. Winchester (founded in 1373) was probably the only school that did anything before 1450 for the education of the poor. Even there the number of poor to paying scholars was as seven to one.

Yet England was, so far as education is concerned, the leading nation of Europe at this time. Progress was steady, and the respect for learning, starting among the lower classes, gradually forced its way upwards. The revival of learning in Italy, and in Europe generally, facilitated the progress of education in England, and disposed of the contempt originally felt for scholarship by the aristocracy; but while the introduction of the study of Greek enhanced the value of education, the recognition of literary culture by the upper classes of society began to take it the privilege of the rich, to the exclusion of the poorer scholars, whose monopoly it had originally been. The great principle upon which the Church had built up its system was abandoned. Rich men's sons were turning poor men out of the endowments meant only for the poor. *Les gros poissons mangent les menus.* "Poore men are supplanted by the rich, the weak by the strong, the mean by the mighty."

But the fatal event was the dissolution of the monasteries, and the final destruction of the Church's system of education, which had raised Englishmen to a height of culture to which the other nations of Europe could not attain. The effects were immediate and disastrous; by one blow the whole English educational system was crippled and almost destroyed; until the end of the nineteenth century the effects of that fatal step were still felt, and it is only recently that efforts have been made to reorganise and restore what at that time was destroyed.

The Reformation, which was the ultimate cause of the downfall of the English system of education, was in Germany the decisive influence which led to the establishing of education upon a broad and stable basis. Up to that time education had been dominated by the Church, and had existed, in the first place, for the Church, and the results had not been so satisfactory as in England. Since then the State, the municipal authorities, and, above all, the parents, have taken an ever-increasing interest in the education of children.

The leader of this great movement was Martin Luther. In his "Epistle to the Burgomasters and Councillors of sundry Cities in German Lands," written in 1524, he declared it to be the duty of cities, and of secular authorities in general, to provide good schools and to encourage attendance; and, at a later date (1530), in his "discourse on the duty of keeping children at school," he urged the authorities, even, if necessary, at the public expense and with the aid of compulsory measures, to draw clever boys to the pursuit of learning in order to provide competent men to fill the public offices.

The outcome of this movement in favour of general education for all, and the pursuit of advanced studies by gifted scholars, is to be seen in the foundation of a large number of grammar schools, in the reform of the universities, and in the establishment of elementary schools in which reading, writing, catechism, and singing were taught.

In spite of various set-backs, such as the thirty years' war, this system of education survived in its main outlines until the end of the eighteenth century. In the nineteenth century it was developed by the introduction of modern sciences, modern languages, and their literatures, as compulsory subjects in secondary schools, and by their admission into the curriculum of the universities; but the present system in Germany has evolved, under the combined influences of Humanism and the Reformation, from that which was established as a result of Martin Luther's movement.

The importance of France in the history of education is

mainly confined to its influence upon higher education. The failure of the Reformation left the educational system of the Church very much as it was; but in university education France took a leading position in the Middle Ages. The University of Paris, which attracted, even in the twelfth century, many students from all countries in Europe, became the prototype of German universities founded in the following century; but elementary education in that country has remained in a deplorable condition. In 1866 24 per cent. of the recruits could neither read nor write, and twenty years later a similar percentage of those who were married were unable to sign the register.

The new era in the political, economic, and educational history of the world may be said to begin with the year 1870. The history of education in the three countries since that date is so familiar to you that I may proceed at once to the present state of affairs, first of all in Germany. In elementary education Germany had a start of more than a century as compared with England. For rich and poor alike attendance at the elementary school had been compulsory in every German State for more than a hundred years before the Forster Act became law. The system is of long standing, and experience has shown that the organisation and working of the arrangement are practically perfect.

The curriculum in German elementary schools is of the simplest. Originally the three R's, religious knowledge, and singing were the only subjects taught; to these have been added at various times the elements of geography and history to stimulate interest and encourage patriotism, and, for pupils of the upper standards, a certain amount of natural history. The compulsory school age is from six to fourteen, and although there is some diversity in the excellence of the school buildings, they are, for the most part, airy and good.

In Germany the State does not exist for the individual: the individual exists for the State, and the State considers that it is to its own advantage to have, above all things, a high average level of knowledge and ability. This the Germans have certainly succeeded in attaining in elementary education, and it is in this high average that their great superiority in elementary education consists.

Let us now turn to the German secondary schools. The organisation is as complete as in the case of elementary schools, and the principle is again the same. Individual prominence must be sacrificed to raise the common average; and to this must be added another principle, equally important and similar in its effects, that all subjects are taught in form; this applies to every school and to every boy from the first to the last day of his career.

The education of a boy in secondary schools may proceed upon any one of three lines. It may be classical, semi-classical, or modern. For centuries Germany clung to a belief in the classical system for higher schools, but the force of circumstances eventually necessitated the formation of two new types of school, each designed to give a liberal education of a different kind. Yet the classical Gymnasium still holds its own (although there is no longer any very close attention paid to composition in Latin and Greek), for in 1908, of the freshmen who matriculated at Prussian universities, 77 per cent. came from Gymnasien, or classical schools.

The Realgymnasium, or semi-classical school, is differentiated from the Gymnasium by the fact that, while Greek is not taught at all, modern languages, mathematics, and science receive greater attention. The Oberrealschule is purely modern in its curriculum, and excludes both Latin and Greek. All three types have a nine years' course, usually begun at the age of ten, preceded by three or four years at an elementary or preparatory school, which is often attached to the college. All these schools are established by the State or by the State in conjunction with the municipality; their fees range between 5*l.* and 6*l.* per annum.

There are some to whom the principle upon which these schools are founded will appear to be radically false, however good may be the discipline and the organisation in its execution. As the main intention is to make it possible for a high percentage of the pupils to pass the leaving examination, practically the whole form has to be pro-

moted from one stage to the next, and the amount of work set for the form to master has to be small enough to be done by some of the more stupid boys in the given time. The inevitable result is that the ablest boys mark time from first to last throughout their school career. They have a year to do work which they could do in half the time, so that their powers are never developed by sustained or strenuous effort.

Individual excellence is sacrificed in yet another way, according to the second guiding principle of secondary education stated above. Since all subjects are done in form, a particular aptitude for a special subject is never developed at school. Our best boys in any given subject attain a far higher standard before they leave school than is possible in Germany. Yet by preventing the possibility of specialisation at school the German system ensures for every boy a sound general education. Every boy is compelled to take all subjects prescribed by the syllabus of his school. Only recently, and in isolated cases, has this rule been remitted in the highest forms by way of experiment.

At the university all this is changed. There is no prescribed course of studies of any kind, and no compulsory attendance. The German student enjoys almost complete liberty, both as regards his studies and his behaviour. Yet in the majority of cases he makes good use of his time, partly because his allowance will not admit of any vast extravagance, partly because his position in life frequently depends upon his passing the final examination, but chiefly, I think, because those Germans who go to the universities do so, for the most part, because they have pronounced and genuine intellectual interests. The freedom which they are allowed in the choice of their subjects, and the general lack of supervision and of interim examinations, react favourably upon the results of their work. They carry into life an active interest in some branch of knowledge, which they frequently pursue as long as they live.

The German Government is convinced that education will be the determining factor in the future of the nation. In 1908 the Prussian Minister of Education framed a whole new scheme of regulations intended to prevent mechanical learning and routine work, to foster self-reliance and personal initiative in the pupils of the elementary schools. Observation is to be encouraged in open-air lessons and expeditions, and the children are to learn something of the working of commerce in modern times, of the means of transport, and of Germany's colonial activity; and in continuation schools commercial education is being put within the reach of an ever-increasing number of students. In 1907 there were, moreover, 1600 industrial continuation schools for boys, and 50,000 students were working at rural continuation schools as compared with 8000 twenty years before. The State contribution for industrial continuation schools has been increased 100 per cent. since 1901.

Besides all this there has been a remarkable increase in *Realschulen* and *Höhere Bürgerschulen* with a six years' course, of which Prof. Sadler has given such a flattering account in special reports. In the technical colleges of university rank the increase in the number of students is almost as striking. Mention should also be made of the National Chemical Laboratory, for which a fund of a million marks is to be raised. The Prussian Government has offered a site for the building free of cost, and the results of its erection should be of world-wide importance. New academies of commerce have sprung up at Cologne, Frankfurt, and elsewhere, and the Hamburg Colonial Institute is to be made into an establishment of university standard for those who intend to give their lives to colonial enterprise.

On turning to France we find, in a minor degree, two of the prominent characteristics which we noted in German education, first, a profound sense of the unique importance of education, and a serious effort in recent years to improve the existing system; secondly, that genuine intellectual interest which is imparted to pupils in the secondary schools.

As in pre-Reformation days, France is chiefly distinguished for its secondary and university education. Primary education is still in a lamentable condition, for the law of 1882, which made it compulsory, is practically

a dead letter. Of four and a half million pupils, nearly one million were recently found not to be in attendance on a given day. The percentage of illiterates is even now increasing. M. Steeg, the chairman of the Budget Committee, in submitting the estimates for 1909, said:—"While in Germany and Switzerland there is not one illiterate in 200 inhabitants, in France, out of every hundred young men, four or five cannot read, and out of every hundred young women six or seven are absolutely illiterate." As a matter of fact (according to the *Haarwörterbuch für Staatswissenschaften* of 1908), the number of illiterates in Germany was two in every ten thousand recruits, in France 400, while in England 300 out of every 10,000 people married were unable to sign their register. The alarm caused by the increasing illiteracy in France has led to severe criticism of the methods and scope of the instruction in primary schools. The main fault found with the official course of instruction is that it is too ambitious. The higher primary schools, intended for children between the ages of twelve and fifteen, are more satisfactory in their results, but they are few in number. There are also practical schools of commerce and industry of which there were sixty in 1907, but they interfere with the general education of the children by taking them for practical training at the early age of twelve. Private enterprise has in recent years provided continuation schools at which there were in 1907 half a million adult attendants and these are at the present moment under the consideration of the French Government. The so-called *universités populaires*, for the spread of political and social theories are on the decline.

Secondary education comprises the Lycées established by the State in conjunction with the municipalities, and the Collèges established by the *communities*. Following a preparatory course of two years, the Lycée course proper is divided into two cycles; the lower cycle covers four years, and comprises a classical course and a non-classical course; the upper cycle comprises three years. The programme for the first two of the three years is arranged in four parallel courses, as follows:—(a) classical course; (b) Latin and modern languages; (c) Latin and sciences; (d) sciences and modern languages. Following these two years is the class of philosophy and mathematics, each side comprising a classical and a non-classical section. The bachelor's diploma is awarded to students who complete either of the full secondary courses of instruction and pass the degree examination.

As regards universities in France, that of Paris stands out with great prominence. It is richly endowed, and receives from the State nearly five million francs per annum. It is a vast and excellent institution for teaching and research. Its library consists of about 580,000 volumes, and the most eminent scholars of the country are among its professors. In January of last year there were 16,935 students attending this great University, while at fourteen provincial universities were attended by over 18,000 students, and their income proper amounted to more than two and a half million francs, besides two million francs from loans; but it is to be expected that the provincial universities in France will have a prosperous future before them, since the energy displayed in the past and the work done by professors and students are of high order.

Besides the universities, France possesses several special schools of university rank, all of which enjoy a high reputation, among them the Collège de France, the *École Pratique des Hautes Études*, the *École Nationale des Chartes*, and the School for Oriental Languages.

Impartial judgment of the French system of education reveals a great deal that is excellent, especially in secondary schools and at the universities. The progress made since 1872 is very considerable, though much yet remains to be done.

If the study of educational systems prevailing abroad of special interest to us at the present time, it is because England's attention has been attracted by the commercial and industrial success of other nations which have long since held the conviction expressed by Signor Luzzatti at the scientific congress at Padua in September last in the words:—"The fate of nations is nowadays decided in the secondary schools." The belief that there may be so

truth in this bold assertion has rapidly gained ground among Englishmen who have the welfare of the nation at heart, and those who are directly interested in the severe competition in trade and commerce that has come with the enormous advances made by Germany and the United States in industrial and commercial enterprise. Although there are probably still a large number of Englishmen who have their doubts about this magic power of education, the experience of the last forty years and the revelations that have been made about other countries, together with the fact that foreign competition is felt to become a little uncomfortable, have made this educational question sufficiently urgent for the Government to take the matter in hand, and as a result we have a large department of the Government with a responsible Minister of Education at its head, and a most active Permanent Secretary, all hard at work to set our house in order.

The schools we require are (1) an elementary school with a modest and simple curriculum; (2) a municipal or county secondary school of the type of the German *Realschule* with leaving age sixteen, in which French, German, and English, elementary mathematics, and elementary science form the staple of education; (3) a modern school with leaving age nineteen, in which the same subjects are taught, but carried further, and in which Latin should be an alternative to one of the foreign languages; (4) a classical school, in which Greek, Latin, and English form the backbone of the teaching, and mathematics, science, French, and German hold a subordinate place. This type of school would naturally be one for the able boys, for they alone can reap the full benefit of such a wide course, but I am convinced that they can cope with it successfully; those who cannot do so should be rigidly kept out of it. Boys of the modern and the classical school should be admitted to the universities after having passed through the top form and after passing a leaving certificate examination in the subjects of their curriculum. Scholars from the elementary school should pass on to the municipal or county or modern school at the age of ten, and there should be attached to the elementary school a technical or industrial department for boys who are apprenticed to a trade, which they should attend for two years—from fourteen to sixteen—as part of their period of apprenticeship. Such a school has recently been opened by the London County Council as a day technical school for boys in book production (printing, book-binding, &c.). A similar department might be attached to municipal or county schools for boys from sixteen to eighteen, in which, according to the locality, agricultural, commercial, or industrial subjects of a practical nature should be taught.

You may think that these ideas are Utopian; I do not; in fact, I am convinced that if the nation has the will the authorities will find the way, and, though it be a costly enterprise, I venture to say that England never made a better investment, not even in Dreadnoughts.

"Caveat consules ne quid detrimenti capiat res publica."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—The ordinary course of instruction given by Captain Lyons, F.R.S., lecturer in geography, has proved so successful that a higher or second-year course has been instituted in addition, with the approval of the Senate and Court of the University.

The annual meeting of the Institute of Metals will be held in Glasgow on September 21 and 22 in the natural philosophy building, which has been granted for the purpose by the University Court.

The principal has received intimation of a gift of 5000*l.* for the general fund of the University from the trustees of the late Alexander Fleming; and of a grant of 2000*l.* for the provision of additional lecturers and assistants in the faculty of arts from the committee for the better equipment of the University.

The first sod on the site of the buildings in Kelvingrove Park for the Scottish Exhibition of National History, Art, and Industry, 1911, was cut by Lord Tullibardine on April 22. The promoters of the exhibition have promised to present to the University a sum of 15,000*l.* from the

profits for the foundation of a chair of Scottish history and literature. Meanwhile, Sir Herbert Maxwell, F.R.S., and Dr. William Wallace have been appointed university lecturers in Scottish history and Scottish literature respectively.

At the graduation on April 18 six graduates received the degree of D.Sc. for original research. One was a lady and one a Japanese naval architect. Thirty-one candidates were admitted to the degree of B.Sc.

Sir William MacGregor, who is a medical graduate of Glasgow, has been requested to represent the Senate at the semi-jubilee of the foundation of the Royal Geographical Society of Australasia, to be celebrated at Brisbane in June.

MR. J. A. SMITH has been elected to the Waynflete chair of moral and metaphysical philosophy in the University of Oxford, in succession to Prof. T. Case, who resigned last term.

THE committee of the Central Bureau for the International Interchange of Students (of which Lord Strathcona is the president and Lord Brassey the treasurer) has opened an office in Caxton House, Westminster, to facilitate educational travel, for all university men, graduates or otherwise, with the view of assisting them to gain a first-hand knowledge of the life, needs, progress, and potentialities of other English-speaking countries. Travelling scholarships for undergraduates are being raised at nearly all the universities. They will be tenable this summer, and will provide a valuable educational tour of a practical character through Canada and the United States for students whose return to their own universities will allow for the dissemination of their widened outlook and inspiration among their contemporaries. Already a few of the scholarships are completed. The scholarship tours are intended to be of great educational interest, and to illustrate the more important spheres of activity—administration, the scheme of education, industry, social work, &c. The places at which stops will be made are chosen accordingly. Private persons who are prepared to conform to the rules made to govern the tours, and to defray their own expenses, will be allowed to join these tours. A number of university men, both staff and students, as well as non-resident graduates, are arranging to travel independently under the auspices of the bureau, which freely provides them with introductions, information relating to places offering the best facilities for the study of a given subject, and special rates of travel. The bureau aims at being a clearing house of information on education of a practical kind for students throughout the world; and among its more immediate objects are the promotion of a standardisation of work among the universities which would enable a student to take a part of his course in another university than his first Alma Mater. It desires to encourage a greater exchange for post-graduate work. The expenses of organising and conducting the scholarship tours are not inconsiderable, and further donations are needed. They should be sent to Lord Brassey. A sum of 1000*l.* has been offered conditionally on a further 6000*l.* being forthcoming. The various sums raised for scholarships will count towards this total, but donations to the central fund are necessary to enable the work to be effectually carried on. Further information will be readily given on application to the honorary secretary, Mr. H. W. Crees, at Caxton House.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 14.—Sir Archibald Geikie, K.C.B., president, in the chair.—E. N. da C. Andrade: The viscous flow in metals, and allied phenomena. These experiments on the flow of metals were carried out on wires, which were subjected to a continued constant stress. The increase of stress which takes place owing to thinning if the wire is stretched by a constant load was avoided by having the stretching weights made in the form of hyperbolæ of revolution, and letting them sink into water as the wire lengthened; the size of such a weight can be chosen so as to keep the load per unit area of cross-

section constant. The metals treated were lead and a lead-tin alloy; the general nature of the results was the same in both cases. When suitably loaded there is a rapid initial flow which gradually settles down to a steady flow, for which the rate per unit length of wire flowing is constant right up to breaking. Throughout the experimental range the extension can be represented closely by the formula

$$l = l_0(1 + \beta t^k)^{1/k}$$

β is taken as a measure of the more rapid initial flow, which we call the β flow; k as a measure of the coefficient of viscous traction. The curves κ /(stress) against stress are hyperbolæ with one asymptote parallel to, one steeply inclined to, the axis of stress. β tends to become constant as stress increases; for a series of experiments on lead done at 160° C. β tends to the same constant value as for the series done at room temperature. This supports the suggestion that β measures a definite physical effect, dependent on some geometrical structure. For the alloy the β flow is relatively very small.—Clive **Cuthbertson** and Maude **Cuthbertson**: The refraction and dispersion of argon, and re-determinations of the dispersion of helium, neon, krypton, and xenon. The refractive index of argon has been determined for seven points in the spectrum with improved apparatus, and careful re-determinations have been made of the dispersion of the other four inert gases in order to bring them all up to the same level of accuracy. The refractivities are expressed in the form

$$\mu - 1 = C/(n_0^2 - n^2),$$

and the constants of these equations, calculated from the observations by the method of least squares, are shown in the following table:—

Element	$C \times 10^{-27}$	$n_0^2 \times 10^{-27}$
Helium	2.42476	34991.7
Neon	5.18652	38916.2
Argon	9.43264	17008.9
Krypton	10.6893	12767.9
Xenon	12.2418	8977.9

The values of the refractivities derived from these equations generally agree with those found experimentally to one or two points in the fifth significant figure. It is satisfactory to find that the values of n_0^2 now obtained by these more accurate measurements do not differ by more than 2 per cent. from those published by the authors last September.

—Dr. J. O. Wakelin **Barratt**: The action of the radiation from radium bromide upon the skin of the ear of the rabbit. The ear of the rabbit was exposed to the action of the radiation from 1 mg. of radium bromide spread over a circular area of 7 mm. diameter, and the resulting pigmentation of the skin was studied. It was found that pigment was deposited most abundantly opposite the edge of the disc of radium salt. The deposit, when viewed under a low magnification, presented a characteristic reticular appearance. The larger spaces enclosed by the pigment, which were more or less polygonal, contained hair follicle groups, but the smaller spaces were free from hair follicles. A certain amount of pigment was also deposited in a diffuse manner, chiefly opposite, or a little outside, the edge of the disc. This, when marked, caused the reticular pattern to be somewhat obscured. The deposit of pigment was not quite uniform, but tended to take on a punctate character. Opposite the centre of the disc of radium salt a varying degree of depigmentation occurred, though at the same time here and there a small amount of pigment, arranged in an imperfect reticular pattern, could sometimes be recognised. The pigmentation was chiefly in the epidermis, the cutis vera being less affected. The depigmentation also affected both epidermis and cutis vera, but was, however, more striking in the latter than in the former. No change in the pigmentation of the hair shafts was observed. In a white rabbit the pupils of which presented a red reflex, prolonged exposure to the action of radium bromide caused the appearance of an exceedingly slight reticular deposit opposite the applicator. With this exception, all the rabbits employed had black or mixed black and white coats. Attempts were made to obtain pigmentation by the action of radium upon human skin, but were not successful.—Prof. Silvanus P. **Thompson**: A physiological effect of an alternating magnetic field. If in a darkened room, or with eyes

closed, the head is placed in an alternating magnetic field of sufficient intensity, there is perceived over the whole region of vision a faint flickering illumination, colourless or of a slightly blue tint. The period of the flicker is not well defined. It does not seem to be the same over the whole field of vision at the same time, nor is it equally bright over the whole field of vision. Even in daylight, with the eyes open, one is conscious of a sensation of flicker superposed on the ordinary vision. It has not yet been definitely ascertained whether there is any relation between the direction of the axis of the field with respect to the position of the skull. No after-effects of any kind have been observed. The alternating magnetic field, the intensity of which (quadratic mean) was about 1000 C.G.S. units, was produced by sending a current of about 180 amperes through a coil of thirty-two turns formed into cylindrical form about 9 inches in internal diameter, the current having a frequency of fifty periods per second. No effect on the senses of smell, taste, or hearing has been observed. (Added April 14, 1910.—Several of the observers have noticed a sensation of taste after two or three minutes in the alternating magnetic field.)

Faraday Society, April 5.—Dr. J. C. Cain in the chair.—W. P. **Dreaper**: Nature of the action of dyeing. The abnormal reactions obtaining in the case of "ingrain" colours when the dye was produced *in situ*, as compared with the same dyeing effect when the same dyes are applied as direct dyes in relation to their subsequent resistance to resolution into solvents; the variations in the rate of fading of picric acid on different fibres under the influence of dehydrating reagents acting through a vacuum as compared with the equivalent action on the acid itself; the abnormal reactions obtained when the dyes of the indicator class (e.g. methyl orange) are subjected to the action of acids in the presence of fibre substances; the variations in resolution of the dyes from the fibres brought about by differences in temperature of dyeing; all these were, it was claimed, proof as to the important influence of certain factors in determining the fixing power of the fibres for dyes, this varying as the conditions of dyeing. It was also pointed out that the dyes were definitely fixed in some way on animal fibres, so that they might even resist the subsequent action of acids, as proved by these colour changes.—Prof. W. W. Haldane **Gee** and W. **Harrison**: The electrical theory of dyeing. The literature relating to the causes of dyeing reveals great differences of opinion as to the physical and chemical phenomena involved. The basis of the electrical theory is that when any two bodies are placed in contact they are oppositely electrified. In the case of tinctorial chemistry, one of the bodies is a non-conducting solid and the other a liquid. There does not seem to be any direct method of obtaining the value of the potential difference between such bodies. The authors avail themselves of the classic theory of von Helmholtz, which enables the potential difference between a liquid and a porous diaphragm to be deduced. They have determined the nature of the charge on the particles in suspension and in colloidal solution, and find that in water all basic substances are positive, the hydrochlorides of basic dyes positive, all acid substances negative, and most neutral substances negative. They find the speed of the particles under electrical stress to be of the order 20×10^{-5} cm. per second, per volt, per cm. Negatively charged particles attain their maximum speed at about 40° C. By measuring the difference of electrical pressure between the two sides of a diaphragm when the liquid is filtered under mechanical pressure, the authors find the approximate value of the contact difference between fibres and water to be:—cotton, 0.06 volt; silk, 0.22 volt; wool, 0.90 volt. The influence of temperature shows a maximum charge at about 40° C., and a minimum at about 80° C.

Linnean Society, April 7.—Dr. D. H. Scott, F.R.S., president, in the chair, succeeded by Mr. H. W. Monckton, treasurer and vice-president.—A. **Henry**: Elm seedlings showing Mendelian results. There are but two species of elm in Britain, *Ulmus montana*, With., and *U. glabra*, Mill.; both are known in the east of England as "Wych-elm." There are, in addition, many so-called varieties, the most remarkable being the "English elm" of British botanists and foresters, confined to the south of England,

nd styled *U. campestris*; this tree is unknown on the continent. The "Huntingdon elm" he regarded as a hybrid, the first cross between the two species cited. The previous year had been noteworthy for the profuse fruiting of every kind of elm in England, due to the fine autumn of 1908 and the abnormal amount of sunshine during the spring of 1909. The author had procured abundance of seeds of numerous varieties and forms, and from many localities. These had been sown, and their progeny analysed. It was shown that the plants thus arising conformed very closely to the Mendelian formula of 9:3:3:1. The author gave, in confirmation of his views, the experience he had with regard to the black Italian poplar, *Populus nigra* × *deltoidea*, the cricket-bat willow, *Salix alba* × *fragilis*, and the Luccombe oak, *Quercus Cerris* × *uber*, namely, that the offspring of a first cross invariably produced a crop of the most diverse character, and this induced the author to formulate his view, that when botanists were unable to agree about the forms of a given plant, it was due to a mixture of at least two species, and where there was practical unanimity, as with varieties of beech and ash, there was only one species concerned, and the varieties were due to individual peculiarities. He finally insisted upon the importance of planting trees of a first cross, on account of their abnormal luxuriance and rapid growth, and their producing timber far more quickly than either parent.—**F. Chapman**: The Foraminifera and Ostracoda from soundings, chiefly deep water, collected around Funafuti by H.M.S. *Penguin*.

Physical Society, April 8.—Prof. H. L. Callendar, F.R.S., president, in the chair.—**B. S. Cohen**: Demonstration of telephone currents in loaded and unloaded lines. The demonstration showed the relationship between the sent and received currents in telephone lines under the various conditions which occur in practice. By the aid of Prof. Kennelly's formulæ it is possible to calculate the relationship between the sent and received currents under any conditions met with in practice, and for some of the conditions used in the demonstration the calculated results had been obtained. Four essentials were necessary for the experiments shown:—(1) A current comparable to the actual telephonic speech current. This was obtained from a vibrating wire interrupter giving a wave with a fundamental of about 100 ~ per second with a damped oscillation of about 800 ~ per second superimposed. (2) A telephone line with or without its load in the shape of inductance coils. (3) Terminal apparatus. The lines were terminated by receivers and induction coils as used in practice for what is known as local battery working. (4) Current measurers. For this purpose barretters arranged as alternating-current ammeters were used. The first experiment showed the relationship between the received and sent current for various lengths of standard cable unloaded. The second experiment illustrated the variation in the current sent when the receiving end was open or closed circuited and the length of cable was varied. The third experiment showed the current distribution along the loaded cable by inserting a barretter at different points along the cable. The author gave explanations of the various phenomena illustrated in the experiments. He pointed out that it is now possible to make both calculations and quantitative telephonic tests which give mutual confirmation.

PARIS.

Academy of Sciences, April 11.—**M. Émile Picard** in the chair.—**G. Bratu**: Certain non-linear integral equations.—**Paul Lévy**: Non-linear integral equations.—**B. Galitine**: The vibration of buildings. Gas engines, not perfectly balanced, and running at a high velocity, have been found to set up vibrations in the surrounding buildings which were not only unpleasant to the inhabitants, but gave rise to dangerous cracks in the masonry. The ordinary seismograph is not suitable for studying this class of vibration, so that an instrument has been specially designed for this purpose. A description of the instrument is given, and the theory of its working.—**M. Dussaud**: Sources of light with reduced surfaces employed normally or obliquely. Movable sources of light. Practical applications.—**F. Charron**: The lubricating action of air in the friction of solids. Friction in a

vacuum. An apparatus is described capable of measuring the critical speed at which the friction of two surfaces is a minimum. By placing the apparatus in a vacuum it was shown that, as the pressure of the air was reduced, the friction varied less and less with the speed. At a pressure of 1 mm. the friction was nearly independent of the speed.

—**E. Haudié**: The general law relating to a generator or a receiver with a derived branch: the case of dynamo.

—**C. E. Guye** and **A. Tcherniavski**: The measurement of very high potentials by means of an electrometer under pressure. By placing the electrometer in air under a pressure of four to nine atmospheres, the errors due to the silent or brush discharge and electric breeze were suppressed. The constant of the apparatus was nearly independent of the pressure of the gas, and the damping was easily under control. A potential of 80,000 volts from a Wimshurst machine was readily measured with this arrangement.—**G. Urbain**: The magneto-chemical analysis of the rare earths. The magnetisation coefficients vary more rapidly than the atomic weights in the rare earths, and the measurements are much more easily made. The results of the application of the method to the separation of a mixture of dysprosium and yttrium are given.—**W. Louguine**: The determination of the quantities of heat disengaged during the addition of bromine to some unsaturated substances. Data are given for the heat of combination of bromine with caprylene, styrolene, cyclohexane, ethyl phenylpropionate, and pulegone.—**E. Kohn-Abrest**: The nitrides and oxides extracted from aluminium heated in air.—**L. Grenot**: The cementation of silicon steels. Silicon steels which do not undergo cementation in wood charcoal can be readily cemented by the use of prussiate of potash.—**M. Vournasos**: The reducing action of alkaline formates on certain mineral compounds. Boron nitride heated with an alkaline formate gives off a mixture of hydrogen, ammonia, and boron hydride. The proportion of the latter compound may amount to 1.5 per cent.—**Léo Vignon**: The phenomena of electric transport in solutions of certain colouring materials. Transportation phenomena are very clearly produced with the colloidal solution of several dyestuffs, proving the presence of undissolved granules carrying appreciable electric charges. With colouring matters in true solution these effects are not produced.—**E. Darmon**: Artificial camphor. It is possible to prepare both the dextro and laevo optically active forms of synthetical camphor.—**F. Couturier**: The condensation of pinacoline with its esters.—**Jacques de Lapparent**: The basic rocks of Saint-Quay-Portrieux (Côtes-du-Nord) and their relations with the pegmatite lodes which traverse them.—**Victor Henri, André Helbronner, and Max de Recklinghausen**: The sterilisation of large quantities of water by the ultra-violet rays. The arrangement of lamps described is capable of sterilising water on the large scale with an expenditure of 36 watt-hours per cubic metre of water treated.—**Ch. Dhéré** and **M. Gorgolewski**: The preparation of demineralised gelatin and some of its chemico-physical properties. Two methods of purification have been used, dialysis and freezing. The gelatin thus obtained is practically free from ash. It forms jellies, but less well than when electrolytes are present. Between certain limits of concentration solutions of this highly purified gelatin are opalescent, this opalescence disappearing on adding traces of alkali.—**H. Stassano** and **A. Daumas**: The double rôle of calcium in the coagulation of blood and lymph.—**M. Weinberg**: The influence of feeding on the production of spontaneous atheroma.—**Ph. Glangeaud**: Archæan formations in the Forez mountains.—**Wilfrid von Södlitz**: The crushed granites (mylonites) of the Grisons, the Vorarlberg, and the Allgäu.—**J. Thoulet**: Marine sediments of atmospheric origin.

CAPE TOWN.

Royal Society of South Africa, March 16.—**Mr. S. S. Hough**, F.R.S., president, in the chair.—**Dr. R. Marloth**: Some new South African succulents. Among the new species are some of special biological interest. *Mesembrianthemum nitratum* was discovered in the desert belt east of Port Nolloth by Mr. Garwood Alston. The shrub bears at the end of the apparently dead branches a fleshy knob. This consists of two closely joined leaves, between

which the flower appears. Flower and fruit are then fed by the sap of the knob until fully developed, when nothing is left of the sheltering knob except its skin. Another species of *Mesembrianthemum* takes the same care of its flower and fruit, nursing them within its own body; but it is even more cautious than its big brother, for it buries itself entirely in the ground and shows only the apex of its few leaves. As the ends of the leaves are flat, flush with the ground, and coloured exactly like the rusty gravel, it is practically impossible to detect them when they are not in flower. *Euphorbia elastica* is the species from which some sort of rubber has been manufactured in Little Namaqualand, and, although the quality was not good, it is not impossible that, with the present boom in rubber, even those barren deserts may see a flourishing industry.—R. A. **Lehfeldt**: Variation of gravity. There have been differences of opinion as to the way in which the value of gravity is affected by height above sea-level, and special interest attaches to measurements on a really larger tableland. The result of observations taken at Johannesburg and Vereeniging is that the variation per metre is 0.000236, considerably less than that given by Helmert.—W. T. **Saxton**: The ovule of the *Bruniaceæ*. The main point brought out in this paper is that the ovule in the *Bruniaceæ* is pendulous and anatropous, with a dorsal raphe. There is a simple massive integument with a long slender micropyle.—R. **Brown**: *Chrysochloris namaquensis*, Brown. *Chrysochloris namaquensis* was named from skulls found at Garies in the disgorged pellets of owls. A description is now given of the skin. A remarkable feature of the species is that the third molar is about as frequently absent as present.

DIARY OF SOCIETIES.

THURSDAY, APRIL 21.

ROYAL SOCIETY, at 4.30.—The Incidence of Light upon a Transparent Sphere of Dimensions comparable with the Wave-length: Lord Rayleigh, O.M., F.R.S.—On the Improbability of a Random Distribution of the Stars in Space: Prof. Karl Pearson, F.R.S.—The Total Ionisation produced in Different Gases by the Kathode Rays ejected by X-Rays: Dr. R. D. Kleeman.—Tone Perception in *Gammarus pulex*: Prof. F. J. Cole.

ROYAL INSTITUTION, at 3.—The Himalayan Region: Dr. Tom G. Longstaff.

CONCRETE INSTITUTE, at 8.—The Effect of Sewage and Sewage Gases on Portland Cement Concrete: S. H. Chambers.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Hydro-electric Installations of Sweden: A. V. Clayton.

ROYAL SOCIETY OF ARTS, at 4.30.—The Arts and Crafts of Tibet, and the Eastern Himalayas: J. Claude White.

ROYAL GEOGRAPHICAL SOCIETY, at 4.30.—Dewponds: E. A. Martin.

LINNÆAN SOCIETY, at 8.—The Seedling and Adult Anatomy of *Welwitschia mirabilis*: Miss M. G. Sykes.—Anthomyiidae auf den Seychellen gesammelt: Prof. P. Stein.—The Dermaptera of the Seychelles: Dr. Malcolm Burr.—The Pteropoda and Heteropoda collected by the Percy Sladen Trust Expedition in the Indian Ocean: Dr. J. J. Tesch.—Die Pilzmücken Fauna der Seychellen: Dr. G. Enderlein.

OPTICAL SOCIETY, at 8.—Historical Exhibit of Spectacles: E. C. Bull.—Abrasives and Polishing Materials: Dr. W. Rosenhain.

FRIDAY, APRIL 22.

ROYAL INSTITUTION, at 9.—The Telegraphy of Photographs, Wireless and by Wire: T. Thorne Baker.

PHYSICAL SOCIETY, at 5.—Further Tests of Brittle Materials under Combined Stress: W. A. Scoble.—The Magnetic Balance of Curie and Cheneveau: C. Cheneveau with A. C. Jolley.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The History and Present Method of Quay-wall Construction at the Port of Rotterdam: H. C. A. Thieme.

SATURDAY, APRIL 23.

ROYAL INSTITUTION, at 3.—Bells, Carillons and Chimes: W. W. Starmers.

MONDAY, APRIL 25.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Aldabra and Neighbouring Islands in the South-west Indian Ocean: J. C. F. Fryer.

ROYAL SOCIETY OF ARTS, at 8.—Modern Methods of Brick-making: Dr. A. B. Searle.

INSTITUTE OF ACTUARIES, at 5.—Analysis and Apportionment of the Expenses of Management of a Life Office with a view to ascertaining the Office Premium Loadings: H. J. Rietschel.

TUESDAY, APRIL 26.

ROYAL INSTITUTION, at 3.—The Mechanism of the Human Voice: Prof. F. W. Mott, F.R.S.

FARADAY SOCIETY, at 8.—Is Water an Electrolyte? Prof. P. Walden.—On the Nature of Molecular Association in the Special Case of Water: Prof. Ph. Guye.—Liquid Water a Ternary Mixture. Solution-volumes in Aqueous Solutions: W. R. Bousfield and Dr. T. M. Lowry.—The Specific Heat of Gaseous, Solid, and Fluid Water: Communications from William Sutherland and Prof. W. Nernst.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Mythology and Superstitions of the Lengua Indians of the Paraguayan Chaco: Rev. H. T. Morrey Jones.

INSTITUTION OF CIVIL ENGINEERS, at 8.

WEDNESDAY, APRIL 27.

GEOLOGICAL SOCIETY, at 8.

ROYAL SOCIETY OF ARTS, at 8.—Irish Linen and some Features of its Production: Sir William Crawford.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

THURSDAY, APRIL 28.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: On the Rotatory Character of some Terrestrial Magnetic Disturbances at Greenwich and on their Diurnal Distribution: R. B. Sangster.—The Chromophil Tissues and the Adrenal Medulla: Prof. Swale Vincent.—The Liberation of Helium from Minerals by the Action of Heat: D. O. Wood.

ROYAL INSTITUTION, at 3.—Blackfoot Indians in North America: Walter McClintock.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Earthed versus Insulated Neutrals in Colliery Installations: W. W. Wood.

MATHEMATICAL SOCIETY, at 5.30.—The Accuracy of Interpolation by Finite Differences: Dr. W. F. Sheppard.—Note on Maclaurin's Test for the Convergence of Series: G. H. Hardy.

FRIDAY, APRIL 29.

ROYAL INSTITUTION, at 9.—Matavau: a New Volcano in Savaii (German Samoa): Dr. Tempest Anderson.

SATURDAY, APRIL 30.

ROYAL INSTITUTION, at 3.—The World of Plants before the Appearance of Flowers: Dr. D. H. Scott, F.R.S.

DYNAMICS IN ENGLAND, FRANCE, AND GERMANY.

- (1) *Elementary Mechanics of Solids and Fluids*. By Dr. A. Clement Jones and C. H. Blomfield. Pp. vi+366+xvi. (London: Edward Arnold, n.d.) Price 4s. 6d.
- (2) *An Elementary Treatise on the Dynamics of a Particle and of Rigid Bodies*. By S. L. Loney. Pp. viii+374. (Cambridge: University Press, 1909-10.)
- (3) *Initiation à la Mécanique*. By Ch. Éd. Guillaume. Pp. xiv+214. (Paris: Librairie Hachette and Co., 1909.) Price 2 francs.
- (4) *Die Mechanik, eine Einführung mit einem metapophysischen Nachwort*. By Dr. Ludwig Tesar. Pp. xiv+220. (Leipzig and Berlin: B. G. Teubner.) Price 3.20 marks.
- (5) *Vorlesungen über technische Mechanik*. By Prof. Dr. August Föppl. III. Festigkeitslehre, 4th edition. Pp. xvi+426. Price 10 marks. VI. Die wichtigsten Lehren der höheren Dynamik. Pp. xii+490. Price 12 marks. (Leipzig: B. G. Teubner, 1909-10.)

NEARLY five years have elapsed since the indefatigable Prof. Perry opened a discussion on the teaching of mechanics at Johannesburg. Mr. Blomfield is a teacher of considerable experience, and this book may be safely assumed to be the outcome of a study of this and other similar reports, combined with a practical knowledge of the difficulties of teaching boys, and of the requirements which a teacher has to satisfy on the part of examining-boards over which, unfortunately, he possesses no power of control. There have been a few, but not many, books on elementary mechanics published since the Johannesburg discussion, and we naturally examine the present book with a somewhat hypercritical eye, in the hope of finding some indications as to whether any real improvement has been effected since then. Let us begin with generalities, and then descend to details.

(1) In the first place, a good deal of discussion has taken place as to how far the use of text-books is desirable in school teaching, the following alternatives being proposed:—

- (a) No text-book.
- (b) A text-book consisting of examples only.
- (c) A text-book containing a complete exposition of the subject.

It is the opinion of many of the best teachers that a text-book should contain a brief but sufficiently complete outline of fundamental principles, but that examples should be the main feature. In this respect Messrs. Jones and Blomfield's book leaves nothing to be desired. It is very largely made up of examples, far more than any boy could work through in a reasonable time, and the teacher who wishes to adapt the course to his own requirements will only have to put a tick against those he means to set to his class.

In the second place, it is undoubtedly desirable, as the authors claim, to teach statics and dynamics simultaneously with hydrostatics, and it is important, not only that the three should for convenience be comprised in one book, but also that the simultaneous treatment should not give rise to serious difficulties in regard to logical sequence in any one of the subjects.

When, however, we examine the result we find that the mixture of the three subjects in each chapter leads to some rather striking anomalies, and the reader naturally asks, What has Atwood's machine got to do with the U-tube and the barometer? Why do Boyle's and Charles's law come in the same chapter with graphical methods? What connection exists between centres of gravity and Archimedes's principle, or between force diagrams and centres of pressure? Would not centres of gravity and centres of pressure go better in the same chapter? If, however, the authors seriously think that this somewhat heterogeneous mixture is found beneficial for teaching purposes on the ground that it keeps a variety of different ideas before the pupils at the same time, no doubt something can be said in its favour, and we should gladly defer to their views.

Passing to matters of detail, we naturally expect to find, in the examples, questions of a rather more practical character than in the older text-books. But the pupil who works through the questions might almost believe that there were only three acute angles in existence— 30° , 45° , and 60° . Why is it that other angles so seldom figure in them? Every boy nowadays has his tables of logarithms, and the first thing he should do when he learns the parallelogram law and Lami's theorem is to calculate resultants, using the tables of log sines, &c. What is the use of teaching him statics if he can only apply the methods to three particular angles? But the absence of other angles is the more remarkable when we speculate as to the sources from which the questions have been taken, especially in view of the fact that Government examination papers have been consulted, and that in some of these, 30° , 45° , and 60° have, we believe, been taboo for some years past. Again, in the chapter on projectiles, a good many examples are to be solved by writing down the equations, but we have failed to find any attempt to make the pupil draw the paths of projectiles by plotting. Is not this calculated to produce the type of student who uses elaborate algebra to prove an almost self-evident result and generally fails? We have had abundant experience of such students' failures in simple projectile questions, and begin to wonder whether it would not be better to omit the subject altogether.

On the other hand, the book contains a good many things which we had believed were at last dead and buried. What is the use of telling a boy that if a particle is going north-east at 10 feet per second for one second "it has travelled a distance OL ($5\sqrt{2}$ feet) due E., and a distance LP ($5\sqrt{2}$ feet) due N."? If he has any common sense he ought to think that it would be equally sensible to say that two people starting from London and Cardiff at 2 p.m., with

tickets from London to Cardiff and Cardiff to Glasgow, could get to their destinations simultaneously by the 2 p.m. London to Glasgow. It would be far better to omit all these old-fangled misstatements, including the one that "if a particle has simultaneously three velocities represented by the sides of a triangle it remains at rest," and merely to give the definition of component velocities in § 5, and some discussions on relative velocity.

Atwood's machine seems too fashionable to be omitted nowadays, but it would be better to bring friction up to the front before discussing the motion of a 10 lb. weight on a table, pulled opposite ways by weights of $1\frac{1}{2}$ lb. and 2 lb. hanging over the edge, or a 4 lb. mass on an inclined plane. In the figure of the condensing pump the arrow seems to suggest that air enters the barrel when the piston is moving the opposite way. "Whole pressure," which is meaningless except for plane areas, again crops up on p. 217. When shall we see the last of it? The oar once more figures as a lever of the second class. It is to be wished that every person who placed it there would try pulling a boat out in shallow water with the ends of his oars touching the bottom and a boy on the bank holding the boat back with a string. Under "machines" the so-called "first and third systems of pulleys" crop up with their usual pertinacity. It would be interesting if those who take so much interest in these particular machines and ignore the crab were asked to arrange for lifting building materials to the top of a high scaffolding, and to watch the result when their instructions were carried out.

Our general conclusion is that if boys have to learn what is contained in this book they will be efficiently and well trained on these lines by following Messrs. Jones and Blomfield; but there are a good many things they had far better leave unlearned, and a good many other things they ought to learn instead. It should be mentioned that calculus is not used, and moments of inertia are not included in the scope of the book.

(2) Controversial questions regarding the teaching of mechanics do not enter so prominently in connection with Prof. Loney's book, for by the time its standard has been reached dynamics has practically become a branch of pure mathematics, while, on the other hand, the student has had a good laboratory course in physics or engineering. The book, in fact, pretty exactly fits the requirements of B.Sc. candidates in a modern university college in the third year of their curriculum. It deals with rectilinear motion (including resisting media), central orbits, motion about a fixed axis, uniplanar rigid dynamics, energy and momentum, a little three-dimensional rigid, Lagrange's equations, &c. There is always a difficulty with these students, because this ground assumes a knowledge of pure mathematics that they cannot acquire before their third year. The appendix on differential equations is useful in this connection. A few points will have to be attended to in a future edition. The equation of motion for varying mass (p. 130) does not generally hold when a body is

parting with matter. D'Alembert's principle requires more explanation than is contained in the statement, "Now the internal forces of the body are in 'equilibrium' among themselves, for by Newton's third law there is to every action an equal and opposite reaction." This explanation the lecturer can, however, give. But a most amazing and doubtless unintentional mistake is made on p. 302, where the equations of motion in three dimensions are given as $Ad^2w_x/dt^2=L$ instead of Euler's equations. We should like to have seen a few more examples in which the answer leads to a definite conclusion in the form of a numerical result instead of so many algebraic formulæ connecting masses m , lengths $2a$, and angles θ . But such questions are, we admit, rather hard to collect, and the teacher and student should, therefore, be grateful for the flywheel questions on pp. 217-9.

Up till the present no one book has sufficed for students taking this course, and, indeed, there has been great difficulty in advising them as to what to get. Prof. Loney has done useful work in providing students with a suitable work, and when he states that he has verified every question, the task cannot have been an easy or profitable one.

In this revision, the paradoxical rough board on a smooth plane seems to have escaped notice. In p. 210, ex. 2, while on p. 217 we have "A uniform rod AB is freely movable on a rough inclined plane whose inclination to the horizon is i and whose coefficient of friction is μ about a smooth pin fixed through the end A." "Coefficient of friction of a rough plane about a smooth pin" reminds us of the newspaper English so often quoted in *Punch*.

The treatment of centrodcs is very useful.

(3) M. Guillaume's "Initiation" is stated to be one of a series intended to be used for teaching children. In this connection, the question arises, What is the age of the children contemplated by the author? In the editorial preface by M. C. A. Laisant four to twelve years is suggested. But, even after allowing for the differences between English and French children, the author's treatment of the subject seems too philosophical for such young pupils. As a preliminary preparation to the study of mechanics we have a chapter on "How Nature is Studied," the headings of the paragraphs being "Observation and Experiment," "Approximation and Simplification," "Need of Simplicity," "The Limits of Experiment," "Illusion," "Education of the Senses; Measurement," "Induction and Deduction." Illustrations are taken from the photographs of moving bullets, photometry, and so forth. In the next chapter, which deals with kinematics, we have a discussion of space, velocity, and acceleration graphs. The author in the preface considers that dynamics should be treated before statics. His argument might, however, very well be used the other way. He asks why the majority of bodies on the earth appear to be at rest, and points out that this is due to the existence of resistances such as friction, and remarks *inter alia* that if these forces are unknown at the time when statics is begun

this becomes an artificial science or a simple abstraction. Would it not, however, be equally correct to describe dynamics as an "artificial science or simple abstraction" because it deals only with what *would* happen if certain existing resistances were absent?

The subject-matter extends up to and including couples, circular motion, a little about properties of matter, such as elasticity and ballistics, and a final paragraph dealing with Jules Verne's hypothetical voyage to the moon.

It is not to be denied that "philosophy of science" is much more studied in France than in this country. It also appears that the book is primarily written for those who have to teach children rather than for the children themselves. All we can say is that a course of instruction based on this book would in all probability be far above the heads of English children of the ages contemplated.

(4) While Prof. Tesar has "said his own say" in his preface and metaphysical appendix, his object in the rest of the book has been to present the principles of mechanics in a clear and intelligent form, and to employ practical illustrations as far as possible. In both these aims he appears to have been very successful. He is careful to distinguish between forces (Kräfte) and force effects (Kraftäusserungen), pointing out that the parallelogram law applies to the latter, and that its truth for any physical vector quantities is based on experience. His readers should learn to discriminate clearly between the formal rational dynamics and its applications to the practical study of mechanics. For want of this distinction the whole subject in less careful hands often becomes more appropriately describable as dogmatics. The practical illustrations are very instructive and suggestive. How many who have taught rigid dynamics have thought of working out the condition whether a bell will or will not ring when it is swung? The author gives practical calculations for a bell in Cologne Cathedral cast from the cannon captured in the Franco-Prussian War, which failed to ring until its clapper was altered in length.

(5) As has been previously pointed out in reviews, Prof. Föppl's treatises on technical mechanics are of a far more advanced character than the mechanics taught commonly to technical students in this country. Vol. iii., which includes a large portion of the mathematical theory of elasticity, now reaches us in its fourth edition. The new volume, "The Most Important Studies of Higher Dynamics," deals with relative motion, systems with several degrees of freedom, in particular compound pendulums, including the bell and its clapper, the gyrostat, and an outline of hydrodynamics. Under the gyrostat we have a detailed discussion of Schlick's ship governor, and in a circular issued with the book we are asked to point out that the Brennan mono-rail came too late to be included in the book, a short note at the end being all that was possible, as the whole of the text was already in print. It is, however, pointed out that the theory of the Schlick gyroscope is applicable with slight modifications to the mono-rail, some terms occurring in the equations having merely to be re-

versed in sign. Thus an interesting exercise is provided for those possessing the necessary mathematical knowledge, to go over the work introducing the necessary changes, and doubtless the next edition will see them in the text.

G. H. BRYAN.

HARDY TREES AND SHRUBS.

Trees and Shrubs of the British Isles, Native and Acclimatised. By C. S. Cooper and W. P. Westell. Vol. i., pp. xxxii + lxxxiv + 108; vol. ii., pp. viii + 261; 78 full-page plates by C. F. Newall. (London: J. M. Dent and Co., 1909.) Price, two vols., 21s. net.

AMID the torrent of books on gardening with which a patient public has been deluged during recent years, we have searched in vain for a really comprehensive and authoritative work on hardy trees and shrubs. Of mere book-making there has, of course, been no end. It is so easy to sit at a desk and boil down from Loudon, Sargent, &c., and from the copious literature in horticultural journals, sufficient to make a respectable-looking volume, without ever taking the trouble to turn over a leaf or dissect a flower on one's own account. But this method has its disadvantages. The same stale old errors are once again repeated, and to them our new author must, perforce, add some of his own. There has been too much of this kind of tree literature in the past, and it was with a feeling of pleasant anticipation that we turned to these two handsome volumes in the hope that a work had at last been written worthy of the subject.

That it marks a considerable advance on much that has appeared is certain, but its scope is somewhat limited, and the authors do not appear to us to have done the best that could have been done within the limits they set themselves. British trees and shrubs are done thoroughly and well, and those portions dealing with them constitute the most valuable part of these volumes. When the authors deal with what they term "acclimatised," as distinct from native, species, their work often suggests the study and the bookshelf, rather than the open air and the living tree. For it is by no means free from error, and at times shows a lack of intimate knowledge of the plants dealt with.

The book opens with an introduction in which the general subject is discussed pleasantly and suggestively. It is an attempt to interest the hitherto uninterested reader, not only in the more evident beauties of leaf and flower, but to get him also to appreciate those profounder beauties of trunk and branch and bud which we are afraid the average reader often does not discern, but which make the leafless woods in their season as full of delight to the real tree-lover as the full leafage of June. This part of the work was well worth doing and is well done.

Some fifty or sixty pages are then devoted to the discussion of injurious and useful insects, galls, and fungoid pests, with directions for the composition and application of various remedies. This, although useful, is too liberal an allowance for such subjects in a

work running to less than 500 pages. Many insects are described and discussed individually which are not particularly troublesome, and might, at any rate, have been treated collectively. We see no mention of the beech-bark coccus, a pest which is causing grave concern both here and on the Continent among owners of beech woods. The remainder of the work is occupied by a detailed description of some 550 species of "native and acclimatised" trees and shrubs. A description of the characteristics of each natural order prefaces the description of the species belonging to it. This space, we think, might have been better occupied with a discussion of the genus. A description of the great order of Ranunculaceæ, for instance, has only a very general bearing on Clematis, and it was scarcely worth while to preface the description of the solitary rubiaceous species here dealt with by an account of the great order to which it belongs.

The old problem of the "popular" name has been met by a brave effort on the part of the authors to provide nearly all the plants they mention with one. If a species had not one before they appear to have invented one. But the result is not always happy. We hardly know whether such a name as "Narrow-leaved Jasmine Box" for *Phillyrea angustifolia* (p. 107) indicates too dull or too vivid an imagination, for this shrub has no relationship with the box, nor does it bear any resemblance to the jasmine either in leaf or flower. The very next species, *P. decora*, is called "Vilmorin's Mock Privet," which is neither pretty nor correct.

The descriptions are carefully done, although somewhat too technical for the amateur, as for example where the flowers of common oak are described as "monœcious, anemophilous, proterogynous," and where the fruit of magnolia is termed an "etærio of follicles." Still, accuracy is the chief thing, and we do not notice many serious lapses. One of the worst is the description of *Ceanothus rigidus* as a deciduous climber with alternate leaves (p. 48). It is a perfectly evergreen bush with opposite leaves. Then *Acer circinatum* is said to have "greenish-white" flowers. Anyone who has had a personal acquaintance with this tree could not fail to have noticed its drooping corymbs of reddish-purple flowers, which make it perhaps the most attractive of commonly cultivated maples in regard to blossom.

The number of cultivated species of hardy trees and shrubs now exceeds 3000, and it would be an impossible task to select one-sixth of these for treatment and satisfy everyone. Yet the selections here made betray an indifferent acquaintance with some groups. *Berberis empetrifolia*, a rare shrub seldom seen in good condition, is included, but of *B. stenophylla*, in some respects the finest of all flowering evergreens, not a word is said; and whilst a weedy shrub like *Stephanandra Tanakae* is described, a fine handsome bush like *Exochorda grandiflora*, its near relative, is ignored. But the worst instance of this defect in these volumes is the inclusion of the American plane (*Platanus occidentalis*). The authors say this is to be found in "parks, gardens, avenues," and that it is "usually larger and more rapid in growth than the Eastern plane" (p. 144, vol. ii.). We had thought it

well known to all tree-experts by now that the American plane is absolutely worthless in this country. So far from being comparable with the Eastern plane, there is not, we believe, a single tree in these islands with a trunk 6 inches in diameter. All the trees so called are forms of *P. acerifolia*, the common plane of London. Thus is an old error dating from Phillip Miller's time, and continued by Loudon, again perpetuated. The cultural notes will be found useful, although an absence of personal experience is again at times evident, as when it is stated that *Cistus ladaniferus*, from the sun-baked hills of Spain and Portugal, is suitable for shady places (p. xxxi).

Whilst we have felt bound to point out the obvious defects of this work, it must not be supposed we are blind to its merits. These are many, and to the great bulk of the matter no exception can be taken. For the drawings of Mr. Newall we have nothing but praise; they are botanically accurate as well as artistic. The coloured plates are of unequal merit; the picture of *Magnolia conspicua*, for instance, is either wrongly named or badly coloured, but this we suspect is more the colour printer's fault than the artist's. The printing, typography, and paper are all admirable.

ANTEDILUVIAN CHRONOLOGY.

The Dates of Genesis. A Comparison of the Biblical Chronology with that of other Ancient Nations. With an Appendix on Chronological Astronomy. By Rev. F. A. Jones. Pp. 333. (London: Kingsgate Press, 1909.) Price 5s. net.

THIS is one of those strange little works which are continually issuing from the clerical workshop with the aim of expounding the early chronology of the Bible. Mr. Jones has many glimpses of real knowledge of archaeological science, and has evidently read widely on the subject, but not always wisely, and he perpetrates several blunders. The most patent impossibility in the book is the absurd date assigned to the building of the Great Pyramid, viz., 2170 B.C., on the authority of Sir John Herschel. This is utterly impossible, on historical grounds.

We do not know what to make of Mr. Jones's views of modern scientific knowledge of the beginnings of human civilisation. He seems to think that human beings were originally placed in the world in a highly civilised condition, and ingeniously explains away the damning fact of the gradual evolution of man's tools and culture from the Older to the Newer Stone age and then to the age of Metal. He says that the ancient flint implements may indicate not "an early period in the development of art," but

"express limitation of opportunity. Wanderers from a civilised centre would, unless possessed of considerable personal ability, soon degenerate into using the simple methods that are characteristic of savage tribes . . . the existence of these flint weapons, in outlying districts, may not be pressed so far as to prove a date as being long before more advanced civilisation in the great centres of population."

That is to say, Palæolithic implements are the tools of degenerate offshoots from the highly civilised pre-

diluvian "patriarchs." For between the Palæolithic degenerates and the Neolithic degenerates came the Flood,⁷ which killed off all the extinct animals, such as the mammoth, which

"at all events, is not such an extremely ancient animal. Its remains are even to-day excavated, in some cases, as in Polar regions, with its flesh and hair intact."

It is difficult to know what to make of a writer who, in the twentieth century, believes, apparently, in the actual historical existence of Noah and his ark, and, by "combining the traditions of Jews, Arabians, and other nations with the story as told in the Hindu Puranas and the Sybylline [*sic!*] Oracles," arrives at the following interesting account, "which may or may not be true," of what happened about the time of the Flood (pp. 164, 165):—

"Mahaleel was a very distinguished man who married a widow in the line of Cain. His son, Jared, thus acquired a claim to the rulership of the world, and exercised it for some time with great distinction. He is said by some to be the great Sesostris of the Greeks. . . . Methuselah maintained the holy traditions, and for his sake the flood was postponed till his death had taken place. Noah was by distinction the righteous man. . . . The nation descended from Ham very quickly turned aside to the old idolatry, and worshipped their ancestors under various names. These may be traced in Egypt, Chaldea, Phœnicia, and elsewhere. The children of Shem became kings of Magadha, but the dynasty ended about 2100 B.C. Noah was soon deposed from his rule by his sons, and driven away from the territory occupied by them. According to one account he was last seen about 2000 B.C., and he was of a colour between white and ruddy, and bald-headed." (!)

FIELD ORNITHOLOGY.

Camps and Cruises of an Ornithologist. By F. M. Chapman. Pp. xvi+432. (London: Hodder and Stoughton, n.d.) Price 12s. net.

FOR seven years the author, with the assistance of artist and *preparateur*, devoted the nesting season of birds to collecting specimens and making field studies and photographs on which to base a series of what have been termed "Habitat Groups" of North American birds for the American Museum of Natural History. These groups are designed to illustrate not only the habits and haunts of the birds shown, but also the country in which they live. The birds, and, in most instances, their nests and young, are therefore placed in a facsimile reproduction, containing from 60 to 160 feet of the locality in which they are found, and to this realistic representation of their habitat is added a background, painted from nature, and so deftly joined to the foreground that it is difficult to distinguish where one ends and the other begins. A reference to the photographs of these groups, which form some of the illustrations of this delightful book of field ornithology, will convince anyone at once of the truth of this remark. Some of these panoramic backgrounds portray not only the haunts of certain American birds, but America as well.

In the pursuit of his calling the author has had

the good fortune to behold some of the most interesting and remarkable sights in the world of birds. The object of the present volume is to perpetuate his experiences and studies by telling the story of the various expeditions of which the groups were the objects, adding such information concerning the birds observed as seems worthy of record, and illustrating the whole with many photographs from nature, and a number of the groups themselves. The result is one of the most readable as well as informing books of the kind we have had the pleasure of seeing.

With the exception of one chapter, the whole book deals with American birds. But this need not be a drawback in the mind of even those whose ornithological interests are almost wholly confined to British birds. The author remarks that next to their native birds there are probably none of more general interest to the average American nature-lover than the birds of England. This is partly due to sentimental reasons. But we can return the compliment, for others. One is that many American birds, although considered by systematists as distinct species, are so like European birds that for all practical purposes of the field ornithologist they may be considered the same, while others are absolutely identical. So that in reading a book about the habits of these birds in America we are learning something more about our own birds' habits, modified a little, perhaps, by a slightly different environment or by different conditions of life. This last comes home to us when we read the account of Gardiner's Island ("within one hundred miles of our most populous city"), where there are no rats and no cats, "the ogres of the bird-world," and hardly any "vermin" destructive to bird-life. This large island, containing 4000 acres, is a place of peace and plenty for the birds. The whole account of it is full of interest, but the most remarkable fact is that the osprey, which is *very abundant*, builds its nest often in lowly situations, and actually in some cases on the ground. A number of illustrations of the ospreys and their nests are given, the great piled-up heaps of sticks built by the birds which breed on the beach affording excellent chances of photographing the old birds at the nest.

Some birds are more get-at-able in the North-West than they are, say, in that almost unknown land, the marshes of south-eastern Europe. Take the great white pelican, for instance. It is a most difficult—nearly impossible—bird to study in Europe; but in many of the numberless lakes of Manitoba, Saskatchewan, and Alberta, invariably upon islands, white pelicans nest, a colony containing anything from a dozen to several thousand birds. This bird so closely resembles the European one that it used to be considered identical with it. The chapter on and illustrations of it are therefore very welcome, for the author saw a good deal of pelicans.

Perhaps the most interesting chapter in the book describes the flamingo—not, indeed, our pink flamingo, but the brilliant red species (*Ph. ruber*). However, a flamingo, so far as life-habits are concerned, seems to be simply a flamingo wherever he lives. It is here truly remarked that there are larger

birds than the flamingo, and birds with more brilliant plumage, but no other large bird is so brightly coloured, and no other brightly-coloured bird is so large. When to these more superficial attractions is added the fact that little or nothing has hitherto been known of the nesting habits of this singular bird, one may, in a measure at least, realise the intense longing of the naturalist, not only to behold a flamingo city, but at the same time to lift the veil through which the flamingo's home life has been but dimly seen. Nearly forty pages are devoted to the lifting of this veil for the reader, and the account is illustrated by more than a score of pictures of the birds at and on their nests, and of the nests, eggs and the young in various stages; included among these are two beautiful coloured photographs of the adult birds, in one of which they are seen feeding their young in the nest.

It is quite impossible to find space even to enumerate all the contents of this charming book, but Florida, Bahama, the western prairies, California, and many other localities were visited by the author, and are here described. Lastly, we have a chapter on his impressions of English bird-life; and the impressions of such an experienced bird-man are distinctly valuable and informing, and will be read with the greatest interest by our field ornithologists. We cannot enter into them widely here. As he approached the coast of Wales the "boreal" birds he saw about the stacks and islands of Wales afforded convincing evidence of high latitude, and, at the same time, an admirable illustration of the faunally composite character of English bird-life, types Americans are accustomed to consider representative of northern and southern life-zones finding in England congenial surroundings. Unlike some visitors, the author was not too late to hear the nightingale; he was disappointed at first with the song of the skylark, but before leaving England found himself listening to it with increasing pleasure. None of the birds seen from the train impressed him more than the peewit. We read:

"The bird's size, form, and colours, its grace of carriage on the ground, and dashing, erratic, aerial evolutions, give it high rank as an attractive part of any avifauna; while its abundance, in spite of the demand which places thousands of its eggs on the market annually, is inexplicable."

This is all true, though most of the eggs come from the Continent; but a bird which can furnish Mr. Chapman with "a brand new sensation in bird-life" must be something we ought to be proud of.

The author visited various parts of England, and many of our famous sea-bird haunts. His pictures of these places (including one of Selborne) are delightful, and everything he has written about our avifauna is well worth reading. It is satisfactory to read that birds are more abundant here than they are in North America. The book is very full of illustrations, and they are excellent—far better than most of the photographs of this kind. But the heavily leaded paper on which it is printed makes it simply too heavy to hold without actual weariness!

O. V. A.

EXOTERIC PHILOSOPHY.

- (1) *In the Abstract.* By N. Alliston. Pp. 156. (London: Swan Sonnenschein and Co. Ltd., 1909.) Price 2s. 6d.
- (2) *Progressive Creation: a Reconciliation of Religion with Science.* By Rev. H. E. Sampson. In two vols. Vol. i., pp. xii+484; vol. ii., pp. vi+517. (London: Rebman, Ltd., 1909.) Price 21s. net.
- (3) *Progressive Redemption.* By Rev. H. E. Sampson. Pp. xxiv+616. (London: Rebman, Ltd., 1909.) Price 12s. 6d. net.
- (4) *Scientific Idealism, or Matter and Force and Their Relation to Life and Consciousness.* By W. Kingsland. Pp. xxiii+427. (London: Rebman, Ltd., 1909.) Price 7s. 6d. net.

THESE books have this much in common, that none of them bears the academic hall-mark. Of the three writers, Mr. Alliston is the most ambitious of a precise logic. His book consists of a group of essays on such various topics as "The Planetary Distances," "Materialism," "The Value of Things." His criticism of the first law of motion is perhaps the most original effort in the book. He is dissatisfied with a formulation which assumes that rest and frictionless motion are alike constant; he holds that frictionless motion would cease as soon as the original force should be exhausted. Mr. Alliston admits that the law as stated must be considered practically adequate; he does not attempt to make any inference, dynamical or metaphysical, from his criticism; and the essential proof for this inconclusive result—the explanation of how an ideal unhindered velocity would be diminished, he has not provided. Mr. Alliston's essay on materialism is a clear and simple re-statement of now commonplace criticism; he does not, however, sufficiently realise the difficulty of finding a moral differentiation between materialism and a spiritualism which does not promise the conservation of individuality. The book is pleasantly written, and might be turned over with interest and profit by beginners in philosophy.

The authors of the other works placed at the head of this notice have each made a bold attempt to reach the final synthesis which is supposed to be the goal of philosophy. Mr. Sampson's interest is, in the main, theological; Mr. Kingsland's effort is more purely philosophical. The system of the former, though presented with much ability, will, it is to be feared, strike most people as fantastic. He starts from the failure of science to account for evolutionary breaks and "missing links." This failure suggests to him that the facts covered by the current theory of evolution represent an interruption rather than an integral part of the great order of true evolution. That true order is, it appears, a progressive creation of beings who pass by successive reincarnations from lower to higher types, culminating at last in perfect Godhood. A condition of its continuity is the preservation of purity of type, a condition violated by our "Adamic" ancestors, who inter-married with an inferior kind. Sin then entered the world, catastrophic physical changes occurred, and our history since has been a struggle towards the ancient

segregation, a "devolution." The incarnation of Christ was the essential effort of the whole Cosmos to redeem the earth. Mr. Sampson provides a cosmogony for the great spiritual order. The planetary circles and the zodiacal angles in their various relations define the home of the spirit in its various stages of development from the "atom" of original divine ætheric essence to the perfection of Deity. Into the elaboration of this scheme the author has worked much ingenious allegorisation of biblical story, and much mysterious symbolism from Astrologer and Rosicrucian. It is a not uninteresting and hence not unsuccessful attempt in mythology; at least it must appear so to all who do not possess, as Mr. Sampson seems to, the clue to the esoteric illumination of church and brotherhood.

Mr. Kingsland writes with much earnestness to show that truth, beauty, and goodness are only to be realised by man in his union with the Absolute, the one primordial substance, who is at once subject and object, whose nature can be expressed only in paradox, the eternal source and sustainer of all finite existence. We approach Him by ascent from plane to plane of existence—for He is essentially differentiated into planes variously approximating to His own self-sufficiency. For Mr. Kingsland individuality is an involution, and its extreme limit is physical determination; from that man is now evolving towards a realisation of the spiritual ego, which is the "universe" of many human personalities or incarnations. It again is but a phenomenal appearance of the spiritual form of humanity, the one "Divine Son," which is itself a phenomenon of the Absolute. Thus, though Mr. Kingsland professes a belief in immortality, it is necessarily an immortality in which individual experience is not preserved as individual. The temporal individuality must be merely a means for a higher life which transcends it; and, though the author may assert that we are at the same time ends, for the One is within us, this paradoxical conjunction has never satisfied man's moral demands for an end which is both personal and metaphysically genuine. The book is well written, and the exposition of recent scientific theory is admirable, but in the more metaphysical portions repetition is a great blemish.

OUR BOOK SHELF.

A Manual of Botany for Indian Forest Students. By R. S. Hole. Pp. xi+250+xxi+xx plates. (Calcutta: Government Printing Office, 1909.)

THIS work has been prepared primarily for the use of the pupils of the Imperial Forest School, Dehra Dun, in which establishment the author holds the post of forest botanist. The manual ought to prove a good text-book. It is quite up to date and is written in clear, concise language. Should a new edition be called for, and when one considers the object the work is intended to serve this will almost certainly be the case, the author will be well advised to treat systematic botany more fully than he has done in the edition before us. A compact synopsis of the natural families of plants to be met with in British India would be of great value as an aid to the student who will, when

he has left the forest school, have occasion to make use of the "Flora of British India," or of one or other of the regional, Indian floras based on that fundamental work. The author might also consider the advisability of adding a glossary to the work. Such an addition, besides being of considerable utility in itself, would have the further advantage of enabling him to relieve the morphological part of the work of a certain amount of purely terminological matter and at the same time of allowing terminology itself to be treated somewhat more completely.

Another point to which the author's attention may be directed is the somewhat meagre character of the illustrations. It is, of course, true that, especially at the outset, there is some difficulty in providing for the full illustration of a work published by Government and prepared for the special purpose which underlies the one under notice. So long as it is understood that the work is merely intended to assist the student generally while he is at the forest school, the want of illustrations in company with the text is not likely to be greatly felt. But the work ought to have, and no doubt will have, a further use. Most students will carry the work away with them when they leave the school, and will find frequent occasion in after life to refer to it and refresh their memories. It is then that the need for good illustrations, which help to restore faded ideas and their associations, will be most acutely felt.

In directing attention to these points we would, however, desire it to be understood that no reflection is intended either on the author or on his work as it stands; what appeals to us in making them is rather a purpose that the work, modified as suggested, is calculated to fulfil than the purpose which, as the author explains, it is intended to serve. That it should serve this latter and narrower purpose well we do not doubt, and Mr. Hole is to be congratulated on the presentation of a useful and serviceable manual.

The Light of Egypt, from recently discovered Pre-dynastic and Early Christian Records. By R. de Rustafjaell. Pp. x+169. (London: Kegan Paul and Co., Ltd., 1909.) Price 10s. 6d. net.

MR. DE RUSTAFJÆLL'S book is a curious mixture; as its title shows. It consists chiefly of a description of various Egyptian objects, some apparently owned by the author (though this is not made quite clear), others bought by him and sold later to the British Museum. These objects are illustrated by fine photographs. They are strung together by means of a general talk compiled by the author from various authorities, which is intended to give an idea of the "light" shed by Egypt upon early civilisation. So far, so good, and the work is not badly done; but the author also launches out into one or two theories of his own, which are hazardous. We may instance his supposed discovery of limestone "vessels" of "Palæolithic" age found with (undoubted) Palæolithic flints on the Theban plateaux. These objects are not artefacts at all, but merely either the hard matrices of flint nodules or else weathered siliceous masses. They are common enough on any Egyptian *gebel* of rough stones. Mr. de Rustafjaell has discovered nothing here. The translation by Mr. Crum of the Coptic manuscript sold by Mr. de Rustafjaell to the British Museum, and included by him in his book, is interesting. The Nubian manuscript also originally obtained by Mr. de Rustafjaell, to whom Mr. Griffiths sends a summary description of it, has already been published in facsimile by Dr. Budge for the Trustees of the British Museum. It is of great importance linguistically.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Precursors of Magnetic Storms.

IN kindly noticing (NATURE, December 30, 1909, p. 259) my short account of the magnetic storm of September 25, attention was directed to the fact that what I called the precursor was experienced all over the world.

As I have little or no opportunities to compare our curves with others, may I be allowed to ask for information through the columns of NATURE?

I call a "sudden start" of the magnet a movement which occurs after several hours of perfect calm, and causes the trace to make a "sharp angle," that is, so sharp that I can unhesitatingly tell the time of the occurrence to the nearest two minutes. Many disturbances, large or moderate, have a "sudden start"—at least here.

My impression has long been that disturbances with a "sudden start" very generally have a kind of "preliminary tremor" some hours before the start; the curve, which we suppose to be quite smooth, is interrupted by a short movement, which lasts but a few minutes, after which the curve resumes its smoothness for the remaining hours. The tremor may be very small indeed, but the two characteristics, to be found on a smooth curve, and to be of very short duration, make it quite easy to point it out and tell the time.

The start of the "preliminary tremor" is in the same direction as that of the disturbance itself, at least as a rule.

I do not venture to hold an opinion as to the connection, fortuitous or otherwise, between the two phenomena, but I should be very glad to know whether the "precursor" is also observed in other countries. The following is the list of all the "sudden starts" of H during the last fourteen months of Zi-ka-wei (January, 1907, to February, 1908, inclusive), with the time of the start and that of the preliminary. A comparison with the curves of some other observatory is invited. Probably the traces will not be found so smooth as here, and some of my "sudden starts" will correspond to progressive starts, but on the whole I hope that a comparison will be possible.

I use Greenwich time.

Sudden starts			Preliminary			Remarks
	h.	m.		h.	m.	
1. Jan. 8	16	45	Jan. 8	1	45	H not quite smooth. D very smooth.

24. Feb. 22	12	8	Feb. 21	19	20	

NO. 2113, VOL. 83]

If we put aside No. 21, we have twenty-three occurrences. In eighteen of these there is no doubt; in the three cases in which no precursor was found, and in the two more or less doubtful cases, the curves were not smooth, that is, the "start" was not quite sudden.

In Zi-ka-wei, during the fourteen months considered, the eighteen disturbances which began with quite a sudden start all had one or two preliminaries. The interval between the forerunner and the disturbance ranges from two to seventeen hours of perfectly smooth trace.

Zi-ka-wei, China, March 11.

J. DE MOIDREY.

Centre of Gravity of Annual Rainfall.

THE mere *a priori* criticism which Mr. Watt, in his letter to NATURE of April 14, has bestowed on my letter to NATURE of March 31, dealing with a large class of concrete physical facts, is, to my mind, far from satisfactory or sufficient. In the last sentence of my letter I anticipated that it might meet with some such "simple" algebraic criticism.

I did not, as is implied, assert that the use of the C.G. of the year's rainfall would dispense with the ordinary graphic representation of the monthly distribution, but that it appeared to be a convenient method for comparing the rainfall distribution at a number of stations in the same country for the same year, as well as at a single station, or for the mean rainfall of the same country, for a succession of years. Obviously, therefore, Mr. Watt's simple types of rainfall for his imaginary stations A, B, C, which belong to very different regions on the earth's surface, have no application, even in theory, to my "suggestions."

As for the practical character of my proposals, the following may be given. They are quite as useful as the comparison of the variation of rainfall with that of population for a decennium in India, which was the subject of a paper given some years ago in the Journal of the Royal Meteorological Society, London. A comparison of the variations in the C.G. of the mean monthly rainfall for the past 50 or 100 years with the agricultural results of those years in the British Isles, &c., for which the data may be available; an examination of these variations in connection with the much-discussed question of weather cycles, so commonly based on rainfall statistics; the detection of serious clerical slips in the tabulation of rainfall; the interpolation of the probable rainfall figures for a month in the event of a rain-gauge or measure-glass being temporarily unserviceable; the detection of the ignorant or inadvertent use of a wrong measure-glass—a matter of frequent occurrence in India, and possibly not unknown in this country.

Rain falls with such seeming irregularity of quantity and date, even in India—and much more so in this "unspeakable" Scotland—that it would appear *prima facie* impossible that there could be any approach to constancy of the date around which the whole year's rainfall balances. If we look at the tables of monthly rainfall for a large number of stations (in the same country) and see that the figures are not even approximately the same for the months or for the whole year, if we consider the difficulties connected with the measurement of rainfall, which are discussed in many of the volumes of "British Rainfall," it is surely surprising that, in spite of all these things, the reported year's rainfall should balance round a date which does not differ by more than a few days for a great many, if not all, the stations in any one year, and that for another year the displacement of this central date is so nearly the same for all of them. By merely looking at the monthly figures or at the graphs of those figures, we cannot accurately estimate either the central date or the amount of its displacement.

The causes which determine the times and amounts of rainfall for any place or country are known only in a very general way indeed. They are so elusive that investigators in their despair have even had recourse to sun-spots or comets' tails as a possible cause of special excess or deficiency of rainfall. They are so elusive that even in India, with its comparatively regular rainfall-seasons and with its special equipment of experts, the problem of

correctly forecasting the monsoon rains either as to time or intensity is still far from complete solution. They are so elusive that the forecasting of rainfall even for three days in this part of the world is not yet conspicuous for its infallibility.

The importance of the laws of rainfall is so incalculably great that it is not extravagant to say that their discovery is the ultimate object of, and excuse for, the millions of meteorological figures that are published annually in all civilised nations. Hence the discussion of rainfall in all its aspects is worthy of encouragement, and in this connection the centre of gravity of annual rainfall may possibly, after all, be of some value.

J. Cook.

Edinburgh, April 18.

I AM glad to read Mr. Cook's reply to my remarks, but believe that my criticism cannot be dismissed as a mere *a priori* one, and that it goes to the root of the matter. It is true that Mr. Cook illustrated his proposal in a most exhaustive manner, and that he did not suggest that his method might be of service in comparing the rainfalls of places in quite different climatic regions. But the general reasoning in the first paragraph of my former letter cannot be both correct and incorrect. Assuming it to be correct, it follows directly that even if we confine our attention to the records for a single station we might have the same C.G. for two years which differed greatly from one another as regards the monthly distribution of rainfall. In such a case, what possible significance could attach to the position of the C.G.?

I am heartily in sympathy with Mr. Cook's feeling that the discussion of rainfall in all its aspects is worthy of attention, but note that he himself does not maintain that his method is, but only that it may possibly be, of some value. It is certainly at first sight surprising that the calculated C.G. of rainfall for a large number of places for a given year in, say, Scotland should be very nearly the same, for the monthly rainfalls as ordinarily tabulated exhibit a bewildering complexity; but if the monthly values for the various stations are expressed as percentages of the year's total, the resulting picture is usually of a very simple and symmetrical character, which would lead one to anticipate that the C.G.s for the various stations would approximate closely.

The Fertilising Influence of Sunlight.

THE beneficial effect of heat on soil is recorded by Virgil in the following passage, to which Mr. F. B. Smith has directed my attention:—

"Often too, 'tis good
To burn the stubbles and with crackling flames
Consume the empty stalks; whether from thence
The earth derives a hidden store of strength
And fattening food, or whether 'tis that fire
Rakes out the subtlest vice and sweats away
Excessive damp, or whether by the heat
New pores are opened and the choked are cleared," &c.
("Georgics," Bk. i., lines 100 *et seq.*)

It is interesting to learn from Mr. Fletcher (April 7) that the natives of Bombay, in certain circumstances, subject their soils to heat. Mr. Fletcher regards the explanation given by Dr. Hutchinson and myself as incorrect, and suggests that the effect is due to the destruction of some toxin. This was the first hypothesis we examined, but was found to be insufficient.

(1) Toluened soil (*i.e.* soil treated with a small quantity of toluene, which is subsequently allowed to evaporate *in situ* without washing anything from the soil) is more fertile and more favourable to bacterial activity than the original untreated soil.

(2) When an aqueous extract of untreated soil is added to the toluened soil, there is a still further increase in fertility and in bacterial activity. The same result follows when a minute amount of the untreated soil itself is added instead of the aqueous extract.

(3) When a larger quantity (5 per cent.) of the untreated soil is added a similar effect is produced for a time, then the bacterial activity begins to be depressed. This action increases, and finally the depression, both in bacterial

activity and in fertility, is out of all proportion to the 5 per cent. of soil originally added.

Experiment (2) is conclusive against the hypothesis that a soluble toxin exists in the untreated soil which can be put out of action by toluene. For such a toxin should cause a decrease, and not an increase, in productiveness. Experiment (3) is equally conclusive against a relatively insoluble toxin; had this been present the depression should have shown itself at once, and should have been proportional to the amount of toxin, *i.e.* of untreated soil, added.

The growth of the injurious factor in experiment (3) seems to necessitate a biological hypothesis. Considering these and our other experiments in detail, Dr. Hutchinson and I see no way out of the conclusion that organisms are present in soil inhibiting the development of bacteria, and therefore of plant food. The organisms, whatever they are, must be larger than bacteria, or they would occur in the extract of experiment (2) along with the numerous bacteria there present—indeed, the beneficial effect of this extract was traced to the unweakened races of bacteria present, partial sterilisation having somewhat weakened the soil bacteria. Further, they develop more slowly than bacteria. As similar phenomena have been observed in all the soils examined, we are justified in supposing that the organisms are widely distributed, and constitute an important factor in soil fertility.

Mr. Fletcher's water-culture experiment is not germane to the point. A toxic body that occurred there would not necessarily come direct from the plant or be found in the soil. It is extraordinarily difficult to keep prolonged water cultures sterile, and until some attention is paid to the bacterial changes going on it is impossible to regard the results as proof of the presence of toxins in soils. Indeed, I know of no satisfactory evidence of their existence in normal soils.

Pneumatolysis.

IT is thirty-nine years this month since NATURE, over diffident initials, published my first scientific communication that ever saw print. For more than thirty of those years I have been much interested in the physics of plutonic rocks. Quite recently an event has occurred which must be almost without precedent in science. The petrologists have apparently repudiated, with unanimity, what is an axiom beyond dispute with chemists.

For some years past the petrology of plutonic rocks has been based on the new doctrine of "pneumatolysis," or the solvent powers of gases over solids.

Perhaps the last published important work on chemistry is the English version of Ostwald's "Fundamental Principles of Chemistry," 1909. Referring in that work to a certain diagram, representing the behaviour of one solid and one gas, the author writes:—

"From this point the liquid phase exists in the presence of the gaseous phase to the end of the diagram, because solid substances do not form solutions with gases" (pp. 186-7). Italics mine.

I believe that every chemist will assent to the above statement. If a gas is to mix with a solid, as a solution, the solid must first be vapourised; but if this be so the greater part of twentieth-century petrology breaks down, because it is everywhere relying on the truth of pneumatolysis.

From the student's point of view the situation is as paralysing as it is stupefying, and there seems nothing to be done but to put away the microscope. It is no work for students to discuss first principles.

Southwood, Torquay, April 18. ARTHUR R. HUNT.

Anomalous Reading of Hygrometer.

MAY not the observation referred to in NATURE of April 7 (p. 165) be a very simple case of latent heat evolution by condensation when the atmosphere is supersaturated with vapour? I think I have seen the wet bulb registering a temperature higher than the dry bulb; but this explanation seemed at the time so obvious that I made no careful verification of the apparent phenomenon.

HUGH RICHARDSON.

Bootham School, York, April 11.

AMERICAN DESERT VEGETATION.¹

THE popular impression of a desert as an endless plain of tawny sand, rainless, and utterly devoid of vegetation, or perhaps showing a distant oasis, bears but slight resemblance to the desert overlooked by the botanical laboratory near Tucson. Here considerable variety of vegetation prevails; in the streams and river aquatic plants flourish; along the river banks rise poplars and willows; on the alluvium of the "flood-plain" is mesquite-forest, in which acacias and another leguminous species, *Prosopis velutina*, live side by side with elder-trees and ash-trees; approaching the hills other types of vegetation appear in the dried water-courses, and on the gravelly and sandy slopes, in both of which sites grows the notorious creosote-bush (*Larrea*); while on the hills are found yet other plant-communities, including giant cacti and *Fouquieria*. In the winter and summer seasons of rainfall—scanty though this be—the scene changes like magic, for thousands of short-lived annual

case near rivers, atmospheric factors militate against luxuriance of growth or multiplicity of species. In less moist soil desert-plants evade or withstand the danger of desiccation by their possession of peculiar characters that may be physiological or morphological and anatomical.

As regards physiological peculiarities, the desert plants that are capable of reviving after thorough desiccation are few in number and are limited to lowly organised types, such as lichens (yet these by no means lack protective arrangements, as is indicated in Dr. Fink's article on lichens in the volume under review). On the other hand, many flowering plants exhibit in their life-history a rhythm that enables them to thrive in the desert without the aid of any adaptive structural features. For instance, in deserts there are many ephemerals that spring up in the rainy season, and within a few weeks produce leaves, flower and fruit, and die. They evade the true desert conditions, and survive in virtue of their rapid completion of the life-cycle at a definite season.

FIG. 1.—Right side of gulch near Laboratory, with generally south exposure.

(ephemeral) herbs spring up and clothe the ground with fresh verdure that contrasts with the ashen or bluish-green tints of the bushes or bizarre succulents.

Variety of water-supply, of slope, and of soil (clay, gravel, sand, alluvium, hard pan, saline spots) evoke corresponding variety in the vegetation of this patch of desert, and render the site eminently suitable for a botanical laboratory and for the solution of ecological and physiological problems by observations and experiments on desert plants in their natural surroundings.

Desert plants are exposed to the danger of death from desiccation by reason, first, of the various intense climatic factors tending to cause excessive evaporation, and, secondly, by the scantiness of the water available for absorption by the roots. Hence even where water is abundant in the soil, as is the

In the Egypto-Arabian desert there is but one annual rainy season, namely, in winter, and consequently only one annual crop of winter-ephemerals. Near Tucson, however, there are two rainy seasons—in winter and summer respectively—and corresponding crops of winter-ephemerals and summer-ephemerals. These two plant-communities consist of entirely different sets of plants, the seeds of which (according to the information in this volume) will not germinate at the particular rainy season during which they are wont to be inactive.

The structural characters enabling desert plants to exist have been dealt with by Volken and other investigators, and additional details have more recently been supplied by workers at the Tucson laboratory. But the main value and novelty of the work conducted in connection with this laboratory lies in the investigation of the behaviour and physiological activity of representative species, also in the thorough

¹ "Distribution and Movements of Desert Plants." By V. M. Spalding. Pp. v+144. (Washington: Carnegie Institution, 1909.)

analysis of the conditions prevailing and determining the precise local distribution of species and communities, including the changes taking place in the arrangement of the vegetation by colonisation and invasion.

In the various sections of the volume under review, interspersed in the discussion of general principles, we find many interesting details regarding certain species that we can piece together. For instance, we learn that the giant cactus, *Cereus giganteus*, which raises its fluted columnar stem up to a height of fifty feet, was shown by Mrs. E. S. Spalding to act as a vast expanding and contracting reservoir, as its ribs and furrows permit of bellows-like action. This plant, like some other desert-plants, possesses extensive shallow roots, which are very efficient collectors of water derived from feeble showers; for Mrs. Spalding found that after a rainfall of 0.5 inch "the stems expanded steadily for three weeks." Such a slight fall of rain would cause an appreciable increase in moisture only to a depth of less than four inches, so that the utility of shallow roots is clearly demonstrated, although so many desert plants have extraordinarily deep, relatively unbranched roots. In connection with the ques-

tion in the study of these newer phases of geology" would perhaps have been nearer correctness a dozen years ago.

One chapter differing from the others in being not particularly applied to Tucson desert is that on the origin of desert floras, written by Dr. D. T. MacDougal, who deals rather with the possible mode of evolution of biologic types than with the origin of the desert flora. He affirms that consideration of the known facts "leads to the inevitable conclusion that the form-characters, moisture-conserving capacities and resistance to desiccation, distinction of xerophytic species, must have made their appearance within comparatively recent geologic time." In the light of the geological evidence suggesting the former existence of deserts, and in view of the difficulty of geological preservation of the remains of desert-plants (except in oases or by rivers), such a conclusion seems open to the gravest doubt; and scepticism as to its correctness will be heightened by our knowledge, not only of the existence of xerophytic Cryptogamia and Phanerogamia of all ranks, but also of the distribution of such remarkably isolated types of desert plants as *Welwitschia* and *Acanthosicyos*. An additional consideration militating against Dr. MacDougal's conclusion is that xerophytic characters are evolved with considerable facility, as is demonstrated by the fact that various xerophytic communities (in deserts, for instance) in different parts of the world generally include a relatively large number of endemic forms that are definitely allied to and derived from the adjacent non-xerophytic flora.

In congratulating Mr. V. H. Spalding and his collaborators on this valuable contribution to our knowledge of the ecology of desert-plants, and on supplying ample justification for the foundation of a desert laboratory, we may perhaps be forgiven for adding a prayer to American botanists that when they use local or popular names of plants, they will, at least on first mention of these, also give the botanical names.

The omission of this precaution causes botanists of other countries to lose more than time in the endeavour to learn what plant is being referred to. For instance, early in the volume under review, reference is made without any explanation to the "sahuaro," the "creosote-bush," "cotton-woods," the "ocotillo"; yet few, if any, European botanists would know the identity of all these, or that these names represent respectively *Cereus giganteus*, and species of *Larrea*, *Populus*, and of—the reviewer imagined that he remembered the generic name of the last, but has been compelled to interrupt this sentence and waste ten minutes in fruitless search.

PERCY GROOM.

NUBIAN ARCHÆOLOGY.¹

THE first publication of the Egyptian Department of the Pennsylvania University Museum, under the direction of Prof. Randall Maciver, is one that shows great promise for the future. Thanks to the enlightened financial support of Mr. Eckley B. Cox,

¹ "Areika." By R. Randall Maciver and C. Leonard Woolley. With a chapter on Meroitic Inscriptions, by F. Ll. Griffith. Pp. 56+plates (Oxford: 1 letterpress and Plates printed by Horace Hart at the University Press, 1909.) Price 1*l.* 1*s.* net.

FIG. 2.—Left side of gulch near Laboratory, with generally north exposure.

tion of water supply, Dr. Livingston, in his valuable article on the soils, shows by means of curves that the effects of atmospheric precipitation on moisture in the soil regularly "lag" behind the actual falls of rain, so that, with certain depths of root, the plant does not immediately profit by showers, nor does it suffer, *pari passu* with absence of rain, from lack of supply of water. To return to the consideration of *Cereus giganteus*, Mr. J. C. Blumer clearly shows that individuals of this species, as of certain others, are more numerous on the southern slopes of hills. Inasmuch as other species show a preference for the more favourable northern slopes, there is a difference in the vegetation of the different sides of hills or gulches; and it is shown that on the northern side of the latter the difference tends to become accentuated with time, because the more numerous individuals and species present tend to cause an accumulation of humus and a consequent amelioration of the soil.

The section of the volume dealing with the geology of the desert, written by a geologist, Prof. Tolman, seems in subject-matter rather out of place, as it abounds in diffuse and irrelevant generalities. Among these the statement that "Europe is behind America

jun., Prof. Maciver has been enabled to initiate a programme of archaeological exploration in Egypt which, if continued, will, under the leadership of this most competent archaeologist, undoubtedly result in interesting and important discoveries.

Prof. Maciver has chosen for the scene of his work a portion of the Nile valley which has hitherto seemed most unpromising, the barren Nubia that lies between the first and second cataracts. The nature of the country, in which the river flows practically through desert, with only the narrowest fringe of cultivation along its banks, seemed to deny the possibility of any important ancient centre having been established there, and the temples that were erected by the river-side seemed to be the memorials more of Egyptian imperio-religious pride than of real civilising energy. There

liminary tour of his Nubian district, which resulted in the publication of a careful and detailed report on the archaeological probabilities and possibilities of Nubia. Then the Survey Department started a thorough and comprehensive exploration of the whole district (including excavations under the direction of Dr. Reisner and Mr. Firth, which began its labours at Shellal, and is now slowly working southwards).

Independent explorers were also summoned to the work. Prof. Garstang, of the University of Liverpool, carried out a season's work at Koshtamneh which was productive of interesting results. Unluckily, it has remained a *ἄπας λεγόμενον*. Prof. Garstang was drawn aside from the comparatively dull antiquities of Nubia to the more beautiful trophies to be found in the necropolis of Abydos, but he has now turned

Nubian Castle near Amada: Period of Thothmes III. View looking from the North-east Corner. From "Areika."

is little doubt that no serious attempt to seek for remains of antiquity in this region would have been made even now had it not been for the fact that the proximate raising of the level of the Aswân Dam threatened the drowning of the ancient banks for a considerable distance upstream, and the consequent destruction of any historical evidence that might be buried near them. The attention of the Service des Antiquités, the archaeological branch of the Egyptian Public Works Department, was at once directed to the necessity of saving such historical evidence so far as possible, and the director-general of the Service, Sir Gaston Maspero, K.C.M.G., commenced the organisation of a general archaeological campaign in Nubia. Mr. A. E. Weigall, the inspector of antiquities for Upper Egypt and Nubia, undertook a pre-

again southwards, to the Sudan, and time may yet bring him back to assist the researches of Mr. Firth and Prof. Maciver in Nubia. Prof. Maciver was last in the field, but has already made most interesting finds, which are described in "Areika," the volume under review. Assisted by Mr. C. Leonard Woolley, he has explored the region between Korosko and Amada, known as El Righa or Areika, which gives its name to the book. Here he has carried out three excavations; first, that of the castle of a Nubian chief of the time of Thothmes III., near Amada; secondly, that of a neighbouring cemetery of earlier date; thirdly, and most important of the three, that of a cemetery of Roman date at Shablul, opposite Korosko.

The Nubian chief's castle is a queer conglomerate-

tion of buildings of absolutely non-Egyptian and more or less negro type, showing all the negro's inability to think out or carry out a coherent plan, or produce any sensible building bigger than a simple hut. There is little doubt that the Nubian population is, and has always been, fundamentally negroid, and no doubt in ancient Egyptian days it was nearer the negro than it is now. The cemetery might, from the nature of the antiquities found in it, be dated to a period contemporary with the Egyptian predynastic period. But Prof. Maciver well points out that the barbaric culture of the Nilotes, which was raised and organised into a civilisation in Egypt before the beginning of the First Dynasty, continued in its primitive form in Nubia throughout history, and even now pottery not distantly akin to the prehistoric Egyptian is still made there. So that we cannot say that primitive remains in Nubia are necessarily primeval in date. This explains the phenomenon of the "Pan-Grave People" of the XIIth Dynasty in Upper Egypt. The isolated Egyptian settlements of this people, whose pottery is so closely analogous to that of the primitive Egyptians, but whose "Middle Kingdom" date is certain, were originally discovered by Prof. Flinders Petrie. They remained an enigma until Mr. Weigall discovered that the earlier Nubian cemeteries were largely of "Pan-Grave" type, and that "Pan-Grave" pottery was common there. It was then supposed that the Egyptian "Pan-Grave" remains were the relics of Nubian conquerors at the time of the XIIth Dynasty. Prof. Maciver, following up the clue, supposes in the present volume that the Egyptian "Pan-Grave" people were Nubian potters imported into Egypt to make their special pottery (which was, in its way, finer than that of the Egyptians). To me it seems more probable that they were not merely potters, and I would see in them simply colonies of deported Nubians, brought back by the conquering Pharaohs of the XIIth Dynasty as the "living prisoners," trophies of their Nubian *razzias* which are often mentioned in the inscriptions, and settled in vacant lands of Upper Egypt.

The discoveries at Shablul are of importance as definitely identifying the products of a peculiar art, long known and correctly identified as of Roman date (it is especially well represented in the collections of the British Museum), as Nubian. The later specimens of the painted pottery of this style clearly connect on to the crude productions of the Coptic potters, and this was always seen, but Prof. Maciver and Mr. Woolley have shown that the same style, which is Nubian only, goes back well into the Ptolemaic period. Its earlier products are quite Egyptian or Greek in the choice of motives, but throughout the whole series there runs a note of peculiar originality of treatment which can only be due to the Nubian potter himself. This painted pottery is splendidly illustrated by coloured plates which accurately reproduce the originals. Its decoration is extremely interesting, and the comments of the authors themselves on it are most illuminating. But to quote the opinions on it of professors of artistic style who are evidently not gifted with much historical sense was unnecessary: Prof. Meurer's opinion that a certain design of a crescent with a cross (a modification of the *ankh*, the symbol of life) on this Roman-Nubian pottery is a descendant of the Minoan Cretan motive of the Double Axe above the Horns of Consecration (so well known from Dr. Evans's discoveries at Knossos) is, frankly, absurd, and we wonder that our authors did not pass over it in respectful silence. As it is, their reviewers have to chronicle it with disrespectful mirth.

Prof. Meurer has supposed that the two designs are connected because they are alike, ignoring the absence of all known connecting links between them during

the space of a millennium and a half. The only possibility of the Nubian design being descended from the Cretan would lie in an Egyptian adoption and naturalisation of the Cretan design in the time of the XVIIIth and XIXth Dynasties; and though the Egyptians did for a time take over some Cretan artistic ideas, they never took over the idea of the Double Axe above the Horns of Consecration; and naturally they did not, because they did not take over the worship of the Cretan gods, whose symbols these were (though cults akin to those of Crete may have been known in the Delta at an early period). We prefer our authors' own ideas without those of Prof. Meurer. Throughout their work they themselves had made only one remark which calls for criticism—the description of the *ankh*, the symbol of life, as the "Nile-key." The *ankh* was not a key, and had nothing to do with the Nile. It was a conventional representation of a man's girdle, with the tied ends hanging down in front.

The book concludes with a paper on the inscriptions in "Meroitic" form of the Demotic script, of which many specimens were found by the explorers, and its relation to the Meroitic hieroglyphic inscriptions, by Mr. F. L. Griffith. Mr. Griffith here makes the first step to a decipherment of both scripts, and has established several curious and unexpected facts with regard to them. This discussion of the relation of their language to the Nubian of Christian times, lately studied by Profs. Schäfer and Schmidt, is very suggestive.

In conclusion, Messrs. Maciver, Woolley, and Griffith must be congratulated on the production of a most interesting contribution to a little-known branch of Nilotic (if we may not, strictly, say Egyptian) archaeology.

H. R. HALL.

FROM THE CAPE TO CAIRO WITH A MAGNETOMETER.

DURING the last twenty years a great many observers have carried on magnetic work in different parts of Africa. A summary of the results up to 1900 at the Cape of Good Hope has been collected and published by Prof. Morrison and the writer,¹ and one for Northern Africa by Mr. B. F. E. Keeling;² since 1898 a magnetic survey of South Africa has been in progress; between that date and 1906 observations were taken at more than four hundred stations by Prof. Morrison and the writer, with assistance at one time and another from Mr. S. S. Hough, Prof. A. Brown, Prof. L. Crawford and Mr. V. A. Löwinger. A report by the present writer on the work during this period, including a summary of the earlier work in Africa, south of the Zambezi, was published for the Royal Society at the Cambridge University Press.³

Notwithstanding the considerable amount of work done, there was, and still is, a lack of magnetic data for great tracts of what is now no longer geographically the unknown continent. With the purpose of obtaining some information in parts magnetically unknown, the writer submitted, in 1907, a scheme of work through Dr. L. A. Bauer, director of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, to the trustees of that body. In this scheme he proposed to continue the line of magnetic stations already occupied between Cape Town and the Victoria Falls to Gondokoro, on the Nile. North of that it was not deemed necessary to observe, as the Survey Department of the Egyptian Government had already put forward proposals for a

¹ "Magnetic Elements at the Cape of Good Hope." By Beattie and Morrison. (Trans. S.A.P.S., vol. xiv., 1902.)

² "Magnetic Observations in Egypt." By B. F. E. Keeling. (1908.)

³ "Report of a Magnetic Survey of South Africa." By J. C. Beattie. (1909.)

magnetic survey of Egypt and the Sudan. It was intended also, should time permit, to make observations in German South-west Africa.

These proposals met with the approval of the trustees of the Carnegie Institution, and they allocated a sum of 2000*l.* for the work. In the first instance the proposals contemplated only one field-party with one observer; later, however, the writer modified his plan so as to include a second observer, in the hope of being able to have two field-parties. At his suggestion the Department of Terrestrial Magnetism in Washington appointed Prof. Morrison as second observer. The additional money necessary was provided by the Government Grant Committee of the Royal Society (250*l.*), and by Dr. L. S. Jameson and Sir Lewis Michell (100*l.*)

The work began at the end of November, 1908, when the writer left Ceres Road, in the Cape Colony, for Windhuk, in German South-west Africa. This journey lasted four months. During February and March of 1909 Prof. Morrison made observations along the railways in the northern part of the same region.

In April, 1909, repeat observations were made in Cape Colony and in Rhodesia, and Prof. Morrison also made observations between the Victoria Falls and Broken Hill, the then terminus of the Beira and Mashonaland Railways.

The two observers left Broken Hill in the beginning of May, and marched to Abercorn *via* Fort Rosebery. After Broken Hill the only means of transport was by porters; one set of instruments was carried from there more than 2000 miles, the other more than 1400, the whole distance being accomplished without mishap to any of the instruments.

At Abercorn the observers separated: Prof. Morrison proceeded to the northern end of Lake Nyasa, then down the Nyasaland plateau and the Shiré and Zambezi valleys to Chinde; from there he went by sea to Dar-es-Salaam, and made observations between it and the terminus of the railway which goes from that place inland. He was able to secure a number of observations which will be of great value for determining the secular variations of the magnetic elements in that part of the world. Finally, he made a number of observations along the Uganda Railway from Mombasa to Port Florence.

The writer went overland from Abercorn to Bismarckburg, a German station on the south shore of Lake Tanganyika. From there he marched to Tabora, an important town in German East Africa; observations could not be made along the shores of Tanganyika, as he had originally intended, because the steamer had temporarily ceased to run—the two white men on it, the captain and the engineer, having contracted sleeping sickness. From Tabora he journeyed overland to Bukoba, a German port originally founded by Emin Pasha, on the west shore of Victoria Nyanza; the march was continued along the west coast of that lake to Entebbe. At the latter place he found it was impossible to take the usual overland route to Gondokoro, on account of sleeping sickness; his caravan had to go *via* Albert Nyanza, and there he conveyed forty-five miles from Butiaba to Koba. The end of the porter transport was reached at Gondokoro, just a little more than 2000 miles from Broken Hill by the route followed. The work was brought to a close by the two observers once more meeting at Cairo, and comparing their instruments with those at Helwan and, finally, with those at Kew.

In addition to the observations taken along the routes mentioned above, a number of stations previously worked at in Cape Colony, the Transvaal, Natal and Zululand were again occupied in 1908; the cost of this was defrayed by a grant from the Royal Society (25*l.*) In all about 360 new stations were

occupied, mainly in regions which formerly were known magnetically only slightly or not at all.

The instruments used for the above observations were the same as in the earlier work in South Africa (1898-1906), and were lent to the writer by the Royal Society, the Royal Observatory of the Cape of Good Hope, and the South African College. By means of the repeat observations, the results obtained in 1908 and in previous years can be reduced to the same standard; and, further, through the comparisons at Helwan and at Kew, can be compared with much that has been done in recent years in other parts of the world.

While making the preliminary arrangements for the journey, the writer received great assistance from the Governor of the Colony of the Cape of Good Hope, Sir Walter Hely-Hutchinson, who communicated with the authorities of the various territories it was proposed to survey, and obtained permission for the observers to enter them, and to enjoy while there special privileges.

In German South-west Africa the authorities allowed the observers to travel free of charge over the Government railways; the same facilities were given by the Cape, the Central South African, the Natal and the Rhodesian, and the Uganda railways; the writer had valuable concessions while travelling in the Sudan and on the Egyptian Government steamers and railways.

In addition to these facilities, the courtesy and hospitality of the English and the German officials did much to relieve the tedium and strain incident to work of this nature in such circumstances. The writer feels that a formal recognition such as this is but a poor return for the help so willingly and generously accorded.

In conclusion, it gives the writer great pleasure to have the opportunity of thanking Mr. R. S. Woodward, the president of the Carnegie Institution, and Dr. L. A. Bauer, director of the Department of Terrestrial Magnetism of that institution, for their advice and encouragement during the progress of the work, and in particular to thank the latter for the great interest he has taken in the reduction of the results, a work which is being carried out at Washington under his direction.

J. C. BEATTIE.

SIR ROBERT GIFFEN, K.C.B., F.R.S.

THE sudden death of Sir Robert Giffen on the morning of April 12, while on a tour in Scotland accompanied by Lady Giffen, is a great loss to economic and statistical science. He joined the Statistical Society in 1867, at the age of thirty, having the already acquired reputation as a writer on financial subjects in the *Globe*, the *Fortnightly Review*, the *Economist*, and the *Spectator*. He was elected member of the council and one of the secretaries of the society in 1876, in which year he joined the Civil Service, and was appointed chief of the Statistical Department of the Board of Trade, and one of the delegates of the Government of England to the International Statistical Congress at Buda-Pest. He submitted to that congress "Considérations sous Forme de Tableaux pour la Préparation d'une Statistique internationale des Chemins de Fer," and was appointed a member of the permanent committee. To the Social Science Congress at Liverpool, in the same year, he contributed a paper on the causes and effects of the depreciation of silver, how far is it an evil, and what are the means of remedying the evil? In his official capacity, he devoted himself with zeal to rectifying and harmonising governmental statistics, and diminishing the overlapping and cost of parliamentary returns. For example, he pointed out that the stati-

tics of emigration were vitiated by the omission of any deduction in respect of the return of persons temporarily leaving the country; and he induced the Government to appoint a committee to consider the whole question of official statistics.

In 1878 he read before the Statistical Society an important paper on recent accumulations of capital in the United Kingdom, which is an excellent example of the comprehensiveness and accuracy of his statistical methods, and of his faculty of drawing trustworthy inferences from materials that at first sight appear insufficient. Great as was the increase of wealth which he had to record, he was sanguine enough to hold that it would be the fault of the English people if their progress were not in future even more rapid than in the past, and his forecast has been verified. In the same year he took part in the foundation of the *Statist* newspaper, and was the delegate of the Government to the International Statistical Congress at Paris.

In 1879 he contributed to the Statistical Society a treatise on the fall of prices of commodities in recent years, and undertook the duty of editor of the society's journal. The Treasury committee on statistics made its report, to which was appended an important memorandum by Sir Robert Giffen on the compilation and printing of the statistics of the United Kingdom. In 1882 he read a paper to the Statistical Society on the use of import and export statistics, and was elected president of the society. His inaugural address was on the utility of common statistics. In the following year the University of Glasgow, of which he had been a student, conferred upon him the degree of Doctor of Laws. His inaugural address to the Statistical Society for that year was on the progress of the working classes in the last half-century. It is characteristic of his thorough devotion to any duty which he undertook that he was present at every meeting of the society held during his presidency. In the year 1884 he was elected a member of the Athenæum club under the rule which enables the committee of the club to confer that honour on persons distinguished in literature or the arts or for public service. In 1885 he contributed to the Statistical Society's jubilee volume a paper on some general uses of statistical knowledge; and, in the following year, read to the society further notes on the progress of the working classes. In 1887 he was nominated by the International Statistical Congress at Rome as the English member of a committee on standards of value; and in the same year he was appointed by the British Association president of the section of economic science and statistics (section F) for the meeting at Manchester, and delivered an address on the recent rate of material progress in England. He also took part in the proceedings of a committee of the association appointed to investigate variations in the value of the monetary standard, and in the following year drew up the report of that committee. He afterwards became its chairman.

In 1890 Sir Robert Giffen took part in the formation of the British Economic Association, now the Royal Economic Society, and became a vice-president of it. In 1891 he was created a Companion of the Bath, and in 1892 elected a Fellow of the Royal Society. In 1894 the Royal Statistical Society (as it had then become) paid him the well-earned compliment of awarding him their Guy medal in gold as a recognition of his great services. In 1895 he took the second step in the ladder of the Order of the Bath, being promoted to the dignity of Knight Commander, and in 1897 he retired from the public service after a career of great usefulness and distinction, having taken a large share in the creation and development of the labour, commercial and statistical depart-

ments, of which he was the first controller-general. In 1900 he was elected president of the Manchester Statistical Society, and delivered an address; and in 1901 the British Association appointed him, for the second time, president of section F, and he delivered an address at Glasgow on the importance of general statistical ideas.

His separate published works were:—"American Railways as Investments" (1872), "Stock Exchange Securities" (1877), "Essays in Finance" (3 editions), "The Case against Bimetallism" (2 editions), "Economic Inquiries and Studies" (2 vols., 1904).

This formal record of a life spent in the study of subjects usually thought to be dry and uninteresting would not be complete if it were not supplemented by the statement that in personal character and private life he was one of the most genial of men.

NOTES.

THE eighteenth "James Forrest" lecture of the Institution of Civil Engineers will be delivered at the institution on Wednesday, June 22, at 8 p.m., by Sir John Gavey, C.B., his subject being "Recent Developments of Telegraphy and Telephony."

A REUTER message from Washington states that the proposed American Antarctic expedition under the joint auspices of the Peary Arctic Club and the National Geographic Society has been abandoned for this year on account of lack of funds.

WE learn from *Science* that Prof. R. P. Whitfield, curator in the American Museum of Natural History since 1877, and the author of important contributions to palæontology and geology, died on April 6, at the age of eighty-two years.

THE death is announced, at sixty-one years of age, of Dr. C. B. Plowright, formerly professor of comparative anatomy and physiology at the Royal College of Surgeons, and the author of a standard work on fungi.

M. DE MONTEFIORE, we learn from the *Revue scientifique*, has given 150,000 francs to the Paris Academy of Sciences to create a new triennial prize of 12,500 francs to assist the progress of electrical science.

It is announced in the *Times* that a National College of Agriculture is soon to be established in Pretoria. General Botha has promised to set aside 100,000*l.* as a first instalment for the execution of the project, and the Town Council has unanimously decided to give the Government the whole of the town lands of Groenkloof as a site. The area comprises 3681 acres, and contains arable and pasture lands as well as a large plantation.

THE Geological Society of France has this year awarded its Danton prize to M. Gosselet. The prize is given to the geologist whose discoveries are likely to benefit industry most, and was awarded to M. Gosselet for the part he has taken in the development of coal-mining in the north of France. The Viquesnel prize, intended to encourage geological research, has been awarded to M. Robert Douvillé for his stratigraphical work on the geology of Spain and his palæontological researches on the foraminifera and ammonites.

THE Geologists' Association has arranged a Whitsuntide excursion to Swanage, Lulworth Cove, and Bournemouth from May 14-18. The party will leave Waterloo on Friday, May 13, at 4.10 p.m. The excursion to Lulworth Cove will be carried out only if the sea is calm, and

should May 14 not be suitable for the excursion, the Lulworth visit will be postponed to May 18. Full particulars of the excursions can be obtained from Mr. W. P. D. Stebbing, 78A Lexham Gardens, London, W.

AN event of importance in wireless telegraphy is the inauguration by the Marconi Company of a service for the direct transmission of public messages between their stations at Clifden, in Ireland, and Glace Bay, in Canada. Both the stations have been recently reconstructed, and communication will be kept up by them continuously both by day and by night. The latter fact is interesting as showing that the difficulties of transmission during the hours of daylight have been overcome. The system is a directive one, the aërials being so constructed as to emit waves principally in the required direction. The discharger used is of the type invented by Mr. Marconi, in which sparking takes place between metal discs cooled by being kept in rapid rotation. By causing the sparks to be formed between equally spaced projections on the discs, the trains of waves emitted are broken up in a regular manner so as to produce in the receiving telephone a musical note which can be clearly distinguished by the operator. The power used for sending is about 400 kilowatts. The service commenced on April 23 by an interchange of greetings between the Postmasters-General of Canada and Great Britain.

THE present spring is proving peculiarly free from spells of really warm weather, and the summary of temperature issued by the Meteorological Office with its Weekly Weather Report shows that for the period of seven weeks ended April 23 the thermometer in the screen did not exceed 64° in any part of the United Kingdom, the highest readings ranging between 60° and 64°. At Greenwich there have, as yet, only been six days this year with a temperature of 60° or above, whilst to the same date last year there were eighteen days with a temperature of 60° or above. The rainfall for the first half of spring is less than the average in all districts, except in the north and east of Scotland and in the south-east of England, the greatest deficiency being 1.08 inches, in the south-west of England. Since the commencement of the year, however, the rainfall is everywhere in excess of the average, and in seven out of twelve districts the excess is more than 2 inches. The mean sea temperature round the British Islands is at present nearly everywhere colder than at the corresponding period last year, and at Kirkwall it is nearly 5° colder.

THANKS to the energy of Mr. C. E. Fagan, and the generosity of owners, a remarkably fine and representative series of trophies illustrating the big game of the Empire has been brought together and dispatched to Vienna for the forthcoming Sports Exhibition. The specimens lent by the Prince of Wales include the record head of the Javan rusa from Mauritius (where the species has been reduced), together with heads of tahr, markhor, musk-ox, and Newfoundland caribou. The Duke of Westminster is sending a magnificent Irish elk skull; Lord Burton an unrivalled twenty-pointer Scots stag; Lord Lamington a pair of Indian lion skins; Captain Collins, of the Wau Garrison, a head of a bull Sudani eland (one of three or four in this country), and Mr. F. C. Selous one of the last really fine heads of the typical South African white rhinoceros.

FOR the purpose of publishing the practical and scientific results obtained through the medium of the Entomological Research Committee (Tropical Africa), it is proposed to issue a journal, to be called *The Bulletin of Entomological*

Research. The journal will contain accounts of the observations which have any bearing on the subject of economic entomology; descriptions of insect life-histories, with figures of their earlier stages; reports on practical methods for destroying or keeping in check any noxious species; papers by specialists dealing with the systematic classification of such groups as are known to be, or are likely to be, injurious to human beings, live-stock, or agriculture; and so forth. It is proposed to issue not fewer than four parts annually, and additional parts will be published whenever sufficient material is forthcoming. Further particulars may be obtained from the scientific secretary, Entomological Research Committee, British Museum (Natural History), Cromwell Road, London, S.W.

THE report of the council and the proceedings of the Hampstead Scientific Society for the year 1909 show that the society has completed ten years of useful work. During the year with which the report deals, an astronomical observatory and meteorological station have been established on the top of Hampstead Hill. The Metropolitan Water Board allows the use for the purposes of the observatory and station of a portion of the surface of the covered reservoir near the Whitestone Pond. Arrangements have been made for the meteorological records to be taken twice daily, and the results are published in the monthly return of the Meteorological Office and in the *Hampstead and Highgate Express*. We notice that Sir Samuel Wilks, Bart., F.R.S., has been compelled, through advancing years, to resign the presidency of the society, and has been succeeded by Prof. W. M. Flinders Petrie, F.R.S. The membership of the society now numbers 274.

DR. JULIUS KÜHN, professor of agriculture at the University of Halle, whose death was announced in these columns last week, was one of the band of workers who laid the foundations for the modern development of the scientific side of agriculture. He acquired a great practical knowledge of the subject in his early days when working as a farmer and, after his student days at Bonn were over, as manager of a large estate. This knowledge proved invaluable when, later on, he was appointed to Halle and devoted himself to the more scientific aspects of his subject. Perhaps his best known work is that in connection with the feeding of animals. It had for many years been customary to compare animal foods with one another in terms of "hay equivalents." The method was necessarily rough, and capable only of limited development. In 1856 Grouven introduced feeding standards based on the amounts of the various food constituents—protein, carbohydrate, &c.—required by the animal; knowing these data and the percentage composition of the foods, it was possible to make up rations suited to the different classes of stock. So attractive was this new view that a tendency arose to regard the feeding of animals as a merely arithmetical problem requiring only a knowledge of the standards and of the composition of foods. Kühn, however, insisted on the necessity of keeping the new work down to the solid ground of fact. Whilst recognising the value and importance of the standards, he also recognised the individuality of the animal and of the crops on which it feeds. His book "*Die zweckmässigste Ernährung des Rindviehes*," which appeared in 1861, and went through ten editions in the course of thirty years, thus had a steadying effect on the development of the subject. He also published a number of papers on the parasitic diseases of plants, and is remarkable for his early advocacy of the view that sugar-beet "sickness" is the result of nematodes, which can be destroyed by burning over the ground. His activity

was great, and he continued publishing some of his manurial results even after the celebration of his eightieth birthday on October 23, 1905.

IN *Revue des Idées* for March M. L. Bréhier, under the title of "Les Origines de l'Art musulman," discussing the recent investigations of MM. H. Saladin and G. Migcon, shows that Mohammedan art is not the result of a "sudden improvisation." It is due to the development by conquered races, Copts, Syrians, people of Mesopotamia, and Greeks, of ideas surviving from the Chaldaean-Assyrian periods, and, particularly in its repulsion against delineation of the human form, was a protest against Hellenism.

MUCH work has of late been done on the action of various organic arsenic compounds as trypanocides. Drs. R. P. Campbell and J. L. Todd find that arseno-phenylglycin is a more active trypanocide than atoxyl in the treatment of experimental infections of white rats by the *Trypanosoma brucei* (*Montreal Med. Journ.*, xxxviii., 1909, p. 795).

IN the *Journal of the Royal Army Medical Corps* for August, 1909, Mr. P. D. Strachan and Lieut.-Colonel C. Birt summarise observations on the occurrence of Malta fever in South Africa. The disease has been met with in Orange River Colony, in Hanover, Beaufort West, Kimberley, and Steytlerville, Cape Colony, and in Bechuanaland, and there is a widespread epizootic of Malta fever among the goats of South Africa.

THE *Philippine Journal of Science* for October last (iv., No. 5), which has only recently come to hand, contains matter of considerable medical interest. An attempt to extend the cutaneous reaction, which has been much used in tuberculosis, to leprosy, is reported by F. Calderon and V. G. Heiser. Fifty lepers were vaccinated with a glycerin extract made from excised leprous nodules. In two or three cases there was a doubtful reaction, but otherwise the vaccinations were in all respects like controls done with a glycerin extract of skin from a cholera patient. The filtration of immune sera (anti-tetanic and anti-diphtheritic sera) is the subject of a paper by E. H. Ruediger. The serum was passed through Berkefeld filters, and the filtrate was found to be just as active as the unfiltered serum.

THE issue of the *Philippine Journal of Science* for November, 1909, vol. iv., No. 6, is entirely devoted to systematic zoology, Mr. A. Seale describing a large number of species of fishes as new, while Mr. C. S. Banks names four new Culicidæ and commences a list of the Rhynchota of Palawan, and Mr. L. Griffin communicates a synopsis of the snakes of the same island.

THE April number of the *Journal of Conchology* contains Colonel Godwin-Austen's presidential address to the annual meeting of the Conchological Society in October last, in which emphasis is laid on the importance of a study of the soft-parts of land molluscs as the only means of determining the affinities of the various forms. Some interesting lines of evolution which have been worked out by these means in the Zonitidæ are quoted.

IN the *Entomologists' Monthly Magazine* for June, 1909, Mr. E. A. Newbery adduces evidence to show that the scolytid beetle described in 1834 by Westwood as *Hypothenemus eruditus*, on the evidence of specimens in an old book-cover, and since then generally included in the

British list, is really an exotic species, one of the habitats of which is the shells of Brazil nuts, while it has also been observed in book-covers from Java and Singapore. It had previously been recorded from tropical America in the "Biologia Centrali-Americani."

THE March number of the *Museums Journal* contains a notice of the collection of Microlepidoptera, with the associated entomological library, recently presented by Lord Walsingham to the Natural History Branch of the British Museum. The collection, which contains about 45,000 species, against some 4000 previously in the museum, has been temporarily deposited in one of the new store-rooms at the base of the building, where it will gradually be arranged in proper order by the additional assistant specially appointed to take charge of it by the trustees.

IN addition to an account of the progress of that institution during the year, the *Aarsberetning* of the Bergen Museum for 1909 contains an illustrated description of the personal relics of Claus Frederik Fastings, which were bequeathed to the museum at his death in 1791. Of the three papers in the third part of the *Aarbog* of the same museum, by far the longest is one, by Mr. O. J. Lie-Pettersen, on the fresh-water rotifer-fauna of Norway. The author has been collecting material for several years, and records a long list of species; but, although it is stated that previously very little was known on the subject, it is remarkable that not a single one of these is described as new.

THE last number of the *Journal of the Marine Biological Association of the United Kingdom* (vol. viii., No. 5) contains a good example of the admirable work which is being carried on at the association's Plymouth laboratory. The director of the laboratory, Dr. E. J. Allen, and Mr. E. W. Nelson, have been engaged for some years past in experimenting on the cultivation of diatoms as food to be used in the rearing of various types of marine larvæ. By the use chiefly of modifications of Miquel's methods they have been able to make, by the addition of certain substances to sterilised sea-water, nutrient solutions in which it is possible to produce "persistent cultures" of a single species of diatom, or mixed cultures containing several species. In these cultures the diatoms multiply rapidly, and continue to thrive for long periods, sometimes extending over many months. The larvæ to be reared are placed after hatching in pure sterile sea-water; a sufficient amount of the nutrient solution is added, if necessary, and the water is inoculated with a suitable culture of diatoms; in some cases other unicellular organisms were used. By this means larvæ of *Echinus* were reared until long past the metamorphosis, being fed in the earlier stages upon the actively growing unicellular organisms, and after the metamorphosis on red seaweed. Larvæ of a sea-cucumber (*Cucumaria*) and a worm (*Pomatoceros*) were also successfully reared, and the method promises to be of great value to the experimental embryologist.

THE controversy between Dr. Florentino Ameghino and his critics respecting the alleged human origin of the "burnt earths" of Argentina was commented on in *NATURE*, vol. lxxxi., p. 534. The last paper then noticed was dated February 17, 1909. Since then, Ameghino has issued four others, up to March 19 of the present year; but it will be well now to await the elaborate memoir which is promised, and in which the evidence of hearths with bones of animals used as food will be set forth. The

strong point about Ameghino's spirited and persistent defence is that he now makes it clear that he has studied thin sections of the earths and of numerous artificially prepared products. It is admitted on all hands that minerals from decomposed lavas abound in the Pampas earths, and thus would occur undestroyed in the products of their partial fusion. This was pointed out in the previous notice in NATURE, and the thoroughness of Ameghino's reply is shown by his references to this notice, and his correction of some of its statements, in his "Examen critique du Mémoire de M. Outes". (*Anales del Mus. Nac. de Buenos Aires*, 1909, p. 459). While Ducloux, and perhaps our own reviewer, seem allowed some saving grace, the work of Outes is said to contain "des hérésies scientifiques tellement colossales que personne ne peut croire qu'il les ait publiées de bonne foi." A paper issued on January 29 (*ibid.*, tomo xx., p. 39) provides a very useful summary, with long quotations, of previous work on these debatable earths down to 1907, and a bibliography of work from 1907 to 1909.

THREE new species of Echeveria from southern Mexico are described and figured by Drs. J. N. Rose and C. A. Purpus in vol. xiii., part ii., of the Contributions from the United States National Herbarium. It is suggested that two, *E. gigantea* and *E. subalpina*, will be found useful in horticulture as bedding plants.

BOTANISTS who are contemplating a summer holiday in the Alps with the view of collecting choice plants will be interested in two articles by Mr. H. S. Thompson, published in the *Gardener's Chronicle* (April 16 and 23), giving an account of the flora of Mont Cenis. Among the plants taken between Susa and the Hospice were *Telephium Imperati*, *Cytisus supinus*, *Dianthus neglectus*, and *Saponaria lutea*. Around the small Lac Clair, a wonderfully rich hunting ground, situated at a height of 9000 feet, the author found *Campanula cenisia*, *Arabis coerulea*, *Cortusa Matthioli*, and clumps of *Saxifraga biflora*. Altogether Mr. Thompson collected 180 plants growing above an altitude of 8000 feet, besides meeting with a rich flora at lower levels.

A CURIOUS gall on the Indian grass *Ischaemum pilosum* is described by Mr. L. A. Boodle in the *Kew Bulletin* (No. 3). It takes the shape of a cylindrical tube about 15 cm. long, resembling a slender gooseneck, which, with a few scale leaves at the base, arises as an erect branch from the creeping rhizome. The gall caused by an insect, *Oligotrophus ischaemi*, is considered to be a greatly elongated internode. Various illustrations are given, including figures of the transverse section of the solid normal and hollow modified stem. Reference is also made in a short note to a method of preparing baobab trees as water reservoirs in the Soudanese province of Kordofan. The trunk is hollowed out to form a cistern about 20 feet deep and 10 feet in diameter; then a shallow basin is prepared round the base of the tree for the collection of water during the rain, from which it is transferred to the hollowed trunk.

THE annual report for 1909 of the Rothamsted Experimental Station is not so adverse as might have been expected considering the heavy rainfall and the low temperatures that prevailed through the summer. The yield and quality of wheat grain was poor, but the yields of barley and mangolds were above the average. A comparative test of nitrate of lime, cyanamide, nitrate of soda, and sulphate of ammonia, together with superphosphate in each case, was initiated with barley as the crop, which

has yielded, so far, no practical difference in the results. The important investigations carried on by members of the staff in connection with the effect of partial sterilisation of the soil, the direct assimilation of ammonium salts by plants and the development of the wheat grain have already formed the subject of a reference in these columns.

THE annual report for 1909 of the Woods and Forests Department of South Australia appears in Nos. 4 and 6 of the *Agricultural Journal* of that colony, and shows that the possibilities of the situation are being realised. It is said that inquiries have been made from America for one million railway sleepers cut from red-gum; the contract could not be taken up, because the supply of red-gum for sleepers is rapidly being used up for Australian railways, but it is of interest as showing that even the United States are having to look about for timber supplies. The expenditure of the Department has been increased from 10,080l. to 17,575l.; the intention is to encourage in every way the planting of pine, gum, and other trees, even to consider the advisability of offering a bonus sufficient to cover the cost of the necessary attention to the trees for the first four or five years of their existence. Wasteful methods of handling mature timber are still in vogue; we are told that only about one-third of the timber on any given area is properly utilised, the rest being destroyed by axe and fire owing to the unsystematic and wasteful character of the lumbering operations.

THE marked increase of the sensitiveness of an instrument for detecting alternating currents of electricity when the free period of the instrument coincides with the period of the current was pointed out by Prof. M. Wien twenty years ago. The property has since led to the production of several forms of vibration galvanometer, and the theory of the instrument has to some extent been investigated. A more complete examination of the theory, and a comparison of the theory with the actual behaviour of three forms of the galvanometer, are to be found in a paper on the subject by Mr. F. Wenner in the February number of the *Bulletin of the Bureau of Standards*. A few new hints as to the design of the instruments are also given. In order to avoid giving the instrument a double period the moving system must be symmetrical. In bridge work the resistance of the galvanometer should be very much less than that of the bridge, and the back electromotive force developed in the instrument should be half that impressed on the galvanometer circuit.

THE Jesuit Fathers at Zikawei are to be congratulated on the addition to their observatory of a seismological station. During the months of January and February this year a Weichert pendulum of 1200 kilos. recorded twenty-six shocks. Twelve of these were also noted by an Ōmori pendulum of 15 kilos. Both instruments record on smoked paper. The difference in the number of records obtained from these two types of instruments is undoubtedly striking, but had there been at Zikawei an apparatus which gave a photographic record of earthquake motion it is probable that the total number of shocks noted would have been more than doubled. During this period at Shide, in the Isle of Wight, photographic recorders of the British Association type noted eighty-one disturbances. An instrument writing on smoked paper at that station, however, only recorded a few of these.

IN the second fascicule of vol. iv. (new series) of the *Annales de l'Observatoire royal de Belgique*, the geophysical results obtained at the observatory during 1908

A SECOND revised edition of an excellent handbook, "Brazil in 1910," by Mr. J. C. Oakenfull, has just been issued by the author, 21 Clifford Terrace, St. Budeaux, Devonport. The work has been brought up to date, and is well illustrated by reproductions of photographs and several maps. There are many statistical details, and an appendix giving information as to salaries and cost of living. The main theme of the writer is that Brazil offers abundant opportunities for the activities of Europeans with capital.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN MAY:—

- May 2. 4h. Mercury at greatest elongation ($20^{\circ} 55'$ E.).
 „ 8h. 32m. to 10h. 57m. Transit of Jupiter's Satellite
 III. (Ganymede).
 4-7. Meteoric shower before sunrise from Halley's comet ?
 8. 17h. Sun eclipsed, invisible at Greenwich.
 9. 11h. 59m. to 14h. 26m. Transit of Jupiter's Satellite
 III. (Ganymede).
 10. oh. Mercury $1^{\circ} 18'$ N. of the Moon.
 11. 11h. 52m. Minimum of Algol (β Persei).
 14. 8h. 41m. „ „ „ „
 18. 14h. Halley's comet transits the Sun's disc.
 23. Moon eclipsed, partly visible at Greenwich.
 14h. 33m. First contact with penumbra.
 15h. 47m. „ „ shadow.
 15h. 57m. Moon sets at Greenwich.

THE TOTAL SOLAR ECLIPSE OF MAY 8, 1910.—This eclipse, which can be observed from Tasmania, is not a very favourable one, because the sun at the critical time is only about 8° above the horizon. Mr. Frank McClean, however, who has made considerable preparations for observing it, is already in Tasmania, and has collected a party of eight observers to help him utilise the numerous instruments he has taken out with him. The point he has settled upon as his observing station is situated in the south-west part of the island, namely, Hixson Point, Bramble Cove, Davey. In a cable to Dr. Lockyer, dated April 19: 11.55 a.m., he states:—"Sunday extensive scrub fire within four feet instrument tent. No damage." While on the occasion of his successful expedition to Flint Island in 1908 his chief enemy was "water," he has now had to combat "fire." Little is known at present about the site, but in a letter to the recipient of the cable he writes that one of his party "is as strong as a horse," and will be exceedingly useful "when we have to clear the 200-feet high trees out of the way and carry the packing cases up a 600-feet hill." It will thus be seen that he is making every endeavour to secure as good a site as possible, and it is hoped that his energy will be rewarded with success.

HALLEY'S COMET.—Reports from a number of places state that Halley's comet has been seen as a fairly bright object, under favourable conditions, with the naked eye. Cloudy weather has seriously interfered with English observers, but the comet was seen, and estimated to be of the second magnitude, at Greenwich on the morning of April 25, and was followed until nearly sunrise. According to the *Times* report, it was probably seen with the naked eye, and photographs were secured with several instruments. Owing to the brightness of the sky, exposures of one minute only were possible, and the resulting plates show only the nucleus and coma, with no reference stars. The appearance of the comet was that of a small whitish cloud with a brighter nucleus. The *Times* also states that good positions of the comet were secured by Dr. Ristenpart, at Santiago, on April 12, 15, and 21, and that he has re-determined the time of perihelion passage as April 19-6803 (G.M.T.), about an hour later than was determined by Mr. Merfield. Observations by Mr. Ryves at Saragossa, Spain, on April 21, showed, from naked-eye comparisons with γ Pegasi, that the magnitude was about 2.7. Mr. Innes also reports a naked-eye observation at Lyme Regis on April 25, between 4h. and 4h. 30m. a.m. Similar observations are reported from Malta and Gibraltar, and, at the former, a tail about 1° in length, and inclined about 40° to the horizon, was seen.

In No. 16 of the *Comptes rendus* (p. 955, April 18) M. Giacobini reports having observed the comet, at the Paris Observatory, between 16h. and 18h. on April 17. He was surprised at the increase in brightness since March 7, when the magnitude was estimated as 9.5; at present he estimates it as 2.0 or 2.5. Taking the ephemeris values for the distances from the sun and earth, this means that on May 18, 19, and 20 the magnitude should be -1.3 to -1.8 , as bright as, or brighter than, Sirius. To M. Giacobini the comet appeared as a circular nebula $30''$ to $35''$ in diameter, with a strong central con-

densation. No tail was distinguished except a small swelling of the circular nebulosity in position-angle 350° , but this measured scarcely one minute of arc in length.

Those observers who are generally unacquainted with celestial objects should note that Venus, as shown in Fig. 1 on p. 224 in last week's NATURE, is a conspicuous object near the comet's position at present; we have heard of a number of enthusiastic would-be observers who have evidently mistaken this planet for the comet, as many did in the case of comet 1910a in January last. Referring to Fig. 2, given last week, it should be noted that the position of Mars was inadvertently omitted from the diagram. On May 22 the comet will pass directly beneath Mars, which should be inserted about half-way between the top of the date (22) and the disc representing β Geminorum.

Mr. Denning writes:—"The meteors supposed to be connected with Halley's comet are due on the mornings of May 4-7, as the earth reaches her nearest relative position to the cometary orbit at that period. This meteoric shower is directed from the immediate region of the equator in about right ascension 338° , and was discovered by Colonel Tupman in 1870, and seen also in the following year. The radiant rises late on the night, so that the meteors can only be seen in the morning twilight. It is doubtful whether or not this meteoric shower is really connected with the celebrated comet of Halley, for the distance of the earth from the comet's orbit at its nearest approach is about 6,000,000 miles, but the computed orbits of the meteors and comet exhibit a significant resemblance. Should any rich display of meteors be presented at the period mentioned, the spectacle will be unique, for the parent comet will be visible at the same time."

COMET 1910a.—Observations by M. Pechüle on April 8 gave corrections of +3s. and +0.6' to the ephemeris published by Dr. Kobold in No. 4393 of the *Astronomische Nachrichten*, and showed the magnitude of comet 1910a to be about 11.0. In No. 4404 of the same journal Herr Tscherny discusses the difficulties attending the calculation of the orbit of this comet, and gives three sets of parabolic elements, which he compares with ten other sets previously published by various calculators.

In No. 2 (1910) of the *Bull. de l'Acad. roy. de Belgique* Prof. Stroobant publishes an account of his observations of this comet, and shows that on January 31, at 6h. 20m., the tail extended to the middle of the Great Square of Pegasus, its length being about 36° .

OPENING OF THE NEW SCHOOL OF AGRICULTURE, CAMBRIDGE.

IN the presence of an assembly fully representative of agricultural interests, both scientific and practical, the new School of Agriculture at Cambridge was opened by the Duke of Devonshire on Tuesday, April 26.

The formal opening was preceded by a luncheon party given at Pembroke College Lodge by the Vice-Chancellor. In addition to the Duke of Devonshire, the heads of colleges, and the principal professors, the guests included the Master of the Drapers' Company, Lord Blyth, Sir George Fordham, Sir C. Dalton, Sir Thomas Elliott, Sir Richard Cooper, Prof. Somerville, Mr. A. D. Hall, and Mr. T. H. Middleton. Speeches were delivered by the Vice-Chancellor, the Duke of Devonshire, the Master of the Drapers' Company, and Prof. Wood.

In declaring the building open, the Duke of Devonshire emphasised the necessity for a close alliance between the scientific and the practical aspects in agricultural work, and promised to exert his influence with the Royal Agricultural Society to further that end. He also expressed the gratitude felt by all workers in the practical field to the University authorities for the extended facilities which it now gives to students of the agricultural sciences.

The new school is situated close to the Botany School. It was erected after the designs of Mr. Arnold Mitchell at a cost of 20,000l. The building consists of three floors, a basement, and attics. It contains three lecture rooms, two large elementary laboratories for chemistry and botany respectively, seven smaller rooms for private research, as well as a library and private rooms for the teaching staff. The accommodation is designed for one hundred students,

and is already barely sufficient for the increased numbers coming forward.

Among the exhibits on view on Tuesday, the one which appealed most to practical men was a series illustrating the work of Profs. Wood and Biffen in connection with the improvement of English wheat. Prof. Punnett showed a number of interesting experiments illustrating Mendelian principles in connection with the inheritance of colour in poultry and rabbits. The forestry exhibits of Messrs. Henry and Burdon were also of extreme interest. Mr. Foreman showed the results of a laborious research on the constitution of the proteids found in linseed.

INTERNATIONAL CONGRESSES ON ORNITHOLOGY AND TROPICAL AGRICULTURE.

WE have received the announcement that the fifth International Ornithological Congress will meet in Berlin from May 30 to June 4 inclusive. Its success seems already ensured by the large number of distinguished ornithologists (representing twenty-three countries) who have intimated their intention of attending. According to the programme, the congress will assemble in the "Festsaal" of the Zoological Gardens, and its sectional meetings will be held in the Landwehrhoffizier-Kasino, close to the Zoological Gardens station of the State railway, where also will be installed on May 29 and following days the business bureau. The president designate is the distinguished professor of the Berlin Natural History Museum, Dr. Anton Reichenow, the subject of whose opening address is "Über die Fortschritte und den gegenwärtigen Stand der Ornithologie." In the ordinary course he would have been introduced by the retiring president, the late Dr. Bowdler Sharpe, and the absence of this genial personality, so familiar at these triennial congresses, cannot but cast a shadow over the meeting. The congress is divided into practically the same sections as at its last meeting:—systematic ornithology, anatomy, palæontology, geographical distribution; migration; biology and oology; bird protection; aviculture and acclimatisation; and economic ornithology. Many important papers are already announced by, among others, the president, Count v. Berlepsch, Herr Csörgey, Dr. Eckstein, Dr. Hartert, Dr. Helms, Herr Nehr Korn, Prof. Neumann, Hon. Walter Rothschild, Dr. Thienemann, and Prof. Virchow. Visits to the following places of interest have been arranged:—on Monday afternoon to the Havelsee, at the invitation of the German Ornithological Society; on Thursday morning to the Zoological Gardens, with lunch to follow; on Friday to the Natural History Museum, or a motor trip round Berlin for those who prefer it. On the evening of Tuesday there will be a cinematograph exhibition of bird pictures at the "Urania" Society's rooms. On Wednesday evening the city will entertain the members and their wives, and on Friday evening the customary banquet will take place in the Zoological Gardens. After the close of the congress excursions will be arranged, if sufficient members apply, to the observation station at Rossitten and to the experimental protection station at Seebach. The subscription for full membership is 20 marks, and for lady associates who do not desire the publications 10 marks. The secretary's address is 43 Invalidenstrasse, Berlin N. 4.

In order to facilitate the study of the problems of tropical agriculture, an International Association of Colonial Agriculture was founded in 1905 at the close of the first International Congress of Tropical Agriculture, held in Paris in that year. The association has arranged to hold a second International Congress at Brussels on May 20-23. A British committee has been formed to arrange for the contribution of papers by those concerned in tropical agriculture and colonial development. The president of this committee is Prof. W. R. Dunstan, F.R.S., and the secretary Dr. T. A. Henry, Scientific and Technical Department, Imperial Institute, S.W. As evidence of the interest taken in the work of the congress, it may be mentioned that the following papers have been promised already to the British committee:—W. L. Balls, (1) the application of Mendel's law to cotton breeding,

(2) some causes affecting the Egyptian cotton crop; G. C. Dudgeon, the cottons in indigenous cultivation in British West Africa; A. E. Humphries, wheat production in relation to the requirements of the United Kingdom; F. B. Guthrie, (1) work done in New South Wales in connection with the improvement and testing of wheats, (2) the work of the late W. J. Farrer on the improvement of wheat in New South Wales; I. B. Pole-Evans, problems connected with maize-growing in South Africa; J. B. Carruthers, (1) new methods of tapping Castilleja, (2) cover plants, as a substitute for weeding in rubber, cacao, and other cultivations; Dr. T. A. Henry and Dr. S. J. M. Auld, the burning quality of tobacco; G. M. Odium, tobacco culture in South Africa; Mr. Easterby, cultivation and varieties of sugar-cane at the Sugar-cane Experiment Station, Mackay, Queensland; Prof. P. Carmody, (1) preparation of rubber, (2) preparation of paper from megass, (3) methods of manuring, suitable for natives, (4) influence of malarial diseases on labour supply, (5) breeding of stock suitable for the tropics; Mr. Benson, manuring of tropical fruits; Dr. S. S. Pickles, the aromatic grass oils; R. N. Lyne, causes contributing to the success of the Zanzibar clove industry; W. Macdonald, dry-farming and land settlement in South Africa; J. H. Barnes, the alkali lands of northern India; E. M. Jarvis, economic zoology in African colonies; W. Gill, the introduction of the remarkable pine (*Pinus insignis*) into South Australia, and its successful utilisation; F. W. Barwick, African wild silks; G. C. Dudgeon, some important insect pests in British West Africa; C. C. Gowdey, insects of economic importance in Uganda. The International Association of Colonial Agriculture has also arranged for the collection, in tropical countries, of information on a number of subjects of special interest, and general reports on these will be presented to the congress, as well as reports by experts in each country concerned. The inquiries already arranged for are on cotton cultivation, labour conditions in the colonies and tropical countries, acclimatisation of European cattle in tropical countries, and alcoholism in the tropics. All communications regarding the congress should be sent to the secretary of the British committee, Imperial Institute, London, S.W. Applications and subscriptions for membership should be sent to M. Vandervaeren, treasurer of the Belgian committee, at the Ministry of the Interior and of Agriculture, Brussels, Belgium.

ECONOMIC GEOLOGY IN CANADA.¹

THE pamphlets mentioned below have been issued recently by the Department of Mines of Canada, mainly with the object of directing attention to the importance of the economic mineral products of the Dominion, and of assisting with trustworthy information those persons who are actually engaged, or may contemplate engaging, in the exploitation of its mineral wealth.

The first work on the list gives a concise but clear description of the general geological features of Canada and of the known valuable minerals that characterise the different areas. For the sake of convenience, the whole of the Dominion is divided into a number of regions, each of which has a more or less definite individual geological structure, and which accordingly produces a distinct series of economic minerals. The scope of the work is perhaps most readily explained by giving a list of the different regions into which the Dominion is here divided, these being as follows:—

(1) The Appalachian region, comprising the Maritime Provinces and that portion of the Province of Quebec which lies immediately to the north of them, consisting mainly of crystalline and Palæozoic rocks, the chief mineral products being coal, gold, and iron ores.

(2) The Lowlands of the St. Lawrence Valley, which consist mainly of Palæozoic strata, and have not, so far,

shown any great mineralogical wealth, with the exception of petroleum; the principal Canadian oilfields, lying in the tongue of south-western Ontario that projects between Lakes Huron and Erie, occur in strata of Devonian age, which form a portion of this region.

(3) The Laurentian plateau, which comprises the greater portion of the Province of Ontario and of the North-western Territory; it consists mostly of pre-Cambrian—largely Laurentian—rocks, and though little more than the southern border of this vast tract has been prospected, it is known to contain many valuable mineral products, such as the Sudbury copper-nickel deposits, the Cobalt silver deposits, gold, iron ores, corundum, apatite, mica, &c.

(4) The Arctic archipelago, which forms an imperfectly known area to the north of Hudson's Bay; it appears to consist mainly of pre-Cambrian and some Palæozoic strata, and so far is not known to contain minerals of any great economic importance.

(5) The Interior Continental plain, which comprises the western portion of Manitoba and the southern portion of Saskatchewan and Alberta, extending westwards to the Cordilleran mountain system, the strata being largely of Cretaceous age. The rocks contain very important beds of coal and lignite, also bitumen, indications of petroleum, and natural gas.

(6) The Cordilleran belt, which comprises the western portion of the Dominion. This is essentially a mountain region, showing a great variety of geological formations; it is noted for occurrences of the precious metals, gold and silver, whilst lead, copper, and zinc also occur; it is also very rich in coalfields, notably in British Columbia, where all varieties of coal from lignite to anthracite appear to occur.

This brief summary of a summary will serve to indicate the arrangement, the scope, and the objects of this little treatise; it should also be added that it is accompanied by two maps, one showing the broad geological features, and the other the distribution of the chief mineral products; the former is very satisfactory, but the latter is by no means so clear as might be desired. The maps serve, however, perfectly well their purpose of elucidating the text and of making the whole subject clear and readily comprehensible. Minute accuracy of detail is not to be expected in such a work as this, and is perhaps not even desirable, so that anything of the nature of criticism would be entirely out of place. It can only be said that the treatise admirably fulfils its objects, and should be of the greatest value to all who are in any way interested in the mineral wealth of the Dominion. The Geological Survey of Canada can only be congratulated upon the felicitous idea of publishing such a pamphlet and upon the excellent way in which that idea has been carried into execution.

If the second pamphlet of the above list Mr. D. B. Dowling has given an account of the coalfields of the Interior Continental Plateau, and is thus able to discuss more in detail than was possible in the general work the nature and mode of occurrence of these important deposits. The author commences with a historical and general review of the coalfields, and then describes them in some little detail. He points out that the coal of this region occurs at three main geological horizons, namely, at the base, about the middle, and close to the top of the Cretaceous formation; it should be noted that he ventures, on what can only be described as imperfect data, to attempt an estimate of the quantity of coal that exists in the region under discussion, which he gives as 143,490 millions of tons, the area of the coalfields being taken as 22,506 square miles. That the amount of development work yet done in these fields is of the scantiest possible description is evident from the fact that the output for the year 1907 was only 876,731 tons. After a detailed description of the coalfields, a large number of analyses of the various coals is tabulated. This list is an exceedingly useful one, and the author has done excellent service in collecting the records into a conveniently accessible form. Following this list is another of analyses of coals from other districts, apparently for the purposes of comparison: it is, however, not at all clear on what principle he has brought together this miscellaneous collection of analyses of coals from British Columbia, Yukon, Nova Scotia, Wales,

¹ Canada Department of Mines. (1) "A Descriptive Sketch of the Geology and Economic Minerals of Canada." By G. A. Young, with an introduction by R. W. Brock. Pp. 151.

(2) "The Coal Fields of Manitoba, Saskatchewan, Alberta, and Eastern British Columbia." By D. B. Dowling. Pp. 111.

(3) "The Whitehorse Copper Belt, Yukon Territory." By R. G. McConnell. Pp. 61.

(4) "Report on the Iron Ore Deposits along the Ottawa (Quebec Side) and Gatineau Rivers." By Fritz Cirkel. Pp. 147.

Australasia, and the United States, still less why the whole of the coals of Great Britain should be considered to be adequately represented by analyses of some half a dozen Welsh coals. Such a comparative list should either be truly representative or else (and perhaps better) be omitted altogether. There appears to be no obvious reason why Mr. Dowling should want any new-fangled mode of classification in order to enable him satisfactorily to classify these coals. For most practical purposes the old classification of Gruner answers perfectly well, and if anything more precise is required, the fuel ratio (or the ratio of the fixed carbon to the volatile combustible matter) suffices for most purposes. The ratio suggested by the author, which he calls the "split volatile" ratio, appears to serve no particular purpose, and, on the other hand, would enable a coal to be put into almost any class at will by merely drying it more or less thoroughly before analysing it.

The two remaining treatises deal in more or less detail with ore deposits in definite regions, differing mainly in this respect that the copper deposits of the Whitehorse Belt have been opened up pretty extensively and are being actively worked to-day, whilst the iron ores of the Ottawa and Gatineau Rivers are not to-day of any economic importance.

The last treatise on the list is in some respects the least satisfactory. So long as the writer keeps to his proper subject, namely, a description of the ore deposits, their modes of occurrence, distribution and geology, there is little fault to be found, although the language is in places somewhat less clear than might be wished. It is, however, when the author ventures into metallurgical discussion that he seems to go widely astray. It is incomprehensible how anyone could write such a sentence as the following in discussing the metallurgy of iron (p. 104):—"By no known chemical or electro-thermic process can phosphorus be eliminated from the bath of any of the diverse metallurgical furnaces." The author seems to be exceedingly sanguine as to the future of the electrical production of pig-iron in the Dominion, an opinion which he seems to share with some other Canadian geologists. It is somewhat curious to note that it is the geologists who are urging on this metallurgical development, whilst manufacturers of iron appear to be more than doubtful as to its economic possibilities. Whether this is due to the well-recognised conservatism of the latter and the advanced scientific enterprise of the former, or whether it is a case of geologists rushing in where iron-masters fear to tread, is not for us to determine.

HENRY LOUIS.

RECENT PAPERS ON BIRDS.

MR. C. W. BEEBE is to be congratulated on his attempt (*Zoologica*, No. 5) to explain the "racket-making" habit of the motmots. These birds, it is almost unnecessary to mention, are in the habit of removing the vanes of the middle pair of elongated tail-feathers for a certain distance, so as to give them a racket-like form very similar to that which occurs naturally in certain kingfishers and humming-birds. It is shown that the length of feather thus devaned is invariably constant, even when the adjacent pair of feathers, which might serve as a guide, has been removed. Further, the portion destined to be stripped has the vanes markedly narrower than in the rest of the feather, while the component barbs and barbules are much weaker and less coherent than elsewhere, so that their removal is a comparatively easy matter. Consequently, in the course of the preening to which these birds subject all their tail-feathers, the weak area in the vanes of the middle pair becomes stripped, with the production of the symmetrical pair of terminal rackets. The original cause of the narrowing and degeneration in the affected area is still unknown, but the author is of opinion that it is not a case of the inheritance of an acquired character.

In No. 2 of the same serial Mr. Beebe gives the results of his observations on the habits of that remarkable bird the hoazin, or hoatzin (*Opisthocomus cristatus*), made during a visit in March, 1908, to Venezuela, and a second in April of the following year to British Guiana. As young birds were not to be found, the notes relate only to the adult. Mr. Beebe commences his account by mentioning

that the crop of the hoazin is unique on account of having assumed the structure and function of the gizzard of other birds, being much larger than ordinary, with the walls thick and muscular instead of thin and flabby. Despite this specialised feature, the primitive character of this bird is indicated by many points, the vestigial claw of the third digit of the wing linking it with Archaeopteryx, while another claim to primitiveness is apparent in the quadrupedal habits of the young. Thickly wooded river-valleys form the haunts of the hoazin, of which Lower Amazonia may be considered the centre, the distributional area, according to our present information, being in several instances discontinuous. The bird has a peculiarly disagreeable odour of its own, which is, however, in Mr. Beebe's opinion, less powerful than commonly reputed, and, at all events, insufficient to render it immune to the attacks of parasites. In general character the nest and eggs are very similar to those of the Guiana green herons (*Butorides*), but are placed higher above the water. Both sexes assist in nest-building, and two eggs seem to be the usual number in a clutch. There is no foundation for the assertion that these birds are polygamous, or, of course, for the old legend as to their snake-eating habits.

The institution and celebration of the first "bird-day" in the Australian Commonwealth is recorded in the January number of the *Emu*. October 29, 1909, was the date selected in Victoria, when the celebration proved a thorough success, parents, teachers, and scholars joining in with enthusiasm, and visits being paid to noted bird-haunts in the different districts. Numerous nests were examined, but in no instance were either birds or eggs molested. A certain amount of preliminary work had to be done in teaching the children the names of many of the local birds, for which purpose special lists were prepared. In the same issue Mr. C. Barrett describes the nesting of the rock-parrakeet (*Neophema petrophila*) on Goat Island, Kellid Bay. Here this appropriately named species rears its young in hundreds, the eggs being often laid deep down in burrows, although higher up on the cliffs they are frequently placed on the bare rock, in most cases under the protection of a raised stone.

In the March number of the *Zoologist* Mr. J. M. Dewar describes the manner in which the oyster-catcher breaks the shell of the purple whelk (*Purpura lapillus*) in order to be able to feed on its contents. As the soft-parts of this mollusc are much more difficult of access than those of mussels and limpets, the bird only occasionally attacks the whelk, and perhaps never does so at all in some localities. When a mollusc is to be operated upon, it is carried to some convenient spot, often a crack or hollow in the rock, or it may be a hard patch of sand, where it is laid with the mouth uppermost. The upper half of the beak is then introduced into the aperture, and an attempt made to punch out a small fragment from the opposite surface of the shell. If this is successfully accomplished, and the piece punched out is of small size, the beak is introduced into the new aperture, and the same process repeated higher up the shell, when, if it succeeds, the soft-parts can be scooped out. In cases where the first hole is larger, the latter operation can be accomplished by that aperture. Frequently the shell defies the bird's efforts.

The January number of the *Victorian Naturalist* contains the report of a paper, by Mr. A. H. E. Mattingley, on the breeding-habits of Australian cuckoos, in which it is stated that only an infinitesimal proportion of their eggs approximate in size, colour, markings, and shape to those among which they are laid. There are, moreover, numerous instances in which Australian cuckoos have laid in the nests of graminivorous birds, with the consequent starvation of the young. In other instances cuckoos lay in nests already containing eggs of their own species, while they also make use of nests too small to contain the young bird in comfort. It is concluded that, so far at least as Australian species are concerned, cuckoos, in place of possessing an instinct leading to the selection of suitable foster-parents, lay their eggs haphazard.

Ever since the year 1904 Dr. F. A. Forel has been endeavouring to ascertain the approximate number of individuals of the black-headed gull (*Larus ridibundus*) which resort to Lake Lemán during certain months of the year, and likewise to explain the reason why many

these birds are to be seen on the lake at seasons when the majority of their kindred are in far distant lands. These observations and their results have been published in the *Bulletin de la Société Vandoise des Sci. Nat.* for 1905 and 1910. The gulls are most numerous from the end of July to the middle of October—during which period their numbers may reach as many as 3600—but the great bulk disappears during the breeding-season, and again in winter. For their breeding resorts in the north the birds take their departure towards the end of March, although a few hundreds remain on the Haut Lac throughout the season. Of these stay-at-home individuals only a small percentage nest on the lake, and it seems probable that the great majority are aged birds the breeding-days of which are over. On the other hand, a certain number of migrating gulls reappear on the lake at the beginning of July, several weeks before their fellows. Several explanations of this have been given, but it seems, on the whole, most probable that these early arrivals are birds which have completed their parental duties in the north at an unusually early date. It is well known that dark barring on the tail are a sign of immaturity in this species, which generally disappear when the birds are about eighteen months old; on the other hand, the dark cap on the head is not assumed until the third year, while the birds do not fly until they are twenty-three months old. A certain number of birds are, however, met with in their second summer with the tail barred and the head dark, and these must probably be regarded as precocious individuals. Finally, the author has succeeded in demonstrating that the black-headed gull is not a diver.

The Land Agents' Society some time ago commissioned Mr. Walter E. Collinge to institute an inquiry into the feeding-habits of rooks, the results of which have been published in pamphlet form by Messrs. Laughton and Co., Ltd., Wellington Street, Strand. Observations made on more than 800 specimens from various parts of England indicate that (1) 67.5 per cent. of the food of these birds consists of grain, this, by the inclusion of roots and fruits, being raised to 71 per cent.; (2) the animal-food is 29 per cent., of which fully one-third is to be reckoned against the utility of the rook; (3) a grain-diet is certainly preferred; (4) the rook is not a particularly beneficial bird to the agriculturist, although its utility might be increased if its numbers were diminished.

In connection with the above, reference may be made to a paper by Dr. J. E. H. Kelso in the April number of the *Zoologist*, where it is shown that, in addition to doing considerable damage to fruit, the starling is nowadays an enemy to the farmer by devouring considerable quantities of wheat, such grain being presumably devoured for its own sake, and not on account of containing grubs. This wheat-eating propensity is considered to be a modern development.

In the same issue Mr. E. J. Stubbs makes out a strong claim, not only that the white egret (*Ardea garzetta*) should be added to the British list, but likewise that in the Middle Ages it was a common species in our islands. From various old works the author quotes passages indicating that a small white heron-like bird, without a crest, was commonly put on the table at state banquets on the north of England, where it was taken in the neighbouring marshes, and that this bird could have been nothing else than the egret, by which name it is indeed mentioned. The idea that the lapwing could have been intended is shown to be altogether untenable, and, indeed, the author adduces evidence to show that the present abundance of the latter bird is a modern feature.

LANGLEY'S CONTRIBUTIONS TO AERONAUTICS.¹

THE award of the Langley medal to the Brothers Wilbur and Orville Wright emphasises the fact that we are living in an age of great achievements. The twentieth century had hardly dawned when the world was startled by the discovery of radium, which has opened up an entirely new field to science, and has led us to modify

¹ Address delivered by Dr. Alexander Graham Bell at the presentation of the Langley medal of the Smithsonian Institution to the Wright Brothers on February 20.

profoundly our conceptions regarding the constitution of matter. Another new field has been revealed to us through the development of wireless telegraphy and telephony, and we now utilise the vibrations of the ætherial medium of space for the transmission of thought.

Then, again, we may note the most revolutionary changes going on before our eyes relating to methods of transportation. The appearance of the hydroplane-boat probably foreshadows a revolution in marine architecture and propulsion. On land we see motor-cycles, automobiles, and electric cars displacing the horse. Petroleum and electricity have become powerful rivals of steam, and we seem to be on the eve of a revolution in our methods of railroad transportation through the application of the gyroscope to a mono-rail system; and now aerial transport has come, dispensing with rails and roads altogether. The air itself has become a highway, and dirigible balloons and flying machines are now realities.

How well the predictions of Langley have been fulfilled. We now recognise that he was right when he said, a few years ago (1897), that:—"The world, indeed, will be supine if it do not realise that a new possibility has come to it, and that the great universal highway overhead is now soon to be opened."

It has been opened; and who can foretell the consequences to man? One thing is certain, that the physical obstacles to travel have been overcome, and that there is no place on the surface of the globe that is inaccessible to civilised man through the air. Does this not point to the spread of civilisation all over the world, and the bringing of light to the dark continents of the earth?

The Pioneers of Aërial Flight.

Who are responsible for the great developments in aërodromics of the last few years? Not simply the men of the present, but also the men of the past.

To one man especially is honour due, our own Dr. S. P. Langley, late secretary of the Smithsonian Institution. When we trace backwards the course of history we come unflinchingly to him as the great pioneer of aërial flight. We have honoured his name by the establishment of the Langley medal; and it may not be out of place on this, the first occasion of the presentation of the medal, to say a few words concerning Langley's work.

Langley's Work.

Langley devoted his attention to aërodromics at a time when the idea of a flying machine was a subject for ridicule and scorn. It was as much as a man's reputation was worth to be known to be at work upon the subject. He bravely faced the issue, and gave to the world his celebrated memoir entitled "Experiments in Aërodynamics." In this work he laid the foundations for a science and art of aërodromics, and raised the whole subject of aërial flight to a scientific plane.

The knowledge that this eminent man of science believed in the practicability of human flight gave a great stimulus to the activities of others, and started the modern movement in favour of aviation that is such a marked feature of to-day.

Everyone now recognises the influence exerted by Langley on the development of this art. The Wright Brothers, too, have laid their tribute at his feet.

"The knowledge," they say, "that the head of the most prominent scientific institution of America believed in the possibility of human flight was one of the influences that led us to undertake the preliminary investigations that preceded our active work. He recommended to us the books which enabled us to form sane ideas at the outset. It was a helping hand at a critical time, and we shall always be grateful."

Contributions to the Science of Aërodromics.

Langley's experiments in aërodynamics gave to physicists, perhaps for the first time, firm ground on which to stand as to the long-disputed questions of air resistances and reactions. Chanute says:—

(a) They established a more trustworthy coefficient for rectangular pressures than that of Smeaton.

(b) They proved that upon inclined planes the air pressures were really normal to the surface.

(c) They disproved the "Newtonian law," that the normal pressure varied as the square of the angle of incidence on inclined planes.

(d) They showed that the empirical formula of Duchemin, proposed in 1836 and ignored for fifty years, was approximately correct.

(e) That the position of the centre of pressure varied with the angle of inclination, and that on planes its movements approximately followed the law formulated by Joessel.

(f) That oblong planes, presented with their longest dimension to the line of motion, were more effective for support than when presented with their narrower side.

(g) That planes might be superposed without loss of supporting power if spaced apart certain distances which varied with the speed; and

(h) That thin planes consumed less power for support at high speeds than at low speeds.

The paradoxical result obtained by Langley, that it takes less power to support a plane at high speed than at low, opens up enormous possibilities for the *aërodrome* of the future. It results, as Chanute has pointed out, from the fact that the higher the speed the less need be the angle of inclination to sustain a given weight, and the less, therefore, the horizontal component of the air pressure.

It is true only, however, of the plane itself, and not of the struts and framework that go to make up the rest of a flying machine. In order, therefore, to take full advantage of Langley's law, those portions of the machine that offer head resistance alone, without contributing anything to the support of the machine in the air, should be reduced to a minimum.

Contributions to the Art of Aërodromics.

After laying the foundations of a science of *aërodromics* Langley proceeded to reduce his theories to practice. Between 1891 and 1895 he built four *aërodrome* models, one driven by carbonic acid gas and three by steam engines. On May 6, 1896, his *Aërodrome No. 5* was tried upon the Potomac River, near Quantico. I was myself a witness of this celebrated experiment, and secured photographs of the machine in the air, which have been widely published. This *aërodrome* carried a steam engine, and has a spread of wing of from 12 to 14 feet. It was shot into the air from the top of a house-boat anchored in a quiet bay near Quantico. It made a beautiful flight of about 3000 feet, considerably more than half a mile. It was indeed a most inspiring spectacle to see a steam engine in the air flying with wings like a bird. The equilibrium seemed to be perfect, although no man was on board to control and guide the machine.

I witnessed two flights of this *aërodrome* on the same day, and came to the conclusion that the possibility of aerial flight by heavier-than-air machines had been fully demonstrated. The world took the same view, and the progress of practical *aërodromics* was immensely stimulated by the experiments.

Langley afterwards constructed a number of other *aërodrome* models, which were flown with equal success, and he then felt that he had brought his researches to a conclusion, and desired to leave to others the task of bringing the experiments to the man-carrying stage.

Later, however, encouraged by the appreciation of the War Department, which recognised in the Langley *aërodrome* a possible new engine of war, and stimulated by an appropriation of 50,000 dollars, he constructed a full-sized *aërodrome* to carry a man. Two attempts were made, with Mr. Charles Manley on board as aviator, to shoot the machine into the air from the top of a house-boat, but on each occasion the machine caught on the launching ways and was precipitated into the water. The public, not knowing the nature of the defect which prevented the *aërodrome* from taking the air, received the impression that the machine itself was a failure and could not fly.

This conclusion was not warranted by the facts; and to me, and to others who have examined the apparatus, it seems to be a perfectly good flying machine, excellently constructed, and the fruit of years of labour. It was simply never launched into the air, and so has never had the opportunity of showing what it could do. Who can say what a third trial might have demonstrated? The

general ridicule, however, with which the first two failures were received prevented any further appropriation of money to give it another trial.

Conclusion.

Langley never recovered from his disappointment. He was humiliated by the ridicule with which his efforts had been received, and had, shortly afterwards, a stroke of paralysis. Within a few months a second stroke came, and deprived him of life. He had some consolation, however, at the end. Upon his death-bed he received the resolution of the newly formed *Aëro Club of America*, conveying the sympathy of the members and their high appreciation of his work.

Langley's faith never wavered, but he never saw a man-carrying *aërodrome* in the air. His greatest achievements in practical *aërodromics* consisted in the successful construction of power-driven models which actually flew. With their construction he thought that he had finished his work, and in 1901, in announcing the supposed conclusion of his labours, he said:—

"I have brought to a close the portion of the work which seemed to be specially mine—the demonstration of the practicability of mechanical flight—and for the next stage, which is the commercial and practical development of the idea, it is probable that the world may look to others."

He was right, and the others have appeared. The *aërodrome* has reached the commercial and practical stage, and chief among those who are developing this field are the Brothers Wilbur and Orville Wright. They are eminently deserving of the highest honour from us for their great achievements.

I wish to express my admiration for their work, and believe that they have justly merited the award of the Langley medal by their magnificent demonstrations of mechanical flight.

INDUSTRIAL ENGLAND IN THE MIDDLE OF THE EIGHTEENTH CENTURY.

THE conditions of the chief industries of the country at the date (1754) when the Society of Arts was founded were surveyed by Sir Henry Trueman Wood in an elaborate paper read by him at a meeting of the society on April 20. In the middle of the eighteenth century England was not to any noteworthy extent a manufacturing country, the most important industry being agriculture and occupations relating to it. At the epoch to which the paper refers, however, an industrial revolution was beginning which transformed England from an agricultural country, with no manufactures beyond those required for the supply of its own population, into the workshop of the world. Sir H. T. Wood described the positions of industries concerned with wool, cotton, linen, silk, various metals, brewing, distilling, tanning, paper, printing, and many other arts. From the mass of historical material brought together in the paper a few extracts are subjoined upon subjects associated with science. The retrospective view which these extracts provide is of interest to students of the progress of science and industry.

Science.

Science, about the middle of the eighteenth century, was not in a condition of active progress either in England or abroad. The time was not, either for science or scientific men, a happy one. International intercourse was impeded by wars; national progress was hindered by political differences. The great days of Newton, Hooke, Boyle, and Halley were past. Those of the founders of modern science were yet to come. Cavendish had just left Peterhouse. Priestley had not yet turned his attention to natural philosophy—his scientific work began in 1758. Banks, who ruled the Royal Society for so many years, was in 1754 a boy of eleven. Gilbert White (b. 1720) commenced his "Garden Kalendar" in 1751, but he did not make Pennant's acquaintance until thirteen years later, when he started the famous correspondence which formed the groundwork of the immortal "Natural History of Selborne." Franklin had completed and made public his

epoch-making experiments, and (in 1752) proposed to protect buildings by the lightning-rod. Black, the friend of Watt, and the enunciator of the principle of "latent heat," produced his first important work as a thesis for his M.D. degree in 1754.

In the earlier part of the century the power of mathematics in enabling us to grapple with the most abstruse problems of nature was first clearly demonstrated. In the latter part the foundations were laid on which the modern science of chemistry was built. The intervening years were not characterised by any marked progress in abstract science.

The Royal Society (to which a charter had been granted in 1662) was now firmly established at the head of British Science. Though it was still deemed a suitable object for the occasional shafts of humorists, and though it was sometimes attacked by quacks whose pretensions it declined to countenance, it was recognised and respected by all serious students of science at home and abroad. It had gathered to itself the best thought of the country, and was affording to what would otherwise have been the isolated efforts of scientific pioneers the advantage of coordination and cooperation.

Scientific attention was then principally, though by no means exclusively, directed to astronomy and to exploration. The transits of Venus of 1761 and 1769 had been predicted by Halley, and great importance was attached to their proper observation. An Act of 1743 offered a reward of 20,000*l.* for the discovery of a north-west passage, and later the discoveries of Captain Cook received full scientific recognition by the award of the Copley medal.

Perhaps no better indication of the state of scientific progress at any time in England could be found than is provided by the list of the Royal Society's Copley medalists. In 1731 and 1732 the medal was awarded to Stephen Gray,¹ the ingenious electrician who contrived a method of sending signals by means of frictional electricity, and who made, therefore, the first electric telegraph. It must, however, be added that the award seems to have been rather in the nature of acknowledgment of a skilful experiment than of appreciation of an important discovery. Bradley received the medal in 1748 for his discovery of the aberration of light, and Harrison in 1749 for his chronometer. In 1753 it was given to Franklin for the lightning-rod, and in 1758 to Dollond for his achromatic telescope.

The nature of these last three awards shows the tendency of the time towards practical rather than towards abstract science, and justifies the conclusion that the leaders of scientific thought of those days were working rather for practical results than for the advance of theoretical knowledge.

Iron.

The history of the origin and growth of the iron manufacture in England has been often told. The first step in its progress was the substitution of coal for wood charcoal in the process of reducing the metal from its ores. In the ironworks of Sussex and elsewhere the iron was made on open hearths, or small furnaces, by the help of bellows worked by hand or water. In early times the natural force of the wind was utilised, which, as an early writer says, "Saveth the charge of the bellows and of a milne to make them blow."

In such furnaces, with their moderate temperatures, uncooked coal could not be used, and the sulphur and other components of the coal affected the product injuriously. Nevertheless, numerous efforts were made—more or less successfully—to use the cheaper and more abundant fuel, and but a very few years before the special date with which we are concerned, the new method may be said to have been placed on a commercial footing.

It was at Coalbrookdale,² in Shropshire, that Abraham Darby established the manufacture of iron by coal about 1730 or 1735. He treated the coal as the charcoal-burners treated wood, and found that in the resulting coke he had the fuel he required. In 1754 he had some seven furnaces

(presumably small blast furnaces or reverberatory furnaces), and for blowing these he had five "fire engines" (steam or atmospheric engines), which pumped water to drive water-wheels which worked the bellows, the "rotative" engine not having then been invented. Such was the point that the manufacture of iron had reached at the time about which we are concerned. A few years later, in, or shortly after, 1760, Dr. Roebuck used blowing engines at the Carron Iron Works in Stirlingshire: These had four single-acting cylinders of cast-iron 4 feet 6 inches in diameter, and the pistons, of which the stroke was 4 feet 6 inches, were worked in alternation, so that a continuous and tolerably equal blast was maintained.¹ They were constructed by Smeaton.

It was the father of this Abraham Darby, Abraham the elder, who introduced into England about 1706 the art of casting iron vessels. The story, old and well known as it is, will bear re-telling. Early in the century John Darby brought over some Dutch brass-founders, and set up a foundry in Bristol. Here he tried to make iron pots instead of brass, but failed, until his Welsh apprentice, John Thomas, "thought he saw how they had missed it," tried the experiment, and, working secretly with Abraham Darby (the son of John), cast the same night an iron pot. "For more than 100 years after the night in which Thomas and his master made their successful experiment of producing an iron casting in a mould of fine sand, with its two wooden frames and its air-holes, the same process was practised and kept secret at Colebrook Dale, with plugged key-holes and barred doors."

It is about this date (1740, or a little later) that Huntsman perfected the process of making cast steel, which is still employed. Before this, "Steel was never melted and cast after its production." "By whatever method prepared, whether by the addition of carbon to malleable iron, or by the partial decarbonisation of pig iron . . . steel in mass was never obtained homogeneous." There is no need to describe the process, with its purely technical details. It may be sufficient to record the fact that the problem of producing ingots of steel of uniform composition was solved by Benjamin Huntsman, and that, as his secret method of working was stolen by a workman, it soon came to be generally employed in the Sheffield steel trade.

These early founders of the great British iron trade were soon followed by many others, chief of whom was Henry Cort with his invention of puddling (1783), and the manufacture, stimulated, in the later days of the century, to meet the rapidly growing demand for iron caused by the development of machinery and the steam engine, soon reached a most important place among the industries of the country.

Copper and Brass.

Without considerable research it might be difficult to give anything like a trustworthy account of the condition of metalliferous mining and metallurgy in the middle of the eighteenth century, and even if the labour were undertaken it would be difficult to ensure accuracy of result. Copper, tin, and lead have been mined and smelted in Great Britain from very early dates. Zinc, in the metallic state, was imported from China (or, at all events, from the East) in the early part of the seventeenth century,² but it does not seem to have been made in England until a century later.

Percy, while he professes himself unable to give a complete history of copper-smelting in England, tells us of early copper-mines in Cumberland and Northumberland, and thinks that the ores were smelted on the spot; but copper was imported from Hungary and Sweden, while calamine (zinc carbonate) was allowed to be exported as ballast. About the end of the seventeenth and the beginning of the eighteenth century copper-smelting was being carried on in Yorkshire and Lancashire, also a little later in Cornwall, in Gloucestershire, and at Bristol. The date of the establishment of copper works at Swansea (now the centre of the trade) is given as 1720, though Percy states that smelting was carried on in the Principality before that date. Brass (an alloy of copper and zinc), as distinct from bronze (copper and tin), was known

¹ Gray it was who first proposed the theory of positive and negative electricity.

² This is the usual spelling. Percy has Colebrook, and gives Coldbrook as the original name.

¹ Percy, "Iron and Steel," p. 829.

² Percy's "Metallurgy" (1851), p. 519.

"early in the Christian era, if not before its commencement"; but this was doubtless made, like early bronze, by mixing the ores before or in the process of smelting. By the middle of the century considerable progress had been made in its manufacture. Though brass, native and imported, was known in England long before, it is believed that it was not until the reign of Elizabeth that its manufacture was seriously undertaken. From that time forward a good deal of brass seems to have been made from British ores, and a goodly number of brass articles produced.

Tin.

Tin is certainly the most ancient of British exports. It was mined in this country before Britain was known to the Romans, and was brought by the Phœnicians from Cornwall and Devon, the *Cassiterides* (tin-lands), far beyond the Pillars of Hercules. For centuries England had what was almost a monopoly in supplying tin to the civilised world, the amount mined in Cornwall and the west of England growing steadily both in bulk and value until the discovery by the Dutch of large supplies of tin in Banka, Sumatra, whence it was first imported into Europe about 1787.

The most important application of tin is to the coating of iron-plate, to produce what is known as tin-plate or tinned plate, and is now popularly termed tin. Until the middle of the seventeenth century this manufacture was not known in England. English tin was exported to Saxony, where it was used to coat plates, which were sent to England. That ingenious projector and author, Yarranton, found out the German methods, and established a factory in the Forest of Dean, where plates were made better, it is said, than the German productions. It seems likely that the secret lay in rolling out the iron, previous attempts having been made with hammered plates. From this date the manufacture of tin-plate, and the use of rolls for the purpose, appears to have been established in England.

Lead.

The reduction of lead from its ores is a comparatively simple process, and it might not be untrue to say that the process has been rather developed than radically changed from the time when Pliny referred to British lead as used for the manufacture of lead pipes in Rome. Down to some time in the seventeenth century wind was relied upon for feeding the Derbyshire furnaces, which (as in Pliny's time) were placed on high ground to catch the breezes. Later, bellows driven by water-wheels were employed. Cupola furnaces were introduced into Derbyshire from Wales about 1747. These are identical with those now used. Coal was employed for smelting lead in the seventeenth century, there being two patents (1678 and 1690) granted for this privilege.

Coal.

The use of coal for fuel is referred to in a grant of land to the Abbey of Peterborough in A.D. 853. Records referring to the existence of collieries in Scotland go back as far as the end of the twelfth century, and in the thirteenth there is evidence that coal was brought to London by sea from the north. Such coal, besides being used for domestic purposes, was at first used for lime-burning, soon after in smiths' forges, and in later times for the smelting of copper and lead, in furnaces for the manufacture of pottery and glass, for drying malt, for making salt, by brewers, and for other industrial purposes.

Curiously enough, many of the earlier references to coal are due to its objectionable qualities. Its smoke and smell were disapproved of, and not without reason. In 1306 there was a Royal Proclamation against the use of coal in London, and there were many complaints about its smoke in later years. As its employment became more popular it became an article of commerce, and in 1563 an Act of Parliament prohibited its export, either in the form of ballast or otherwise. By the middle of the century it was, of course, worked on a large scale. As the shafts of the collieries grew deeper, in the effort to comply with the growing demand, fresh difficulties were encountered. The deepest shaft in 1754 appears to have been that at

Whitehaven, which reached a depth of 130 fathoms (or about 800 feet), and this must have been quite exceptional, for probably hardly any coal was worked at a greater depth than 100 fathoms.

Early in the eighteenth century fire-damp began to claim its victims. Its existence had been recognised long before, but very little was known about its nature. There were in the first half of the century several serious explosions with a considerable loss of life. The earliest effort to improve matters by ventilation was made about 1732, when the first attempt was made to produce a draught by means of furnaces. Between that date and 1754 considerable improvements were made in ventilation, and at that time, or a few years later, something like the modern system had been introduced by Spedding.

The great danger, connected with fire-damp was, of course, the use of naked lights. From the earliest times lamps and candles were employed, and miners had got to be very expert in detecting the presence of fire-damp by the use of the latter.² When it was found that the use of naked lights was dangerous, attempts were made to provide a light which would not fire the inflammable gas. The best of these was the "steel mill," the date of which is probably somewhere between 1740 and 1750. This apparatus was introduced by Spedding in consequence of some experiments by Sir James Lowther, which seemed to show that fire-damp was not ignited by sparks from a flint and steel. It consisted of a steel disc rotated by hand, against which a flint was held. The result was a shower of sparks, which gave a very faint, dim light, and for long it was erroneously believed that the apparatus was not capable of firing the gas. Nothing better, however, was known until Dr. Clanny's lamp in 1812, the precursor of the safety lamps of Davy and Stephenson.

Another great difficulty—perhaps the greatest felt by the miner—was that of keeping the mines free from water. From the early part of the century Newcomen's steam, or rather atmospheric, engine had been successfully used for this purpose, all other attempts at pumping having been found quite unable to deal even with the short shafts then existing.

In the earliest coal mines the mineral had been raised to the surface by men climbing ladders, or in baskets worked by horse-gins; but the successful use of the steam engine for pumping suggested its application to haulage, and about 1753 attempts were being made to apply it to this purpose. In the earliest of these "a basket of coals was raised by the descent of a bucket of water, the steam engine being employed to re-pump the water to the surface."³

Later in the century the hardly less clumsy method was employed of pumping water to a height and causing it to work water-wheels, which served to wind the coal to the surface. This roundabout and costly device was coming largely into use, when the application of the crank to the steam engine enabled the necessary rotation of the winding drum to be obtained direct from the engine.

Glass.

From a very early date glass had been manufactured in many places in England, and on a considerable scale. Most of this early glass was inferior, greenish in colour, and principally used for windows, though drinking-vessels of tumbler shape were also produced of the same material.⁴ At the date with which we are dealing large amounts of this same glass were being made in London, Newcastle, Birmingham, and elsewhere.

The materials employed were sand or "rock" (ground sandstone) and a crude alkali obtained from the ashes of plants. In this country the best alkali was obtained from burning kelp, and the collection and burning of that plant was a considerable industry on the coasts of Ireland and Scotland until the discoveries of Leblanc in 1792 enabled salt to be converted into carbonate of soda, and so put an end to the treatment of ashes for the potash and soda they contain. For making the commonest sort of green glass for glazing purposes the ashes of various plants were

¹ Wills' Cantor Lectures on "Explosions in Coal Mines" (1878), *Journal of the Society of Arts*, vol. xxvi, p. 458. Galloway, "History of Coal-mining."

² Wills' Cantor Lecture, *J. urnal*, vol. xxvi, p. 474.

³ Galloway, "History of Coal-mining."

⁴ Hartshorne, "Old English Glasses" (1897).

employed, fern being one of the most common. The ashes of kelp were not only rich in alkali, but contained a large proportion of lime, which was a necessary ingredient.

The best alkali, known as barilla, soda of Alicante, &c., came from the East, and was produced by burning kali (hence, of course, the name of alkali) plants of the genus *Salicornia*, or glass wort. This Eastern alkali was certainly used in Venice, Bohemia, and France, and perhaps it may have been imported here also for the better sorts of glass. Saltpetre, either imported or obtained from accumulations of animal and vegetable refuse (nitre-heaps), was also occasionally used. The use of manganese for improving the colour of the glass was well known.

The most important feature, however, of the English glass manufacture in the middle of the century was certainly the production of what is still known as "flint" glass, and was at the time also commonly called "cristal" or "crystal." This was far whiter and more brilliant than any glass which could then be made by other methods. It was employed chiefly for making drinking-vessels, but also for mirrors. The name "flint" arose from crystal glass having originally been made from crushed flint, which provided a nearly pure form of silica. The so-called "flint" is really a lead glass. The best authorities seem to hold that the use of lead was first proposed in England some time in the seventeenth century, though neither the name of the inventor nor the precise date of the invention is known.¹

Nesbitt thinks the glass-works established by Sir R. Mansell near Newcastle under his patent of 1614 owed their success to the use of lead, and it seems that England had for long a practical monopoly of the manufacture. Hartshorne quotes a French writer as his authority for the statement that in 1760 English flint-glass makers sent four-fifths of their output abroad, the whole of France being supplied with flint glass from England.

Watch-making.

During the eighteenth century the art of horology reached a high level in this country. Tompion, "the father of British watch-making," died in 1713, but his friend and successor, Graham, lived until 1751. Both were buried in Westminster Abbey. Graham invented the mercurial pendulum for compensating variations of temperature, and described it before the Royal Society in 1726. The lever compensation pendulum, acting by the different expansions of brass and steel, and commonly called the "gridiron pendulum," was invented by John Ellicott about 1735. In 1728 John Harrison showed his first chronometer to Arnold, who gave him the good advice that he should go back home into the country and perfect it. This he did, and in 1735 he brought it up to London again to enter it in competition for the reward offered by an Act of Parliament passed in 1714, which promised 10,000*l.* to the inventor of a chronometer capable of determining, within certain limits of accuracy, the longitude of ships at sea. The following year (1736) the Board of Longitude gave him 500*l.* after an experimental voyage, and in 1761 the chronometer was more completely tested by a voyage to Jamaica, when the Board awarded Harrison the full prize, though he did not get paid the whole of it until 1769. In 1749 he received the Royal Society's medal. Mudge (1715-94) and Arnold (1734-99) improved Harrison's chronometers, and practically brought them to their present form.²

Many of the clocks and watches made by these and other skilled mechanics of the period are still keeping good time, and the work of these men, though sometimes a little lacking in finish, will bear comparison, not only with that of their contemporaries in other countries, but with that of any who have succeeded them.³

Salt.

In mediæval England salt was important rather as a food preservative than as a condiment, as it provided the only known means of keeping meat and fish in an edible

condition. As Thorold Rogers points out,¹ for five or six months in the year the majority of people lived on salted provisions. They had to eat salted meat or go without meat at all. In Lent everybody had to live on salt fish—an unwholesome diet, which was a fruitful source of disease. The salt, which was always more or less impure, and often dirty, was originally obtained from sea-water all round the coast, evaporated first by solar heat and afterwards by fuel. The manufacture of salt was among the earliest applications of coal. The process was carried out sometimes in pans or ponds with clay bottoms, but in later years in metal evaporating pans heated by coal. Sussex, Devonshire, Shields, Bristol, Southampton, all had large salt works. From the southern coasts salt was exported to France, whence, centuries before, when the manufacture had depended on the heat of the sun, it had been imported.

The brine springs at Droitwich were certainly utilised before the early part of the eighteenth century. The salt-bearing strata at Northwich are said to have been discovered in 1670 in the course of boring for coal.

It is to be remembered that the idea of making soda from salt, the foundation of all modern chemical industry, had not yet been realised, though it was perhaps in the air. A little later Roebuck, the friend of Black and the associate of Watt, who was the founder of the great Carron works in Scotland and the first maker of sulphuric acid on a commercial scale, ruined himself by various speculations, amongst which was one for making soda from salt.²

Saltpetre.

Saltpetre or nitre (nitrate of potash) was a very important product, since it was a principal ingredient in the manufacture of gunpowder. It was also used in glass-making and for other purposes. It was first imported from the East, India and Persia. It was made in England and elsewhere in Europe, where it does not occur as a natural product, in "nitre heaps." These nitre heaps were composed of mixtures of animal excrement with wood ashes and lime. The process dates from the time of Elizabeth, when a German named Honrick discovered to the Queen for a sum of 300*l.* the secret of making "artificial saltpetre." The heap was watered with urine, and after a sufficient time the material was lixiviated, and the salt crystallised out. As time went on, native saltpetre was imported in considerable quantities, and the need for the strenuous search for saltpetre materials passed away, but much was obtained from the nitre heaps at the date with which we are concerned.

Gunpowder.

The earliest English gunpowder mills were those established at Long Ditton, in Surrey, by George Evelyn (John Evelyn's grandfather) about 1590. Another very important powder factory was that at Chilworth, established about 1654 by the East India Company, or leased by them about that time.³ This changed hands several times, was flourishing in the middle of the eighteenth century, and is still at work. There were also mills at Dartford and at Battle, in Sussex. Defoe tells us that the best powder in the country was made at Battle. The materials, saltpetre, charcoal, and sulphur, in the same proportions as in modern black powder, were crushed in mills driven by water-power, pestles being used, and later stones. The Waltham Abbey mills, started early in the seventeenth century, were purchased by Government in 1787. The method of manufacture remained unchanged from a very early date until quite recent times, and until the introduction of modern powerful explosives.

Copperas.

Copperas (green vitriol, or sulphate of iron) was made at many places in England, and was a product of considerable importance. It was used in the manufacture of ink, in dyeing, and as a source of sulphuric acid (oil of vitriol). A certain amount of it was obtained in the manufacture of alum from shale, but the bulk of it was

¹ Nesbitt, "Glass Vessels in the South Kensington Museum," (1878);

obtained from iron pyrites. The pyrites (sulphide of iron), or "gold stones," as it was termed, was stacked in heaps and allowed to weather. The drainings from the heap were boiled, with some iron added, and evaporated, the sulphate of iron crystallising out. There were important and old-established works at Deptford, Rotherhithe, and Whitstable. About 1754, works were established at Wigan.

Sulphuric Acid.

Sulphuric acid, known as "oil" or "spirit" of vitriol, was obtained by two processes, both invented by the alchemist Basil Valentine in the fifteenth century. In one of these crystals of sulphate of iron ("copperas") were distilled in earthen retorts, the resulting oil of vitriol being condensed in glass or earthenware receivers. The process is still employed at Nordhausen, in Saxony, and Nordhausen, or "fuming" acid, is still an article of commerce. It differs slightly in its chemical composition from the ordinary modern acid. The second process is the original form of the modern method. In it sulphur was burned under a bell-jar over water, and the acid liquor evaporated. Valentine also burnt a mixture of sulphur, nitre, and antimony sulphide in the same way, and this was an important improvement. About the middle of the eighteenth century a French chemist found that the antimony was not needed, and considerable amounts of the acid were then made.

Up to the middle of the eighteenth century all, or nearly all, the oil of vitriol made in England was made by the distillation of copperas, but in 1740 Ward introduced its manufacture by the method of burning sulphur and salt-petre. In 1749 he obtained a patent for the process. He set up works for making the acid, first at Twickenham and afterwards at Richmond. Dr. Roebuck improved on the process by substituting lead chambers for the glass receivers, and by this important modification the evolution of the modern method was practically completed. Roebuck and his partner, Garbett, first used their improved system in 1746 at Manchester, and in 1749 they set up work at Preston-Pans, near Edinburgh. This invention revolutionised the industry, greatly lowered the cost of production, and, among other applications, enabled the acid to be used for bleaching instead of the sour milk previously employed.

The method used at the present day for the manufacture of the vast quantities of sulphuric acid now required is really only a development of Roebuck's. The principle is the same, though it has been changed by chemical knowledge from an empirical manufacture to a highly scientific process. Iron pyrites (sulphide of iron) has generally replaced the sulphur first used, details have been improved, and the methods rendered more economical, but it remains in its essential features almost identical with that of a hundred and fifty years ago.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—An exhibition of 50*l.* a year, tenable for two years, is offered by the governing body of Emmanuel College to an advanced student commencing residence at Cambridge as a member of Emmanuel College in October. The exhibition will be awarded at the beginning of October. Applications, accompanied by two certificates of good character, should be sent to the Master of Emmanuel not later than October 1.

The chairman of the special board for biology and geology gives notice that applications to occupy the University's table in the Zoological Station at Naples, or that in the laboratory of the Marine Biological Association at Plymouth, should be addressed to him (Prof. Langley) on or before Thursday, May 26.

It is proposed to appoint a syndicate to consider the financial administration of the various scientific departments of the University and the financial relations between these departments and the museums and lecture rooms syndicate; that the syndicate confer with the financial board, the general board of studies, the museums and lecture rooms syndicate, the heads of the various scientific departments, and such other bodies or persons as they may

think fit; and that they report to the Senate before the end of the Lent term, 1911.

At the Congregation to be held at 2 p.m. to-day, April 28, it is proposed to confer the degree of Doctor of Law, *honoris causa*, upon Colonel Theodore Roosevelt.

PROF. SENIER delivered a lecture on March 9 last before the Royal Dublin Society on "The University and Technical Training," which has now been published by Mr. Edward Ponsonby, of 116 Grafton Street, Dublin. The lecture formed the subject of a note in our issue of March 24 last (vol. lxxxiii., p. 118).

MR. MILTON C. WHITAKER, general superintendent of the Welsbach Company's works, has been appointed professor of industrial chemistry at Columbia University, to the vacancy caused by the retirement of Prof. Charles F. Chandler. Dr. Marston Taylor Bogert has been appointed to succeed Dr. Chandler as head of the department of chemistry.

THE annual conference of the Association of Teachers in Technical Institutions will be held this year at Birmingham on May 16-17. Among the subjects for discussion are technical universities, relation of evening continuation schools to technical institutions, registration, superannuation of technical teachers, &c. An address will be given by Mr. Cyril Jackson, chairman of the Education Committee of the London County Council, on the extension of day technical work, and a paper will be read by Dr. T. Slater Price on the relation of technical institutions to universities.

THE second International Conference on Elementary Education is to be held at the Sorbonne, Paris, on August 4-7. It is being organised by an International Bureau, consisting of representatives of the various associations of teachers throughout Europe. Among the subjects to be discussed by the conference may be mentioned the aim and object of elementary science teaching in primary schools; compulsory attendance; the professional training of teachers, inspectors, and educational administrators; and educational continuation work. Further information may be obtained from Mr. Ernest Gray, 67 Russell Square, London, W.C.

IN connection with the appeal for 70,000*l.* for the purchase of a site and the erection of new chemical laboratories thereon at University College, London, to which we directed attention in the issue of NATURE for February 17 (vol. lxxxii., p. 462), the Lord Mayor has arranged a meeting of city men to be held at the Mansion House on May 10, at 4 p.m. The chair will be taken by the Lord Mayor, and the following gentlemen will speak:—the Earl of Rosebery (Chancellor of the University), the Earl of Cromer, Lord Avebury, Sir Felix Schuster (treasurer of University College), Dr. Miers (principal of the University), Sir Henry Roscoe (chairman of the appeal committee), and Sir William Ramsay, K.C.B.

THE attention of the Chancellor of the Exchequer was directed on April 22 in the House of Commons to the grave difficulty experienced by local education authorities in respect of the grant for secondary education based on the reduced amount of the "whisky money" for the present year. The amount received by local education authorities for higher education under the Local Taxation (Customs and Excise) Act has become greatly diminished, and many authorities have had to consider the question of reducing their work for next year, particularly in regard to evening classes. As was pointed out in the House by more than one speaker, it is highly unsatisfactory that the grant for higher education should depend upon the consumption of whisky in the country. The Chancellor admitted that something ought to be done in the course of this year to put the revenue of these local authorities on a more dependable basis. He said the loss owing to the decrease in the whisky revenue was 253,000*l.*, and he suggested, on behalf of the Government, that half the land taxes—which, it is expected, will be, in respect of last year, 490,000*l.*—shall be allocated for the purpose of making good the deficiency; and, secondly, that the

Government shall undertake, when it makes the financial arrangements for the year, to put on a more satisfactory and stable basis the whole question of the existing subvention from Imperial sources.

In the House of Commons on April 20 a satisfactory and altogether sympathetic discussion on the care and education of adolescents indicated that the efforts of educationists during the past few years to instruct public opinion as to the need of a system of compulsory attendance at continuation schools have not been in vain. Mr. Whitehouse moved a resolution, which was subsequently agreed to, "That, in view of the relation of unemployment to adolescent and child labour, this House regards an improved educational system, with more adequate provision for the care and training of adolescents, as a matter of urgent necessity, and considers that the Imperial Exchequer should bear an increased share of the cost of this national service." The chief educational change which he advocated was a system of compulsory education at continuation schools from the time of leaving school until the age of seventeen or eighteen. Mr. S. H. Butcher, in seconding the resolution, pointed out that the great blot of our educational system is that with one hand we spend millions of money on elementary education, and with the other we throw away a large part of the results of that education. There is lavish expense on one side, sheer waste on the other. A system which can lead to such results is economically unsound and educationally ruinous. A change is needed in the curriculum, and that change ought to be in the direction of less insistence upon mere book work, more direct contact with nature, more manual training. The school age must be raised, whether it is to fifteen or to fourteen, and we must abolish, by degrees but ultimately altogether, half-time exemptions below thirteen. Mr. Trevelyan expressed sympathy with the resolution on behalf of the Board of Education. He pointed out that the present is a session in which the Board is not required to produce any legislation, but he said the Board is prepared to move in several directions if time, money, and public opinion are favourable. A drastic method of dealing with street trading, the abolition of the half-time system, the raising of the school leaving age, and the encouragement of attendance at continuation schools, were instanced as subjects on which the Board has been at work and is prepared to act.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 21.—Sir Archibald Geikie, K.C.B., president, in the chair.—Lord Rayleigh: The incidence of light upon a transparent sphere of dimensions comparable with a wave-length. The investigation is on the basis of the electromagnetic theory of light, the transparent sphere being supposed to have a dielectric constant different from that of the surrounding medium. The case of a very small sphere, or of an obstacle of any size and shape under the restriction of very small refractivity, was treated in 1881. In the numerical calculations of the present paper the refractive index is supposed to be 1.5, and the ratio of circumference to wave-length has the values 1, 1.5, 1.75, 2, and 2.25. When the ratio in question is small and the incident light is unpolarised, the scattered light is polarised in all directions except, of course, those parallel to the incident ray; and the polarisation is complete at right angles to the primary ray. As the ratio increases, this condition of things is departed from. The maximum polarisation is now to be found in an oblique direction, inclining backwards. A little later the polarisation in certain directions is reversed, such changes occurring very rapidly as the ratio alters. Experiments similar to those made in 1881 upon sulphur particles precipitated from a dilute and acidified solution of "hypo" are described, and it is shown that a passage from red to blue light may reverse the polarisation, although there is no change either in the liquid or in the direction of observation.—Prof. Karl Pearson: The improbability of a random distribution of the stars in space.—Dr. R. D. Kleeman: The total ionisation produced in different gases by the cathode rays

ejected by X-rays. The results are given in the annexed table, in which are also placed the total ionisations obtained by Prof. Bragg with the α particle. It will be seen that the two sets of values relative to air are very nearly the same. The energy spent in making an ion thus seems not to depend in any marked degree on the nature of the ionising agent.

—Prof. F. J. Cole: Tone perception in *Gammarus pulex*. The paper has reference to the occurrence of a definite and visible physiological response on the part of the freshwater amphipod *Gammarus pulex* to stimuli of an auditory character. Audition in the lower animals cannot be satisfactorily studied in most cases, since a stimulus produces no response that can be seen or measured. *Gammarus*, however, when confined in a microscope live box, responds in an energetic and striking manner by flexing its first pair of antennæ under its body. A response can be elicited after the second pair of antennæ have been removed, but not after the removal of the first pair. The instrument generally used to produce the stimulus was a tenor trombone, and the experiments were conducted either on the ordinary laboratory table or on a table specially constructed to filter off vibrations from the ground, and thus to ensure that the stimulus reached the animal through the air. It was found that *Gammarus* was most sensitive to the B flat below middle C, and that its range of tonal sense was so limited that it might almost be adduced as an example of absolute or physiological tonality, i.e. of an animal specially sensitive to one note. Only a small percentage of individuals, however, responded at all, and then, probably owing to fatigue, the power of response soon disappeared. One specimen responded to every note of the trombone. The experiments may be interpreted as either tactual or auditory reactions—if it can be held that these two senses have segregated out in such a simple and true aquatic species as *Gammarus pulex*, and do not merely form a part of an indefinite common sensibility.

Geological Society, April 13.—Prof. W. W. Watts, F.R.S., president, in the chair.—Dr. Tempest Anderson: The volcano of Matavanu in Savaii. Savaii is one of the German Samoan Islands. It is volcanic, formed of varieties of basic lavas, and for the most part fringed with coral reefs. The volcano of Matavanu was formed in 1905. The eruption was at first explosive, but since the first few weeks has been mainly effusive and accompanied by the discharge of fluid basic lava, which has run by a devious course of about ten miles to the sea, formed fields of both slaggy and cindery lava, filled up a valley to a depth in some places of probably 400 feet, and devastated the most fertile land in the island. The crater contains a lake, or rather river, of incandescent lava, so fluid that it beats in waves on the walls, rises in fountains of liquid basalt, and flows with the velocity of a cataract into a gulf or tunnel at one end of the crater. It then runs underground until it reaches the sea, into which it flows, and causes explosions attended with the discharge of showers of sand and fragments of hot lava, and the emission of clouds of steam. The resemblances to, and few differences from, the volcano of Kilauea are discussed.—Helen Drew and Ida L. Slater: Notes on the geology of the district around Llansawel (Carmarthenshire). The stratigraphy and geological structure of a small area some nine miles to the west of Llandoverly, and to the north of Llandeilo, are dealt with. The rocks consist of a series of sediments, including a coarse conglomerate, grits, shales, and tough blue mudstones. The structure in the eastern part of the district is more complicated than in the west. The repeated outcrops of the conglomerate in the hilly region around Shon Nicholas give the clue to the structure. The paper concludes with a comparison of this district with those of Rhayader and Pont Erwyd.

FORTHCOMING CONGRESSES.

MAY 14-22.—International Botanical Congress. Brussels. General Secretary: Dr. E. de Wildeman, Jardin botanique, Bruxelles.
MAY 16-21.—International Congress of Americanists. Buenos Ayres. General Secretary: Dr. Lehmann-Nitsche, Calle Viamonte 430, Buenos Ayres, Argentine Republic.

MAY 20-23.—International Congress of Tropical Agriculture. Brussels. Secretary of British Committee: Dr. T. A. Henry, Scientific and Technical Department, Imperial Institute, S.W.

MAY 30 TO JUNE 4.—International Orthnological Congress. Berlin. President: Prof. A. Reichenow. Address for inquiries: Berlin N 4, Invalidenstr. 43.

JUNE.—International Congress of Mining, Metallurgy, Applied Mechanics and Practical Geology. Düsseldorf. General Secretaries: Dr. Schrödtter and Mr. Löwenstein, Jacobi-strasse 3/5, Düsseldorf, Germany.

JULY 10-25.—International American Scientific Congress. Buenos Aires. Address for inquiries: President of the Executive Committee, c/o Argentine Scientific Society, 269 Calle Cevallos, Buenos Aires.

JULY 27-31.—International Congress on the Administrative Sciences. Brussels. Secretary of British Committee: Mr. G. Montague Harris, Caxton House, Westminster.

AUGUST 1-6.—International Congress of Entomology. Brussels. Chairman of Local Committee for Great Britain: Dr. G. B. Longstaff, Highlands, Putney Heath, S.W.

AUGUST 1-7.—French Association for the Advancement of Science. Toulouse. President: Prof. Gariel. Address of Secretary: 28 rue Serpente, Paris.

AUGUST.—International Congress of Photography. Brussels. Correspondent for United Kingdom: Mr. Chapman Jones, 11 Eaton Rise, Ealing, W.

AUGUST 2-7.—International Congress on School Hygiene. Paris. General Secretary: Dr. Dufestel, 10 Boulevard Magenta, Paris.

AUGUST 15-20.—International Zoological Congress. Graz (Austria). President: Prof. Ludwig von Graff. Address for inquiries: Präsidium des VIII. Internationalen Zoologen-Kongresses, Universitätsplatz 2, Graz (Österreich).

AUGUST 18-26.—International Geological Congress. Stockholm. General Secretary: Prof. J. G. Andersson, Stockholm 3.

AUGUST 29 TO SEPTEMBER 6.—International Union for Cooperation in Solar Research. Mount Wilson Solar Observatory. British Member of Executive Committee to whom inquiries should be addressed: Prof. A. Schuster, F.R.S., Victoria Park, Manchester.

AUGUST 31 TO SEPTEMBER 7.—British Association. Sheffield. President: Prof. T. G. Bonney, F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

SEPTEMBER 6-8.—International Congress of Radiology and Electricity. Brussels. General Secretary: Dr. J. Daniel, 1 rue de la Prévôté, Brussels. Correspondents for United Kingdom: Prof. Rutherford and Dr. W. Makower, University of Manchester, and Dr. W. Deane Butcher, Holyrood, Ealing, W.

SEPTEMBER 18-24.—German Association of Naturalists and Physicians. Königsberg. Secretaries: Prof. Lichtheim and Prof. F. Meyer, Drummstr. 25-29, Königsberg.

SEPTEMBER 27-30.—International Physiological Congress. Vienna. President: Prof. S. Exner. General Secretary for United Kingdom: Prof. E. B. Starling, University College, London, W.C.

OCTOBER 6-12.—Congrès International du Froid. Vienna. Correspondent for United Kingdom: Mr. R. M. Leonard, 3 Oxford Court, Cannon Street, E.C.

DIARY OF SOCIETIES.

THURSDAY, APRIL 28.

ROYAL SOCIETY, at 4.30.—On the Rotatory Character of some Terrestrial Magnetic Disturbances at Greenwich, and on their Diurnal Distribution: R. B. Sangster.—The Liberation of Helium from Minerals by the Action of Heat: D. O. Wood.—The Chromophil Tissues and the Adrenal Medulla: Prof. Swale Vincent.

ROYAL INSTITUTION, at 3.—Blackfeet Indians in North America: Walter McClintock.

CRYSTALLOGRAPHIC RESEARCHES.

Crystalline Structure and Chemical Constitution. By Dr. A. E. H. Tutton, F.R.S. Pp. viii+204. (London: Macmillan and Co., Ltd., 1910.) Price 5s. net.

THE series of science monographs projected by Messrs. Macmillan and Co. has opened auspiciously with a fascinating account by Dr. Tutton of the exhaustive crystallographical researches upon which, for the past twenty years, he has been engaged. It is a goodly story that he has to tell, and well is it told; without wearying the reader with an unwieldy mass of details, he presents in all essential completeness a vivid picture of an unusually coherent series of investigations. The immensity of the labour involved can be fully appreciated only by those who may have undertaken work of somewhat similar character, but the most casual reader can scarcely fail to be amazed at the extraordinary amount of work the author has contrived to squeeze into the leisure hours of a busy official life; by strenuously utilising every spare moment he has found time to accomplish a task which has set an ideal of what a complete study of the physical properties of crystallised substances should be. Those at least who have at heart England's position in the world of science are grateful to Dr. Tutton that, thanks largely to his efforts, in crystallography, at any rate, she stands so high.

Dr. Tutton completed his scientific training, and was looking round for a field for research at an opportune moment. It was at that time being increasingly felt by those speculating on the molecular arrangement of crystals that little real advance could be made towards a solution of the problem until more numerous and more accurate measurements of crystallised substances, especially those constituting isomorphous groups, were available. Principal Miers had already published his important memoir upon the characters of the red-silver minerals, pyrrargyrite and proustite. From that and similar work it seemed clear that small, but perceptible, differences existed between the crystalline forms of the constituents of an isomorphous series; in fact, the conclusion established by Dr. Tutton's investigations was not so wholly unforeseen at that date as might be supposed from the opening pages of his book. It was, however, very desirable that research of a similar, and, if possible, more comprehensive, character should be extended to artificial salts, because in such the purity of the material, and the perfection of the crystals, could be secured with far greater certainty than when the process had been in nature's unfettered control. To an investigation of this kind Dr. Tutton determined to devote himself, and he selected for his initial task the three members containing potassium, rubidium, and caesium of the isomorphous group of which $K_2Mg(SO_4)_2 \cdot 6H_2O$ may be taken as a type; their

crystalline form had not previously been properly studied.

It was part of Dr. Tutton's design that his research should be carried out with instruments as perfect as mechanical skill could produce. He found, indeed, at hand a most efficient goniometer for the measurement of interfacial angles of crystals, but, when he came to the determination of the optical and other vectorial characters, he was compelled to design an entirely novel equipment, since nothing of the requisite standard had hitherto been constructed. The first of these instruments was a grinding and cutting goniometer, by means of which it was possible to prepare sections and prisms with absolute confidence in the accuracy of their orientation in the crystal. The natural faces are seldom suitably developed for optical research, and the lapidaries' method was far too untrustworthy for Dr. Tutton's standard. This apparatus naturally called for a companion instrument, which should provide light of any desired colour at will. Sodium light, which is adopted as the standard in all measurements of refractivity, is, of course, readily available, but no optical investigation can be considered complete unless the colour dispersion has also been studied; previously crystallographers had been restricted to the lithium and thallium flames, of which the latter is actually poisonous, and, moreover, the study of interference figures often demanded light of intermediate wave-lengths. Dr. Tutton accordingly designed a most efficient monochromatic illuminator, in which the dispersive agent is a single prism of very dense glass. Spurred by the success achieved, he proceeded next to plan, using the principle of the interference of light, an instrument of extraordinary delicacy for the measurement of variations in length. He himself employed it in conjunction with the necessary additional apparatus, which he fully describes, for the measurement of thermal expansion and elasticity constants, and an interferometer of his design was recently installed in the Standards Department of the Board of Trade (*NATURE*, vol. lxxxii., p. 338). The whole of Dr. Tutton's instrumental apparatus has been characterised by the painstaking care bestowed upon those apparently small details which have such an important bearing upon efficiency of performance.

As already stated, Dr. Tutton opened his researches with a study of the crystalline form of the double sulphates of potassium, rubidium, and caesium, with magnesium. He subsequently extended his investigation to similar compounds of ammonium and thallium, which were found to possess closely related properties, and also to the corresponding selenates. Up to date he has studied the sulphates and selenates, and many of the double sulphates and selenates with magnesium, zinc, iron, nickel, cobalt, copper, manganese, and cadmium. Altogether forty-four salts—Dr. Tutton gives the number as fifty-four, but appears to have inadvertently reckoned ten of them twice—have been prepared and investigated, the greatest possible care being taken to ensure their purity and perfection of development; no fewer than 25,000

angles were measured, and upwards of four hundred sections, and the same number of prisms, have been cut. The optical study incidentally raised some interesting points in connection with the phenomenon known as crossed-axial-plane dispersion. Beautiful photographs of the interference figures given by cæsium magnesium sulphate in light of different wave-lengths at ordinary temperatures and at 78° are reproduced on p. 169. The thermal expansion of the sulphates of potassium, rubidium, and cæsium alone have as yet been determined; the exacting nature of this work may be gathered from the remark on p. 71 that each series of observations, sixty-four in all, entailed five hours' continuous labour.

Certain definite conclusions have been established by Dr. Tutton's work. The variation in the morphological and physical properties of the members of the same isomorphous series, though slight, is progressively related to the atomic weights in the case of the three elements belonging to the same family group. The relations between members containing these elements are, indeed, so intimate that they may be regarded as forming an inner circle—a eutropic series, as it is termed—within the isomorphous series; members containing ammonium and thallium, though undoubtedly belonging to the same isomorphous series, show greater deviations from the general properties. Corresponding changes of the same order, but in the reverse direction, take place when selenium is substituted for sulphur. The results are so tabulated that the relations and differences are easily grasped.

Throughout the book Dr. Tutton has realised the importance of not intruding upon observed facts about which no possible doubt could be raised any speculative matter which might be open to dispute, and he refrains from dwelling at any great length upon the many interesting questions relative to molecular arrangement which are suggested by the results of his investigations. He does, however, argue that the possibility of ammonium replacing a single atom without much effect upon the crystalline form is incompatible with Barlow's theory of close-packing, which has recently been attracting so much attention. On the other hand, Pope and Barlow, in their first paper, discussed the isomorphism of potassium chloride and ammonium chloride, and showed that the relationship in this case was in strict consonance with the close-packing of the spheres of influence. Close-packing is, indeed, merely a way of representing the state of equilibrium between the mutual interactions of atomic forces emanating from definite centres; it is difficult to attach any physical significance to loose-packing in connection with crystalline structure.

Enough has been written to show that the book is one that should be read and studied by all interested in crystals, their properties, and their formation. Finally, we hope that Dr. Tutton may enjoy, for many years to come, health and strength to carry on the splendid work that constitutes his recreation.

SOIL MANAGEMENT AND PLANT GROWTH.

The Principles of Soil Management. By Profs. T. Lyttleton Lyon and E. O. Fippin. Pp. xxxiii+531. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 7s. 6d. net.

THIS book is the first of a new series designed by Dr. Bailey for "class-room work and for special use in consultation and reference," and the volumes are therefore larger and fuller than those of the Rural Science Series, which were meant for general reading and popular use. In the present series the subject is to be presented in such a way that it shall develop "clear thinking, sound argument, constructive imagination, and effective application to the needs of life."

Dr. Bailey contributes a vigorous introduction, strong in its condemnation of our present lack of interest in soil problems.

"We are accustomed," he says, "to think of the power of man in gaining dominion over the forces of nature,—he bends to his use the expansive powers of steam, the energy of electric currents, . . . but while he is doing all this he sets at naught the powers in the soil beneath his feet, wastes them, and deprives himself of vast sources of energy."

Among the national resources that demand conservation the soil takes a high rank.

Turning to the volume itself, the subject is treated under seven headings; the soil is considered as a medium for root development; as a reservoir for water; as a source of plant food; the organisms of the soil are studied, the composition of the soil air, and the relation of soil to temperature. Finally, methods of soil management are discussed. The general idea is to treat the soil as a medium for plant growth, to regard it from the agricultural and not so much from the geological point of view. There is, of course, no particular novelty in this position, and several books have already been written in which the subject is dealt with in the same way; the arrangement of the matter therefore calls for no comment.

Liberal use is made of photographs to illustrate the various points brought up, and there are some very good photomicrographs showing the structure of certain common rocks. A considerable amount of time and trouble must have been spent on these, and also on the tables of figures which have been pretty freely introduced. The results obtained at the various experiment stations in the United States have been drawn on, and a good deal of material is collected that will be new to the English reader and interesting to the American student.

But when all this is said, it must be admitted that the book somehow leaves an unsatisfactory impression. In spite of the attractiveness of the subject, the present writer has to confess that he found the volume rather boring. It is hardly a book that the American student would "enthuse" about, and it does not adequately repay all the labour that must have been bestowed upon it. We somehow get a suspicion that the authors have searched more amongst the latest text-books and the latest bulletins

than amongst the depths of the subject they are expounding, and so the book lacks that invigorating freshness that can only be given by men who are for ever probing the secrets of nature and working among the things they talk about—its atmosphere is wrong.

We cannot help thinking that the authors would have obtained much better results had they worked on the model set many years ago by Johnson, one of the best writers on agricultural chemistry the United States, or, for that matter, any other country, ever produced. He sets before the student accounts of the investigations that have made the subject, shows pictures of the apparatus used in the classical experiments, and gives some details of the actual working. The result is a book that after forty years still retains its freshness and its power of inspiration, because it shows how men have wrestled with nature to win her secrets. If when a second edition of the present book is called for the authors would, in a similar way, make room for some of the classical work of the great masters, without extending the size of the book, it is certain that their industry and painstaking efforts would meet with a more fitting reward.

E. J. R.

MECHANICS OF HEREDITY.

Das Vererbungsproblem im Lichte der Entwicklungsmechanik betrachtet. By Prof. E. Godlewski, Jun. (Being Part ix. of Roux's "Vorträge und Aufsätze über Entwicklungsmechanik.") Pp. 301. (Leipzig: W. Engelmann, 1909.) Price 7 marks.

IN this book the author attempts a critical review of our knowledge of the mechanism by which hereditary characters are transmitted, and makes it his chief object to distinguish clearly between ascertained facts and the inferences based upon them. Part i. contains an outline of the facts of heredity, only so much being given as is necessary to an understanding of their relation with developmental mechanics. The possible inheritance of "acquired" characters is discussed, inheritance in non-sexual reproduction, including an account of Winckler's recent work on graft-hybrids, and, finally, inheritance in sexual reproduction. This is classified under the heads of blended, mosaic, and alternative. Under mosaic heredity, cases like Toyama's gynandromorphic silkworm are included, which seems scarcely justifiable. Under alternative inheritance and Mendel's law the author seems not thoroughly to grasp the independence of the facts of dominance and segregation, and the same want of clearness in this respect reappears in the general summary. Also in discussing the relations of the different forms of heredity we note a couple of slips in his account of Galton's and Pearson's statements of the law of ancestral heredity.

In part ii. the author is more completely master of his subject. Essentially the problem to be solved is whether a substance which determines the appearance of inherited characters exists and is transmitted from generation to generation; if so, where it is

localised and how it acts, so as to produce the different kinds of heredity found in different characters in the same or different organisms. The theory originally made familiar by Roux and Weismann, that the nucleus, and especially the chromosomes, are the "bearers of heredity," is first discussed, and the work of Driesch and his hypothesis of "Entelechy" are explained, and, finally, the theories of Semon and others are reviewed. It is pointed out that writers are divided into two schools—those who believe in a transmitted substance as the basis of inheritance, and those who regard such a substance as a medium for the action of inherent properties. The next four sections deal with work which seeks to discover a transmitted substance, and especially with work on the nucleus. Recent work on amitosis, the structure of the germ-cells, and the facts of fertilisation leads the author to conclude that from these phenomena no "nuclear monopoly" in inheritance can be deduced. A review of recent work on the chromosomes leads to the same conclusion; although their constancy in number and form for each species is admitted, Fick's "Manövriehypothese" is regarded as equally consistent with the facts with Boveri's theory of individuality. Perhaps insufficient weight is attached to the work, especially of American cytologists, on the behaviour of the chromosomes in the maturation divisions, and in the general summary the author admits that he regards the appearance of their conjugation, and of the relative independence of paternal and maternal elements, as illusory. Since the reality and cause of Mendelian segregation is nowhere fully discussed, this question might have been treated more completely with advantage.

Perhaps the most important section of the book deals with experimental work on hybridisation and fertilisation of non-nucleated fragments (Boveri, Seeliger, Delage, &c.), combination of artificial parthenogenesis and hybridisation (Herbst), and the results of polyspermy (Boveri). These experiments are very thoroughly described, and the conclusion is arrived at that from them also no evidence for nuclear monopoly is obtainable. That the nucleus is of primary importance is proved, but the relations between nucleus and cytoplasm, rather than the nucleus itself, are regarded as the basis of heredity. At the end of this section a summary of the evidence for the action of the cytoplasm is given; although relatively little work has been done in this field, yet one feels that the treatment is rather meagre compared with that devoted to the nucleus.

In the last sections are discussed the nature of the determining substances (possibly enzymes, &c.), and work on the influences of external factors on changing the "Vererbungsrichtung." The work of Guthrie and Magnus on transplantation of ovaries is mentioned, but the author does not seem to know the paper of Tower on the beetle *Leptinotarsa*.

The book, on the whole, is eminently readable, and succeeds well in its difficult task of summarising the results of recent work and of disentangling ascertained fact from deduction. The author regards experimental facts as the only legitimate proofs of the basis of heredity, and a tendency to be perhaps

unduly critical of all other evidence is a fault on the right side. He has succeeded in including work which appeared almost up to the time of publication of the book, and has produced a most valuable account of what is known of the subject.

AMERICAN GEOLOGY.

Geology: Shorter Course. By Thomas C. Chamberlin and Rollin D. Salisbury. Pp. xviii+978. (London: John Murray, 1909.) Price 21s. net.

A College Text-book of Geology. By the same. Pp. xviii+978. (New York: Henry Holt and Co., 1909.)

THESE are respectively the English and American editions of the same work, and each weighs 3 lb. 10 oz., without in any way approaching the dimensions of a German "Handbuch." We are not clear in this case if the insertion of an English title-page adds to the price of the work; but we note that the larger text-book by the same authors costs 63s. in London and 50s. in New York. This "shorter course" is not one that could be used in colleges in our island, except as a description of the geology of North America; while as a reference-book on this subject and on the valuable original views of the authors the larger work is manifestly superior.

It is a misfortune, which often must be felt in our own colonies, that text-books on natural history require a local setting and foundation; even the first 413 pages of Messrs. Chamberlin and Salisbury's shorter course, dealing with physical geology, are almost entirely illustrated from American sources, and are, of course, all the better on that account, in view of the intentions of the authors. Maps of the United States Topographic Survey are utilised effectively, as in Mr. Salisbury's treatise on physiography; and the photographs of landscape-features, such as the rippled sand-dune on p. 100, the Bad-land topography on p. 135, and the dust-cloud of Pélée on p. 381, are so beautifully reproduced that we cannot blame the publishers for their choice of heavy paper. "La Croix," by the by, in the description of the last-mentioned picture, should be Lacroix; "Gyrvan" on p. 406 is our Scottish Girvan; and "the Achäischen earthquake" on p. 348 is surely an accidental hybrid. The esker of Punkaharju, shown on p. 273, is not in Scandinavia, but in Finland. But there are very few misprints in this handsome volume.

The account of glacial phenomena is of especial interest, and the views of various writers as to glacier-motion are carefully stated (pp. 280-8). There is probably less difference between the views of Tyndall and James Thomson (not "Thompson") than is here suggested; Tyndall himself wrote in his "Forms of Water,"

"the gist of the Regelation Theory is that the ice of glaciers changes its form and preserves its continuity under pressure, which keeps its particles together."

He does not appear to have insisted upon actual fracture as necessary to glacier-motion.

Other interesting discussions are that of the planetesimal origin of the solar system, which is here

concisely treated (p. 420), and that of the depth to which water from the surface may penetrate the earth (p. 197). Excellent diagrams are given of the effects of faulting and folding on the outcrops of strata on a level surface.

In the stratigraphical section of the book, we may note that an Archeozoic era is accepted, its rocks being in part sedimentary, but lying unconformably in most places beneath those of the Proterozoic (Algonkian) era. Diagrammatic maps after De Lapparent are given to show the distribution of certain strata in Europe; but their scale is too small to render them serviceable as guides. That of the Devonian system, for example, allows of the existence of only the Lower Devonian series in the British Isles, and the disposition of the Devonian lakes in Wales and Ireland is singularly capricious. Maps of North America are given for each system, usefully discriminating between actual outcrops and conjectural extensions.

The Carboniferous period is divided into a lower Mississippian and an upper Pennsylvanian period; the Cretaceous into Comanchean and Cretaceous proper. This last subdivision, however, raises exactly the same difficulties as the attempt to restrict Silurian to the upper part of the old Silurian system. European readers will gain greatly from the last half of the book. Though they cannot accept it as their only text-book of geology, they will recognise at all points the originality and perception of the authors.

G. A. J. C.

ELECTRIC WAVES IN THEORY AND PRACTICE.

- (1) *Electric Waves. An Advanced Treatise on Alternating-current Theory.* By Prof. W. S. Franklin. Pp. x+315. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1909.) Price 3 dollars net (10s. net).
- (2) *Wireless Telegraphy and Wireless Telephony. An Elementary Treatise.* By Prof. A. E. Kennelly. Second edition. Pp. vii+279. (London: T. Fisher Unwin, 1909.) Price 4s. net.
- (3) *Wireless Telephones and How They Work.* By Dr. J. Erskine-Murray. Pp. iii+68. (London: Crosby Lockwood and Son, 1910.) Price 1s. 6d. net.
- (4) *Handbook for Wireless Telegraph Operators.* Published for official use. October, 1909. Price 3d.

(1) PROF. FRANKLIN'S treatise, although by its title it might be expected to deal more particularly with that class of electric waves used in Hertzian telegraphy, deals with the whole subject of electromagnetic waves, and is more adequately described by its sub-title. Indeed, the subject of wireless telegraphy is given, if anything, less than its fair share of attention on the ground that it is already adequately treated in Fleming's "Principles of Electric Wave Telegraphy." It is to be wished that all authors showed a similar moderation and restraint. The volume opens, after a brief introductory chapter, with two chapters on water waves and wave trains, which serve as a useful introduction to the principal ideas of wave motion. The next four chapters deal

with the general mathematical theory of electromagnetic waves, with special reference to transmission and telephone lines, and in the sixth chapter Hertzian telegraphy is briefly discussed from the practical side. The next two chapters, forming the second part of the volume, deal with harmonic analysis and non-harmonic E.M.F.'s and currents, and bear directly on the problems met with in alternating-current machinery. The mathematics is advanced, and the book is only suitable for advanced students. In an appendix are given eighty-eight problems for the student to work out, and there are a number of very excellent diagrams.

(2) Prof. Kennelly describes his book as an elementary treatise; it covers both the theoretical and practical side of wireless telegraphy and telephony, and is admirably suited for the reader with only very slight technical knowledge. The exposition of the theoretical side is clear, and the description of practical methods, though short, is sufficient to give a general idea of the present position of the art. The only objection which we have to raise against the book is on account of the diagrams, which are numerous but far from clear. Those in the earlier part of the book especially are on so small a scale that they are practically unintelligible; this is the more to be regretted as the type and paper are excellent, and there is no apparent reason why the diagrams should not be equally well reproduced.

(3) Dr. Erskine-Murray's little book is a popular exposition of the methods and present position of wireless telephony. Dr. Erskine-Murray combines a thorough knowledge of his subject with the power of clear and simple explanation, and we know of no better book for those of the general public who are anxious to know how wireless telephony now stands. We are rather doubtful whether the somewhat rosy view of the future taken in the last chapter is likely to be realised, although the advances already made make one chary of expressing too strong a doubt.

(4) No stronger evidence of the assured position of wireless telegraphy as a commercial means of communication could be afforded than the publication of this little Government handbook. The book itself does not call for much comment, since it contains only instructions and regulations for operators on board ship or in coast stations, but that such regulations should be called for is a more convincing proof that wireless telegraphy has settled down to the steady enjoyment of its own kingdom than any number of treatises or popular booklets. The position of wireless telephony to-day is much the same as that of wireless telegraphy ten years ago. Will 1920 see the issue of a Government handbook for wireless telephone operators?

OUR BOOK SHELF.

The Liverpool Geological Society. A Retrospect of Fifty Years' Existence and Work. By W. Hewitt. Pp. 117. (Liverpool: C. Tinling and Co., Ltd., 1910.)

The Liverpool Geological Society, which was established on December 13, 1859, has signalled its jubilee by the publication of this volume, which in-

cludes an account of the history of the society and its geological labours, a list of papers printed in the Proceedings, and biographical notices of some past members. The society originated from a meeting held at the residence of G. H. Morton, who was its real founder, and for about forty years the chief moving spirit among the members. A capital portrait of him is given. Well known as the author of a volume "On the Geology of the Country around Liverpool," and of a series of important papers on the stratigraphy and palæontology of the Carboniferous rocks of Flintshire, he was one of the most distinguished of provincial geologists. By regarding the country within fifteen miles of Liverpool as their proper sphere of study, the society took the Carboniferous limestone series of Flintshire as their foundation-rocks, together with the succeeding Millstone Grit, Permian, Trias, Pleistocene, and Recent deposits.

On all these formations the members of the society have done excellent work. Undoubted Permian strata, including a bed of magnesian limestone with *Schizodus*, were described by Mr. E. Dickson at Skilaw Clough, near Parbold. The researches of the late T. Mellard Reade on the Triassic rocks, the Glacial Drifts, and the recent physical changes in the Lancashire district are well known. His portrait is included; also that of Dr. Charles Ricketts, another enthusiastic worker who dealt with many local physical problems. There is one other portrait, that of Joseph Lomas, who had done much in investigating the fauna, flora, and origin of the Trias. Unfortunately, a railway accident in Algeria terminated the life of this zealous and genial worker at the early age of forty-eight. Photographic plates are given of the famous footprints of *Cheirotherium* from the Keuper Sandstone of Storeton, in Cheshire, described by Morton; and of the gypsum boulder from the Glacial Drift of Great Crosby, described by Mellard Reade. The volume has been carefully prepared, and is a valuable and interesting record of the work of Liverpool geologists.

Catalogue of the Lepidoptera Phalaenae of the British Museum. Vol. ix. Catalogue of the Noctuidæ in the Collection of the British Museum. By Sir George F. Hampson, Bart. Pp. xv+552; plates cxxxvii-cxlvii. (London: Printed by Order of the Trustees British Museum [Natural History]; Longmans and Co.; B. Quaritch; Dulau and Co., Ltd., 1910.) Catalogue 15s.; plates, 12s.

WE have again to congratulate the authorities of the British Museum and the indefatigable author on the appearance, within less than a year, of another volume of this highly important descriptive catalogue of moths. It is the sixth which has been devoted to the Noctuidæ, and is the third and last volume dealing with the great subfamily Acronyctinæ, of which 385 genera and 2288 species (a large proportion new) are described, and a great number illustrated in the three volumes devoted to the subfamily.

It may be useful to note that at the commencement of his work Sir George gave a table of fifty-two families of Lepidoptera, of which seven (families 33-39 inclusive) are butterflies, placed between family 32, Castiniadæ, and family 40, Euschemonidæ, the remaining forty-five families being moths. Of these, the first three, the Syntomidæ, Arctiæ, and Agaristidæ, are described in the three first volumes of the work; while of the fifteen subfamilies into which the Noctuidæ are divided at the commencement of vol. iv., only the first four subfamilies have yet been dealt with. It therefore follows that the nine volumes which have hitherto appeared cannot be expected to represent a quarter, and perhaps not even a tenth, of the whole work, although

many of the families of moths and the subfamilies of Noctuidæ still to be monographed are undoubtedly much less numerous in species than those already described.

When we consider how very few species of insects were known to entomologists a century, or half, or even a quarter of a century ago, the enormous increase in our knowledge of this subject within the last few years is simply marvellous, even to those who have witnessed, and to some extent kept touch with, its progress from day to day.

Report on the Poultry Industry in Belgium. By Edward Brown. Pp. viii+112. (London: National Poultry Organization Society, Ltd., 1910.) Price 1s. net.

IN 1906 and 1907 Mr. Brown visited America, Denmark, and Sweden to inquire into the methods followed in the poultry industry, and during last year he visited Belgium with a similar object. Probably in no country in the world is intense production more general than in Belgium, one consequence being that it supplies its own poultry and egg requirements, and is not dependent, like England, on imports from foreign countries; indeed, it has a surplus for export.

Although in some respects the conditions in Belgium resemble those obtaining in England, there is the fundamental difference that the Belgian farmer specialises in small animals, like poultry, rabbits, even in pigeons and cage-birds as a hobby, whilst the English farmer has gone in for larger stock. Poultry-farming pure and simple is not common. But everywhere Mr. Brown found that poultry figured as an adjunct to the farm, particularly on the small holdings. In some cases, indeed, land did not come under cultivation until it had been run over for some years by fowls, and fertilised by their droppings. Thus the Campine district, which extends from Malines east and north to the Dutch frontier, was at one time merely a sandy plain covered with fir trees. About thirty years ago the peasants began to raise chickens for sale to the fatteners; the industry spread, and now the trees are gone and the whole district is farmed. It would be interesting to know how many tons of purchased food were consumed per acre in effecting this change. Egg-production is stated to be the main object, and the birds are looked after by the women and children; the methods are, however, essentially simple, no more elaborate appliance being used than is absolutely essential.

The report contains a number of useful details, and concludes with a number of recommendations. The small holder in particular is urged to devote some, though not all, of his attention to poultry, and it is suggested that poultry-keeping should be encouraged on land at present waste. Various methods of management are also recommended.

Halley's Comet: its History, with that of other noted Comets, and other Astronomical Phenomena, Superstitions, &c. By Rev. John Brown. Pp. 52; illustrated. (London: Elliot Stock, 1910.) Price 1s. net.

As a useful collection of facts and references concerning Halley's comet this small volume will take a place in the mass of comet literature now appearing so profusely. It contains nothing startlingly novel, being, to a great extent, a compilation of interesting oddments gathered, with due acknowledgments, from various sources. In many places extraneous material is introduced, rendering the book perhaps more interesting, but less suitable as a precise account of what it presumes to deal with. The four illustrations are rather crude and of no especial interest.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Orientation of Crystals of Ice in a Flux of Heat.

It was found by Forbes many years ago that the thermal conductivity of ice was better along the principal axis than at right angles to it. Straneo, in 1897, does not come to any definite conclusion in deciding that such is the case. It is well known, however, that the formation of surface ice by conduction always shows the principal axis of the crystals to be normal to the freezing plane, or, in other words, in the direction of the flux of heat from the underwater. Since ice is a better conductor of heat than water, it is to be expected that if any difference exists in the conductivity in the two directions, the ice crystal would form in such a way as to dissipate the heat more readily.

During the process of the formation of an ice mantle in a rather large Bunsen ice calorimeter, my assistant, Mr. F. H. Day, directed my attention to a rather interesting case, which, I think, proves the better conduction along the axis of the crystal. The bulb of the calorimeter was about two-thirds immersed in a freezing-point mixture. This particular calorimeter was unusually difficult to start, and always refused to freeze when ether was rapidly evaporated in it, or when a saline ice mixture was introduced. In consequence, our custom has been to add some liquid air or solid carbon dioxide, as most convenient at the time. In this case we used solid carbon dioxide. The undercooling must have been considerable around the inner glass tube, and a sharp temperature gradient resulted between the lower part of the glass and the walls of the calorimeter. Heat was flowing in from the freezing-point mixture, but near the surface the heat flowed in more rapidly around the exposed portion of the bulb. The ice formed as usual, but on withdrawing the calorimeter for inspection we found, growing out from the solid mantle of ice, long needles and thin plates, which were perfectly orientated along the lines of the flow of heat. The crystals near the top of the mantle were directed at an angle upwards, while those at the base were found normal to the mantle surface. Between these positions the crystals grew at a corresponding inclination to the mantle surface. This, I think, conclusively shows the path of best conductivity in the ice crystal to be along the principal axis.

Zeeman Effect of the Yellow Mercury Line λ 5770.

It is well known that the separation of the mercury line λ 5770 in a magnetic field into a triplet is abnormal, inasmuch as the value of the ratio e/m of vibrating electrons is much greater than that obtained from experiments on cathode rays or from measurements of the Zeeman effect on other lines of mercury and of other elements. Lohmann first noticed that the line is separated into a nonet in strong fields, but did not investigate its type. By using an echelon spectroscope of resolving power 430,000 for $\lambda=0.5\mu$, I found that the distribution of lines in the nonet can be accurately examined by using a vacuum tube of special construction. From a field of 18,000 gauss upward, the lines composing the nonet were distinctly observed with my instrument. They are distributed in three groups of three lines each, closely arranged at equal intervals, and each group occupies the position of the normal triplet. No dissymmetry with respect to the middle line was noticed. Several measurements in fields between 18,000 and 28,000 showed that the separation of lines in each group is proportional to the field strength, so that in weak fields each group appears as a single line. The lines of the middle group are equally bright, but the intensity of the remaining two groups of lines diminishes as we proceed outwards, just as is the case with the mercury line 5461, which is also divided into

a nonet. Runge's law is applicable to 5770; the type of the nonet is such that the lines form aliquot parts of $\lambda = e/m.H/4\pi$, and the difference in the number of vibrations of these lines can be represented by

$$0, \pm \frac{a}{8}, \pm \frac{8a}{8}, \pm \frac{9a}{8}, \pm \frac{10a}{8}.$$

Considered as a triplet, which corresponds to lines 0, $\pm \frac{9a}{8}$, Gmelin found that $e/m = 2.02 \times 10^7$; v. Bayer and Gehrcke obtained 2.06×10^7 , which is also the number I have arrived at from the same standpoint. Considered as a nonet, however, we have to multiply the above number by $\frac{8}{9}$, so that the corrected result turns out to be:—

Gmelin	...	...	...	...	1.80×10^7
Gehrcke and v. Bayer	...	...	...	...	1.83×10^7
Nagaoka	...	...	...	...	1.83×10^7

This is in close agreement with the same constant obtained from measurements on the nonet of the mercury line 5461, for which $e/m = 1.80 \times 10^7$.

The above examination of the line 5770 shows how the different types of a class of nonets are derived from normal triplets.

Starting from the normal triplet A, we get nonets of types B, C, and D by doubling the intervals of component

FIG. 1.

lines of each group, as shown in Fig. 1. Considered as aliquot parts of a , they are represented by

$$B. 0, \pm \frac{a}{8}, \pm \frac{8a}{8}, \pm \frac{9a}{8}, \pm \frac{10a}{8}.$$

$$C. 0, \pm \frac{a}{4}, \pm \frac{4a}{4}, \pm \frac{5a}{4}, \pm \frac{6a}{4}.$$

$$D. 0, \pm \frac{a}{2}, \pm \frac{2a}{2}, \pm \frac{3a}{2}, \pm \frac{4a}{2}.$$

with direction of electric force as shown in the figure, p indicating that it is parallel, and s at right angles, to the direction of the field. B is represented by the line 5770, C by the neon lines 6678 and 6305, and D by the mercury line 5461. Probably there is also a type

$$0, \pm \frac{a}{16}, \pm \frac{16a}{16}, \pm \frac{17a}{16}, \pm \frac{18a}{16},$$

intermediate between A and B. Of the different lines which I have examined, the copper line 5105 seems to belong to this type, but as it requires high resolving power I have not been able to clear up this point. It appears to me quite probable that triplets, which show broadening of lines and no asymmetry in high fields, and give values of e/m greater than 1.87×10^7 , belong to some of the intermediate types.

The Fertilising Influence of Sunlight.

IN NATURE of February 17 is a communication from Mr. and Mrs. Howard pointing out that the probable explanation of the advantage of leaving land rough ploughed during the hot weather in India is that the biological changes which occurred under the conditions of Messrs. Russell and Hutchinson's experiments occur here also.

The following temperature record, which is one of the highest I have, will be of interest in this relation:—

Date, May 28, 1906.

Maximum shade temperature	...	...	107° F.	...	42° C.
Maximum temperature of soil 3 in. deep	...	...	109	...	43
"	"	"	6	"	43
"	"	"	9	"	40
"	"	"	12	"	38
"	"	"	24	"	34

Other records of soil temperature in Behar are published in "An Account of the Research Work in Indigo at Dalsing Serai, 1903-4," by Bloxam, Leake and Finlow (Appendix ii.). Temperatures approximating to 50° C. at 1 inch from the surface were recorded.

The hot-weather temperature here (Behar) is not so high as in some other parts. Jacobabad "enjoys" one which runs up to 127° F. on occasions, and the whole of the western part of the Punjab (an area equal to about twice that of the British Isles) is liable to maximum air temperatures of 110°-115° F. (43°-46° C.), so that the surface soil in that part may be assumed to attain an average temperature some 10° F. (5° C.) higher than here at Pusa; but it is certain that, however uncomfortably hot India is, its soils never attain a temperature anything approaching 100° C.

Dr. Russell mentions (NATURE, March 3) that biological changes at temperatures below 100° C. are being studied, so that we shall doubtless learn shortly in how far they assimilate under these conditions to the effect at 100° C. In any case, it must not be forgotten that there cannot be much difference in temperature between roughly ploughed land and unploughed land which has carried a cold-weather crop; in both the amount of moisture in the first 6 inches will be nominal, and the thermal capacity of each must be much about the same. The roughly ploughed soil will include more air, and I should expect the rise of temperature at 6 inches to be rather greater in unploughed land. Hence if this agricultural practice is found to be accompanied by important biological changes, this must be due to some cause other than mere temperature.

Regarding the effect of sunlight, this can only affect the outside surface; in unploughed land this is better defined than in broken-up land, and during the ploughing operation more soil is exposed (temporarily) to the sun than in the former case, but the ploughing here referred to is commonly one ploughing, not a "multiple stirring" such as occurs in the preparation of the seed bed.

Finally, it is perhaps unnecessary to mention that this rough ploughing results in other advantages than those mentioned. One is that the soil absorbs more of the first monsoon rain than unploughed land, and can be prepared for monsoon crops much more quickly.

Pusa, April 13.

J. WALTER LEATHER.

Observations of Halley's Comet.

I saw Halley's comet through field-glasses on Sunday morning, April 24, at 3.40. It was then about 10° above the horizon, 20° to the left of Venus, and slightly under it. It was very distinct from 4.0 to 4.20. At its best, 4.15, I could just distinguish the head by the naked eye, but only for a minute.

The tail appeared broad and short, only about twice the moon's apparent diameter in length, with its axis at 40° to the horizon. The tail began to grow indistinct at 4.30, but the head was visible to 4.45.

The sky was not ideal, Pegasus not distinct, Cassiopeia only partially seen, but Venus was very distinct and bright.

I saw the comet again yesterday—Monday, April 25—from 4.0 to 4.15. The sky was not at all clear. The comet was in a line with Venus, and still about 20° to the left. I could not see it with the naked eye.

This morning, April 26, comet was clearly seen from 3.45 to 4.30. The tail appeared longer and more elegant in appearance. It was perhaps 5° above Venus, and less than 20° to the left. The head was easily seen at intervals by the naked eye, but the tail showed only a trace, and that only once.

The measurements are only by the eye, but are, I think, fairly correct.

C. LEACH.

Malta, April 26.

Anomalous Reading of Hygrometer.

MR. RICHARDSON's explanation in *NATURE* of April 28 of the anomalous readings referred to does not seem very satisfactory, because, owing to the presence of dust in the atmosphere, the air is never supersaturated; indeed, it is seldom even saturated, owing to the presence of some particles having an affinity for water vapour. But even supposing there had been supersaturated air at the time, then the "dry bulb" would also form a condensing surface and would have been heated as well as the wet bulb. Fortunately, the observer of the anomalous reading noted that the temperature was rapidly falling at the time, and the bad conducting covering of muslin would quite account for the wet bulb falling slower, and so reading higher than the dry.

J. A.

THE LONDON TO MANCHESTER FLIGHT.

THE success of M. Paulhan in reaching Manchester from London by *aéroplane*, and thus gaining the *Daily Mail* prize of 10,000*l.*, for which Mr. Grahame-White had made such a valiant struggle, is the second case in which an English aviator has been within measurable reach of a success which has actually been achieved by a Frenchman. Last summer it was Latham who attempted and failed to cross the Channel, and Blériot who carried off the palm.

The success of the present effort affords a striking measure of the rapid progress that has been made within the last three years in extending the performances of *aéroplanes*. When first the offer of the prize for the Manchester flight was announced it certainly looked as if a more useful purpose would be served by offering a prize to anyone who could fly at all. It is hardly likely that if the only inducements offered to aviators had been prizes for such long distance flights as the present one, the same amount of attention would have been devoted to short flights; but numerous private individuals, notably in France, filled up the gap by offering a large number of smaller prizes for more modest achievements, and, as soon as a flight of a hundred yards had been performed, the main difficulty of performing a flight of a hundred miles was overcome. All that remained necessary was experience, and such increase in the carrying capacity of *aéroplanes* as was necessary to provide an adequate supply of energy for the journey.

Owing to the fact that both aviators used Farman biplanes, the results do not teach us anything regarding the relative merits of different types of machine; and it would be premature to draw any inferences regarding the relative merits of "monoplanes" and "biplanes," in view of Blériot's monoplane success last summer. The Farman biplane, like most other *aéroplanes*, is probably longitudinally stable and laterally unstable, and in a short trial which Mr. Grahame-White made early in the afternoon before starting, the machine is described as swaying from side to side dangerously. In this respect, both competitors had the same difficulties to contend against, and in view of the fact that Mr. Grahame-White is a proficient flyer both on the Farman biplane and on the Blériot monoplane, and that he made a good sixty-five-minutes flight on the Farman machine, it is probable that under reasonable weather conditions the contest would have resulted in a tie. Mr. Grahame-White's failure was certainly attributable to the bad weather. He only started from London at 6.29 p.m. on learning that Paulhan had started an hour before, and thus he was only able to get that night to Roade, about the time when M. Paulhan descended at Lichfield, fifty-seven miles in front.

On the following morning chances were again against the English competitor, for, after struggling

against the wind, he was "twisted from side to side and progress seemed impossible, so he decided reluctantly to come down"; four minutes after Paulhan had again started and only ten miles behind him. If the result proves anything, it is that the French aviator was either more skilled in checking the lateral oscillations of his machine in a high wind, or that his greater experience of meteorological conditions enabled him to seize opportunities which Mr. Grahame-White missed. Possibly, too, the difference of altitude may have affected the conditions, for, according to all chronicles, M. Paulhan seems to have flown higher than Mr. Grahame-White. At any rate, Mr. Grahame-White was at a disadvantage, for he started off without waiting for a meal on the first day, after hearing of M. Paulhan's start, and was probably less fit for his task the next morning. Whatever the explanation, however, it is abundantly shown that the time has not yet come when *aéroplanes* can be generally used for touring or for regular purposes of transport, but that much practical experience and fair weather are still required before a successful flight can be relied on. It is, indeed, a matter of congratulation that the landings were all effected in safety, and that neither Mr. Grahame-White nor M. Paulhan had any misfortunes of a serious character. At the same time, M. Paulhan is reported to have stated that he would not repeat the experience for double the prize, adding:—

"People fancy that because I did the flight well within the time it was all plain sailing. I can assure them that from the time I left Crewe the strain and anxiety with my machine was a tremendous burden, and when I put on speed and came within sight of Manchester I felt a perfect rag, wondering all the time if I could ever reach my goal. I don't believe, now that it is all over, that I could have kept it up a quarter of a mile further."

M. Paulhan has well earned his prize; but it is sincerely to be hoped that those who have money to give away in the future, and wish to promote the development of aviation, will devote it to competitions which are less strenuous tests of physical endurance, and more rigorous tests of the development of real advances in the construction of *aéroplanes*. The Aerial League's appeals in this direction have not met with too generous a response from the British public.

The use of the Gnome motor in these flights clearly demonstrates that the rotating-cylinder type of engine has a future before it. It obviates the vibrations necessarily associated with reciprocating engines, and affords a simple means of cooling the cylinders. The principle is old enough, and mathematicians have long puzzled over how to apply it, but the practical difficulties appear not to have been overcome until quite recently.

The flight has not been without its lessons regarding the means of finding one's way in the air. In this case the London and North-Western line was followed, the course being indicated by whitening the sleepers in places, and the possible halting places also being clearly marked.

If one success has thus been scored in April, the *Deutsche Zeitschrift für Luftschiffahrt*, on the other hand, describes April as the black month for aerial navigation, and April 3 as the *Dies irae*. In the issue for April 20 are portraits of Prof. Abegg, Dr. Delbruck, and Herr Benduhn, victims of the accidents to the balloons *Schlesien* and *Pommern*, both of which sailed on that day; next we have Dr. Alberti's accident with a Blériot machine in Munich, Le Blon's death at St. Sebastian, Molon's misfortune at Cannes, Grade's accident at Leipzig—all chronicled or figured in this single number of the journal. In view of this series of misfortunes, we again express the hope

that future friends of aviation will discover means for advancing its development that will not tempt men to repeat such dangerous adventures as were inevitably associated with the London to Manchester flight, and that M. Paulhan's success will not stimulate a number of less experienced followers to attempt to emulate his achievement. G. H. BRYAN.

THE FIGHT AGAINST SLEEPING SICKNESS.¹

THE report of the German Sleeping Sickness Commission is an attractive work in which even those who are not specially concerned with the problems of sleeping sickness may find much to interest them. In addition to a great mass of detail bearing on the etiology, diagnosis, treatment, and prevention of a disease which is at present the most important economic problem of European administrations in Africa, the work contains many facts and observations of interest to the naturalist and the anthropologist, and is illustrated by numerous exquisite photographs. A certain number of the illustrations have, as might be expected in a work of this kind, a melancholy interest, representing the ravages of the disease as shown by sufferers from it, or even more significantly by deserted homesteads; but others give a vivid idea of the scenery of the shores of the Victoria Nyanza and of the dwellings, habits, and appearance of the natives of that region.

After a brief introduction and an account of the general course of the expedition, by Dr. Koch, there follow sections on the etiology of sleeping sickness, by Dr. Koch; on diagnosis and on clinical observations, by Prof. Beck; on the treatment of the disease, by Prof. Beck and Prof. Kleine; and on preventive measures, by all three authors. In an appendix are to be found meteorological observations made during the expedition, and a history of 180 cases of sleeping sickness that came under observation and treatment, with their temperature charts.

The section on etiology is divided into two parts, dealing respectively with *Trypanosoma gambiense* and *Glossina palpalis*. Trypanosomes were found not infrequently in the blood of persons whose glands did not show the characteristic swellings and who presented no symptoms of disease. The number of trypanosomes in the blood of infected persons was always small, and appeared to be subject to periodic variations. In the lymphatic glands trypanosomes were more numerous than in the blood. It is stated that the trypanosomes in the blood were always uniform in appearance, and showed no differentiation of form; but all preparations seem to have been made by methods which, though suitable for clinical diagnosis, were quite inadequate for accurate study of structural details.

Many animals were examined with the object of discovering a vertebrate host other than man for *Trypanosoma gambiense*. Of mammals, only in a single monkey were trypanosomes found, similar in type to *T. gambiense*; those found in birds, on the other hand, were of a distinct type. In reptiles, trypanosomes were found in tortoises and crocodiles. The trypanosome of the crocodile is described as large, and similar in appearance to the European *T. rota-*

torium of frogs. In view of the erroneous statements that have been so often made, attributing to Dr. Koch the discovery of a connection between sleeping sickness and crocodiles (see NATURE, February 18, 1909, p. 458), attention should be directed to his clear statement that "in any case there is no connection between this crocodile-trypanosome and *Trypanosoma gambiense*."

With regard to the transmission of *T. gambiense*, Dr. Koch believes it to be effected by *Glossina palpalis* alone. Nearly three thousand tsetse-flies of this species were examined, and 189 of them were found to contain trypanosomes; of which four types are distinguished and described with the aid of coloured figures drawn from stained preparations. Three of these types of "wild" trypanosomes are considered to be distinct from *T. gambiense*, with which species, however, "Type IV." is identified; it was found five times in tsetse caught on the Sese Islands. "Type I," the commonest of the four types in occurrence, is identified with the trypanosome of the crocodile. Attempts were made to infect tsetse-flies with *T. gambiense* by feeding them on infected animals, but in all cases the trypanosomes died out in a few days in the alimentary tract of the *Glossina*. The infection of the tsetse-fly can only be brought about, it is suggested, under certain definite but as yet unknown conditions. The more recent work of Prof. Kleine and Sir David Bruce will doubtless, when completed, make clear the nature of these conditions and solve a problem which has baffled previous investigators.

A number of observations upon the habits of *Glossina palpalis* are set forth. Dr. Koch is of opinion that crocodile-blood is the principal food of this fly, but that other animals also contribute to its nourishment, especially the hippopotamus. Experiments were made on the effects of clearing the vegetation in spots haunted by the fly, with results confirmatory of the experience of others, that this is an effective method of banishing the fly.

At the beginning of the section dealing with etiology in this report, Dr. Koch points out that the more important facts bearing upon this subject have already been made known by the work of others, and that consequently the investigations of the German Commission can only pretend to fill some gaps and contribute towards "completion of the etiology." It is doubtless for this reason that Dr. Koch so seldom mentions the results of other investigators in his account of his own observations, and often writes in a manner which might lead those unacquainted with previous work on the subject to think that his observations were new. As a matter of fact, the only discovery which can be claimed by Dr. Koch and his collaborators as entirely original, so far as the etiology of sleeping sickness is concerned, is that of the occurrence of trypanosomes in the salivary glands of the tsetse-fly. This important discovery, which was first announced in a preliminary communication to a German medical periodical in 1907, had not been made previously by any investigator, and was received at first with some scepticism, but has since been confirmed by Prof. Kleine and Sir David Bruce.

Prof. Beck's section on the diagnosis of sleeping sickness deals in turn with gland-puncture, lumbar puncture, and blood-investigation. The last of these methods is considered the surest when carried out in a manner which was employed by the Commission, and is described in detail; it is stated to have often given positive results when other indications were negative, especially in those cases in which the glands had become normal under treatment.

(4) Report on the Measures adopted for the Suppression of Sleeping Sickness in Uganda. By Sir Hesketh Bell, K.C.M.G. Colonial Reports.—Miscellaneous, No. 65, December, 1909. Pp. 27, 1 map.

With regard to the treatment of sleeping sickness, Prof. Beck deals with the use and effects of atoxyl, and Prof. Kleine with those of other drugs, of which a variety were tried, but with results inferior to those yielded by atoxyl. For combating sleeping sickness Dr. Koch lays stress on the importance of discovering the infected persons in the earliest stages of the disease, both because curative treatment has then most chance of success, and also in order to prevent them from spreading the infection. The treatment should be carried out in concentration camps situated in places free from tsetse-flies. Healthy populations should be hindered from access to the lake-shore except at places cleared of the vegetation which shelters the tsetses, and the collection of rubber should be forbidden so long as there is danger of infection in the forests on the shore. The tsetse-flies should be kept in check by clearing vegetation in their haunts and by destroying the crocodiles, their principal food supply; this object is to be effected by encouraging the destruction of the nests and eggs of these reptiles. In view of the voracity of tsetse-flies and the readiness with which they suck the blood of any vertebrate animal, it may well be doubted whether the extirpation of crocodiles, though very desirable for many reasons, if practicable, would have the desired effect of diminishing the numbers of the flies to any appreciable extent.

(2) The bibliography of trypanosomiasis issued by the Sleeping Sickness Bureau is a labour-saving publication that will be most useful to those occupied with any problems, whether medical or scientific, relating to trypanosomes and their hosts, vertebrate or invertebrate. It aims at being complete up to March 31, 1909, and contains references, alphabetically arranged, to about 1900 original memoirs, articles, and treatises, catalogued under the authors' names, and numbered in order. In addition to these numbered references, the titles of journals that contain literature on trypanosomes or tsetse-flies are inserted without numbers, followed by a list of the articles or memoirs they contain, so that it is possible to look up the title of a journal in the catalogue and find what papers on trypanosomes or tsetses have been published in it. It is stated that a subject-index is in course of preparation, to be issued as a supplementary pamphlet, indicating the numbers in the bibliography to be consulted for the various subjects.

(3) The thirteenth Bulletin of the Sleeping Sickness Bureau begins a second volume of this most useful publication. Amongst other subjects, the present number deals with the transmission of trypanosomes, the treatment of trypanosome-infections, methods of destroying tsetse-flies, and the alleged occurrence of "ultra-microscopical" forms of trypanosomes. An interesting account is given of a method of destroying tsetse-flies, discovered by Mr. Maldonado, manager of an estate on the island of Principe, who observed that these flies attacked the backs of labourers stooping at their work in the fields; he caused the labourers to wear on their backs black cloths coated on the outer surface with a glutinous substance. In this way 133,778 tsetse-flies were trapped on one plantation during some twenty months. This method may be found useful, it is suggested, for keeping down *Glossina palpalis* in places where clearing is impracticable. A very useful feature of the Bulletin is a section entitled "Sleeping Sickness News," in which information is given concerning recent developments of the disease and measures taken to check it.

(4) Sir Hesketh Bell gives a historical account of the progress of discovery and research, and a summary of the results gained, with regard to sleeping

sickness. He then describes the administrative measures taken in Uganda to combat the disease. These measures may be summarised as follows:—

(1) The removal of infected persons into fly-free areas, that is to say, more than two miles away from the lake-shore, in order that they shall not render the tsetse-flies infective and capable of transmitting the disease to healthy persons; for this purpose segregation camps have been started in which those afflicted with the disease are put under medical treatment; (2) the removal of healthy persons from areas infested by tsetse-flies, until such time as the flies may be supposed to have lost their infectivity; (3) the extirpation or banishment of the fly, by clearing the forest on the foreshore of Lake Victoria, in those places, such as ferries or ports of main trade-routes, from which it is not practicable to remove the population. The task of keeping the foreshore clear is stated to have been aided greatly by planting the cleared areas with citronella-grass, which grows rapidly, and is also of commercial value, yielding a considerable amount of valuable oil.

These measures, when first planned, were based on the belief that the tsetse-fly only transmitted the disease mechanically and did not remain infective for a longer period than forty-eight hours, a belief founded on the experimental results of scientific investigations which had at that time demonstrated clearly the existence of so-called "direct" or "mechanical" infection, but had failed to obtain evidence for the occurrence of deferred or "cyclical" transmission. Consequently it was thought that the flies would lose their infectivity very quickly when they could no longer suck the blood of diseased persons. The recent researches of Kleine and Bruce, however, have shown that the trypanosome of sleeping sickness goes through a developmental cycle in the tsetse-fly, and that when once the trypanosome has established itself, the fly remains infective, apparently for the rest of its life, without again feeding on the blood of an infected person. It follows from this discovery that the period for which healthy persons must be removed from the fly-belts, in order to ensure that the infection has died out in the flies, is much longer than was thought, and cannot at present be stated definitely. There are two further possibilities to be borne in mind, neither of which have as yet been proved, though often suspected, to exist, and which greatly complicate the problem of the transmission and spread of the disease. One is that an infected tsetse-fly may transmit the infection to its offspring; the other, that some vertebrate animal other than man may harbour the trypanosome of sleeping sickness in its blood, and so be a "reservoir-host" which keeps up the infection in the flies. It must also be remembered that to keep the natives, probably much against their inclinations in many cases, more than two miles from the shore along the immense coast-line of the Victoria Nyanza must be a task of considerable difficulty and of uncertain result. The natives concerned are evicted from the homes which they and their ancestors have inhabited for untold generations, and, moreover, they are for the most part extremely sceptical as to the agency of the tsetse-fly in the transmission of the disease. It is therefore extremely probable that in spite of administrative prohibitions, leakage, so to speak, sometimes occurs, and natives evade the regulations against frequenting the danger zone. In a recent communication to the Royal Society (*vide* Proceedings, 1909) Bruce and his collaborators state that they have found tsetse-flies still infective that were caught in localities from which the natives had been removed, and conclude that the tsetse-flies "can retain their

infectivity for a period of at least two years after the native population has been removed." Whether this very discouraging result is to be explained by longevity of the flies, by hereditary transmission of the trypanosomes in the flies, by the existence of "reservoir" hosts, or by leakage and transgression of official orders, cannot be decided positively at present. Time alone can show if the measures adopted will be efficacious in stamping out the disease and the result will be awaited anxiously by all who have the interests of our African colonies at heart.

E. A. M.

DEVELOPMENT OF UNIVERSITY (AND OTHER) EDUCATION IN INDIA.

THE recent publication of the "Fifth Quinquennial Review of the Progress of Education in India, 1902-7," by Mr. H. W. Orange, C.I.E.,¹ Director General of Education in India, indicates clearly that very considerable and satisfactory progress is being made in India in all branches of education, and that the university standards in particular are being raised and made more real and effective. The review deals with the period 1902-7, and it is probable that during no previous five years has there ever been such rapid and sound progress.

The best indication of the increased amount of attention which education is securing will be found in the expenditure, which is mainly met from public funds. Thus in 1902 the total expenditure on education in India was 401 lakhs of rupees, while in 1907 it had advanced to 559 lakhs, or an increase of nearly 40 per cent. This increased expenditure has been accompanied by a very large increase in the number of pupils in all stages and branches of education. Thus there were nearly 1200 more pupils studying university courses, nearly 77,000 more secondary school pupils, and about 860,000 more primary school pupils under instruction in the year 1907 than there were five years previously. In certain cases much more progress was made in the five years, 1902-7, than had been made in the previous fifteen years. This is specially the case in the matter of training of teachers, in female education, in the special education of Mohammedans, and in the primary standards for boys generally, of whom, of course, the great majority are Hindus. These are all very healthy signs, and perhaps the first and second named may be considered as of almost vital importance to the satisfactory progress of Indian education and of India as a nation.

These great improvements have been mainly brought about by the fact that, under Lord Curzon's government as Viceroy, a general inquiry was held which extended to all kinds and grades of educational institutions, from the universities to the primary schools. This inquiry brought under examination the methods, organisation, tendencies, and results of Indian education as a whole, and resulted in the meeting of various committees, conferences, and commissions. As the result of these, certain general lines of policy were laid down by the Imperial Government, and these have since been continuously applied by the various local governments and authorities in meeting the local educational needs of the various provinces.

In the case of university education in India, a good deal of leeway had and still has to be made up. In many cases standards of teaching had become antiquated, and were also unsuitable. In previous years a great many art colleges had been started by persons wishing to help forward the great cause of

education, and these had been affiliated to the various universities. Many of these were known to be insufficiently staffed and very imperfectly equipped generally, the main cause for such conditions being the exceedingly slender financial resources of these institutions. This has been due to their having no endowments and to the exceedingly small fees charged to the students, an annual fee of two to three pounds being commonly paid by a student for education up to B.A. and M.A. standards. Added to this, many colleges were endeavouring to teach a great variety of subjects instead of confining their attention to one or more simple courses, which could have been efficiently carried through with the means at their disposal. As a result of these conditions, a considerable proportion of the students sent up for examination had only received an imperfect training, and this state of affairs having gone on for a considerable period, it had almost insensibly reacted on the standards of the examinations themselves, which had become much lower than was desirable.

To remedy this state of affairs, after certain preliminary inquiries a University Commission was appointed which exhaustively examined into university education in all parts of India, and this reported in June, 1902. As a result a new Act was passed early in 1904 which reconstituted the five existing universities. Under the previous Acts of Incorporation the work of the universities was confined practically solely to the examination of students, while the new Act declared that the universities were "incorporated for the purpose (among others) of making provision for the instruction of students, with power to appoint university professors and lecturers, to hold and manage educational endowments, to erect, equip, and maintain university laboratories and museums, to make regulations relating to the maintenance and conduct of students, and to do all acts which . . . lead to the promotion of study and research."

This contrast shows the different aspect in which Indian universities are now being regarded, and these provisions will probably gradually exercise a powerful influence, though from their nature their effect can only come slowly, but even now, in certain branches of study, university courses of lectures are being delivered.

Certain other provisions also appear in the new Act which even in the short time which has elapsed since it was passed are having important and far-reaching effects.

The senates were reconstituted, and steps were taken to make them more representative of those actually engaged in teaching in the affiliated colleges than had hitherto been the case, and appointments to the Senate were limited to five years instead of for life. These new senates are now working much more efficiently than was formerly the case. Under the Act also, new sets of regulations had to be prepared for all branches of study, and the Government of India was given the power, after consulting the Senate, to make such additions and alterations as might be considered necessary. Speaking generally of the new regulations, they are a very great improvement on the old ones, for they require a much higher standard of study, and also that such study shall be practical rather than of a theoretical nature. Indeed, in all the science subjects practical work is made an essential part of the course of study, whereas formerly theoretical book-work frequently sufficed to carry a student successfully through some of the science examinations.

Perhaps, however, the clauses of the Act which are having the most immediate and tangible effect are those dealing with the affiliation of colleges to the

¹ Published in Calcutta by the Superintendent of Government Printing in India, 1909.

various universities. Formerly, if a college was once affiliated, the university had practically no control of any kind over it, and though it might be known that a college was doing very inferior work, no effective remedial action could be taken. Under the new Act the connection between the college and university is much closer and more effective than it has hitherto been. The conditions which a college must fulfil in order to receive and retain the privileges of affiliation are prescribed in some detail in the Act, and in order that the university may be satisfied as to the fulfilment of these conditions, systematic and periodic inspection of colleges by university inspectors is established, and this is coupled with the power of calling upon a college so visited to amend within a specified period any points over the wide range of requirements laid down by the Act. These inspections took place almost immediately after the passing of the University Act, and it is not too much to say that the condition of affairs disclosed showed abundantly the absolute necessity of the action taken to secure the passing of the new Act. Some colleges, indeed, have already had, or will have, to disappear if they do not rise to the required standard within a reasonable time. In other colleges where defects were found, due mainly, perhaps, to want of funds, arrangements are being made to remedy them, and these efforts are being supplemented by annual grants of money made by Government, which grants are administered by the universities.

Another direction in which radical changes are taking place under the new Act and its consequent regulations is in the matter of the residence of students. Formerly, in many cases, these conditions were deplorable, but gradually a much better state of things is being evolved, and here again the change is largely due to improvements made with money given for building hostels, &c., by Government and by other donors.

That educational activity is increasing is also shown by the fact that at Allahabad in January of this year, the foundation stone of some important new university buildings was laid by Sir John Hewett, the Lieut.-Governor of the United Provinces, who is also Chancellor of the Allahabad University, and by a demand which is now coming from Burma for a new university to be established there, in addition to the existing universities at Calcutta, Bombay, Madras, Allahabad, and the Punjab. As time goes on, indeed, there will probably be room, not only for the Burma University, but for others at such places as Nagpore, in the Central Provinces, and perhaps at Aligarh, which is now the centre of a large and exceedingly well-managed Mohammedan college.

Such are the main lines on which the improvements in university education in India are being conducted, but the effect of the new University Act does not end here, and it has also had an important bearing on the schools for secondary education. In most Indian universities, students usually can only go up for the matriculation examination if they have studied at a high school recognised by the university. The standard set by the university matriculation, therefore, largely influences the secondary schools. Formerly these standards were low, and in many ways unsatisfactory, while the schools which had been "recognised" were many of them most inferior in every way, specially in teaching and discipline, and they could not possibly impart sound education or develop character. Now the standards for the matriculation examination have been revised and generally raised, while also the conditions under which the secondary schools receive recognition have been formulated under the various university regulations, and unless

a school is shown by inspection to be satisfactory in respect of constitution, management, and financial stability, premises and equipment, staff, instruction, and discipline, it cannot be recognised by the university, and hence cannot send up its pupils for examination. Inspection, therefore, has to be made of schools as well as of colleges, and this is rapidly raising the tone of the education given.

Hence the new University Act of 1904 is having a very marked and beneficial effect on all forms of college and high-school education, and India appears to be entering on a more prosperous era in the matter of higher education in all its branches than has hitherto been possible.

THE NUTRITIVE VALUE OF BLACK BREAD.

DURING the last General Election much was heard about the hard lot of the German workmen and peasants who are compelled to eat black bread, and much political capital was made of it. It may therefore be interesting to inquire how much of a hardship this is from the point of view of nutritiveness and also of tastiness. The so-called black bread is made of rye, and has the property of keeping moist for a much longer time than wheaten bread, although if kept too long it is apt to turn sour. It is quite a mistake to suppose that it is nasty; in New York, where wheaten bread is the staple article of diet, the German bakeries almost always also sell black bread, even in the best quarters of the town, and it is said that black bread is always to be found on the Emperor's table. So those who habitually buy white bread by no means entirely discard the use of black bread, though it does not appear to have found very much favour except with those of German extraction.

From the various analyses which have been published, the amount of nitrogenous material contained in the different cereals does not differ greatly nor constantly; but wheat has its nitrogenous matter partly in the form of gluten, a sticky material almost wanting in the other cereals. So far, then, as nitrogenous constituents are concerned, everything turns upon whether gluten is more nutritious than the other nitrogenous bodies. There is no reason to suppose that it is, but its adhesive properties are valuable in causing the dough, when permeated by carbonic acid gas, as a result of fermentation, to rise into a more porous, spongy mass. The nitrogenous material contained in the flour of all cereals when it is made into dough commences to decompose, and in this state acts as a ferment, breaking up a portion of the starch into dextrin and glucose, whilst some part of the starch undergoes a further fermentation into alcohol and carbonic acid gas. In this state the dough is called "leaven," and small portions of it are capable of setting up the same action in much larger masses of dough.

This is the old way of preparing bread, and is still employed in the making of black bread; in the making of finer breads it is not wholly discarded, although yeast is used for the initiation of the process. If this change goes far the bread loses in whiteness, and the addition of alum as an adulterant is made with the view of checking the fermentation. It is not generally known that the comparatively dark colour of whole-meal bread is not due to the particles of bran which it contains, but to the fermentative changes having gone further. This is due to the husk containing another nitrogenous body, which also acts as an active ferment. In fact, in white bread a large proportion of the starch remains unchanged.

But whole-meal bread is well known to have a

higher nutritive value than white bread, probably partly on account of this conversion of the starch, which is a process indispensable to its digestion if it has not happened before it is eaten; and, of course, the whole-meal bread is richer in inorganic salts by the retention of the husk.

And it must not be supposed that rye bread is of necessity "black"; a bread that is lighter in colour than our brown bread can be made from rye flour, the depth of colour being dependent upon the treatment.

So far, then, there is not the smallest reason to suppose that black bread is inferior as a nutritive food to white bread, but rather the contrary.

Passing from the consideration of the nitrogenous (vegetable fibrin) constituents, rye contains as much or more starch and fatty matter as wheat. It contains more lime, about the same amount of magnesia, a good deal more silica, and slightly less phosphoric acid.

As the phosphates of lime and magnesia are needed for the calcification of bones and teeth, there is little to choose in this respect between a whole-meal wheaten bread and rye bread, both being superior to white bread. Formerly it was supposed that teeth of poor quality were actually deficient in lime salts, but this has been found not to be the case. Good teeth, whatever may be their chemical difference, and this has not been ascertained as yet, are unquestionably associated with good general nutrition in the growing person, and, of course, an adequate supply of lime and magnesia is essential to their formation. It should be added that the differences between samples of the same cereals are considerable, being apparently dependent upon the season, soil, and other conditions, so that in many cases the analyses show discrepant results.

But a consideration of the chemistry of the different breads gives no support to the idea that black bread is an inferior article of diet, and the German peasant is not to be pitied for having to use it. In texture it is moister, a little more sticky and doughy, does not get stale so soon, and it might not be wholly to the taste of those accustomed to wheaten bread, at all events at first. It is good food, nevertheless, and those accustomed to it often actually prefer it.

During the Crimean war the Russian prisoners in the hands of the French did not thrive, but after, on the advice of a Russian surgeon, they were given the black bread to which they were accustomed they did much better.

The political orator is not too particular about his facts so long as he thinks they will serve his turn, and the allegations made about black bread have been, to say the least, wanting in scientific accuracy, and so may be classed with much else that is heard from electioneering platforms as calculated, whether with intent or from ignorance, to convey a perfectly false impression.

COMMANDER PEARY'S EXPEDITION TO THE NORTH POLE.

NO geographical goal has been so long and ardently desired as the North Pole. The glamour of the Dark Continent, the mystery of the South Polar lands, the lure of Potosi and Golconda, have never touched the popular imagination like the attraction of the North Pole. The whale and seal hunters of the seventeenth and eighteenth centuries developed the art of Arctic travel; while the Eskimo, the polar fauna, and the heroism of the knights of the frozen seas, kept an undue share of popular geographical interest "North where the bergs careen."

The commercial hopes that led to the search for the North-West Passage and the Franklin tragedy for a while made the Arctic Archipelago the centre of popular interest, but the North Pole, as a fixed spot, as definite as the winning post of a race, has kept its own as the goal most prized by sporting geographers.

It has at length been won, and the lecture by Commander Peary to the Royal Geographical Society, in the Albert Hall last night, told the story of the winning. The quest has been Commander Peary's one interest for twenty-four years; he has led four expeditions to reach the pole, after his remarkable exploration of the North Greenland ice-cap had given him the necessary experience, and had yielded him geographical results of perhaps greater scientific value than those of his last and most famous journey. He has carried through his work in an appropriately serious spirit. He has not regarded his quest as a mere matter of geographical athletics, but as a mission so important that he has been tempted to regard the Eskimo as placed by Providence in their inhospitable home on purpose to help him to his goal.

Commander Peary's lecture was a simple statement of the narrative of the expedition, and it gave no details as to the determination of the high latitudes, which geographers at this stage would have preferred to the short appendices giving the soundings and preliminary notes on the temperatures and tides. The expedition was apparently successful because a large force was able to start early in the season. Like Russia, according to Czar Nicholas, the pole has been protected by its ally, "General February"; but on this occasion the expedition began its journey from winter quarters in the middle of February. The party consisted of seven members, accompanied by seventeen Eskimos, 133 dogs, and nineteen sledges. With so large a staff a light advance party could be used to prepare the trail and successive divisions sent back from different stages, so that the final dash for the pole could be made by a party well equipped and comparatively fresh.

Commander Peary says that he and his comrades increased in fitness and training every day of the northern march. At a camp determined by Captain Bartlett as at $87^{\circ} 48' N.$, that gallant officer and the last supporting party returned, leaving Peary, his negro servant Henson, and three Eskimo, with forty of the best dogs and five sledges. On April 1 Peary continued northward, hoping to reach the pole by five marches of twenty-five geographical miles each. At the end of the fifth march a temporary break in the clouds at "approximately local noon, Columbia meridian," enabled Peary to determine the position as $89^{\circ} 57'$. A few hours later, with a light sledge carrying only instruments, drawn by a double team of dogs, he went on for another ten miles, and, as the sky cleared, he took observations, which showed that he had gone beyond the pole. After returning to camp he went eastward for eight miles, and both then and after his second return to camp he secured more observations, which confirmed his faith that he had reached and crossed the pole. Five miles from the pole he found a crack, and through a hole in it bored with a pickaxe he took a sounding of 1500 fathoms, and found no bottom. The expedition returned south by forced marches, and it reached Cape Columbia in such fine trim that it crossed to Cape Hecla, and thence to the ship, in two marches of forty-five miles each.

The only definite scientific contributions announced are the soundings, which indicated a depth of only 310 fathoms at $85^{\circ} 23'$; the depth had increased to more than 700 fathoms at ten miles further north, while at $87^{\circ} 15'$ the result was 1260 fathoms, with no

bottom. Further soundings were prevented by the loss of the wire, which broke on two occasions, detachable sinkers not having been employed.

The expedition gives convincing proof that the sea extends over the North Pole, confirming the view of the eighteenth-century whalers, who claimed to have occasionally found such open seas that they were able to attain high latitudes. So many British whalers claimed to have reached 82° and 83° in open water that it is difficult to disbelieve them all; and as the Greenland Sea was then being scoured by whalers, it is quite probable that they were occasionally able to attain these latitudes. The view that the sea extended to the pole was then partly based on the evidence of Dutch ships, that are said to have reached latitudes of 86° , 88° , and 89° ; but the evidence for these latitudes was found unconvincing when it was discussed by Barrington in 1774.

Considering the exceptional interest in the achievement, and the impossibility of leaving any permanent record at the pole, Commander Peary's observations when published will, no doubt, be scanned critically, though in no hostile spirit. As Captain Bartlett accompanied him to $87^{\circ} 48'$ —about 150 statute miles from the pole—and Peary thence made five long marches northward, there seems no reason why so expert an ice traveller, prepared to make the supreme effort of his life, should not have reached either the pole or sufficiently near it for all practical purposes.

As the great goal of Arctic enterprise has been won, we may now hope Arctic research will be continued in a more scientific spirit. There is much work still to be done. Geographically, the area now of most interest is that to the north-west of the Arctic Archipelago, and as Peary has shown that a large expedition can journey for four hundred miles out from land and back again, the search for the furthest islands of that group is possible by sledge journeys. The contour of the Arctic Ocean has still to be determined, and this work can hardly be done by sledge journeys, which can give but meagre results, compared with the work in a floating laboratory drifting, like the *Fram*, across the polar seas. Such work is slow, but the risks are probably not excessive. The Arctic death-rate has been far lower than the African, and, with the opportunities of life on a well-found ship, much of the biological and other scientific work might be done during the voyage. The reaching of the pole should change the methods but not lessen the interest of Arctic work.

REPORT AND CONCLUSIONS ON PEARY'S ARCTIC WORK.

A full report of the speech delivered by the Hon. J. Hampton Moore, of Pennsylvania, in the U.S. House of Representatives on March 22, with reference to Commander Peary's work in Arctic regions and his attainment of the North Pole, has lately been issued. The subjoined extracts from this report will serve to supplement the information which Commander Peary was able to give in his lecture last night, and to substantiate his claims to distinguished eminence as a polar explorer.

Memorandum of Peary's Northern Voyages.

1886. May to November; about seven months: Penetrated 100 miles on the inland ice of Greenland east of Disco Bay, about 70° N. latitude; altitude, 7500 feet.

1891-2. June, 1891, to September, 1892; about sixteen months: Right leg broken on voyage north. Five-hundred-mile march out and same distance back, across northern part of Greenland, discovering Independence Bay on the north-eastern coast.

1893-5. July, 1893, to September, 1895; about twenty-seven months: Entire party except Peary and two men returned at end of first year. Spring of 1895 Peary repeated the march across northern end of Greenland, and gained some miles beyond his farthest of 1892. Discovered

the great Cape York meteorites, and brought the two smaller ones back with him.

1896. July-October; about three months: Unsuccessful attempt to bring home largest of the Cape York meteorites.

1897. July-October; about three months: Brought home largest of the Cape York meteorites—the Alnigito, the largest in the world—weighing about 90 tons.

1898-1902. July, 1898, to October, 1902; about four years, three and a half months: During this time made four separate attempts to get north, resulting in the rounding of the northern end of Greenland and the attainment of the latitude of 83.59° north of the extreme northern point of Greenland; also the attainment of the latitude of 84.17° north of the northern point of Grant Land. All the instruments, records, private papers of the Lady Franklin expedition at Fort Conger brought home.

1905-6. July, 1905, to November, 1906; about seventeen months: Highest north, $87^{\circ} 6'$, attained in this journey.

1908-9. July, 1908, to September, 1909; about fifteen months: Attainment of the Pole.

Summary.—Eight voyages, six attempts to reach the Pole, and some twelve years spent inside the Arctic Circle.

	Degrees N. Lat.		Degrees N. Lat.
1886	$69^{\circ}00'$	1900	$83^{\circ}59'$
1892	$81^{\circ}35'$	1902	$84^{\circ}17'$
1895	$81^{\circ}40'$	1906	$87^{\circ}60'$
1899	$81^{\circ}50'$	1909	$90^{\circ}00'$

Peary's ability as a commander is thoroughly demonstrated by the success of his various expeditions. Twice his ship was driven through the ice to the highest point ever reached in the western hemisphere, and to a point higher than any ship has ever attained under her own steam. Many other ships attempted this same voyage; four of them accomplished part of it, and two were lost. As to his work being civil and distinct from naval, it may be observed that Peary's bringing of the *Roosevelt* home in the autumn of 1906, fighting her way through the heavy Arctic ice, from Cape Union to Littleton Island, and thence down along the savage Baffin Land and Labrador coasts, encountering storm after storm, with rudder and sternposts torn away, propellers crippled, and pumps going constantly, has been characterised as one of the ablest, most resourceful, and courageous affairs of its kind in the annals of Arctic exploration. Indeed, it was the wonder of everyone who saw the ship when it was taken out on the dry dock.

With regard to the expedition that was successful, the expedition of 1908-9, resulting in the discovery of the Pole, he fitted out this expedition at his own expense and that of his friends, and was then granted leave of absence by the Navy Department, taking with him instructions which gave him an unqualified official connection with the Government.

Upon Commander Peary's return, the Navy Department asked the Coast and Geodetic Survey to furnish the results of the late expeditions carried on by him under the auspices of the Peary Arctic Club.

In reply to this request, Commander Peary sent a profile of soundings taken by the expedition, and tidal and meteorological records.

The following table shows the soundings from Cape Columbia to the Pole:—

Sounding by—	Latitude	Fathoms	Remarks.
	$83^{\circ} 7'$	0	
Marvin	$83^{\circ} 10'$	98	Edge of glacial fringe.
Marvin and MacMillan	$83^{\circ} 25'$	96	
Bartlett	$83^{\circ} 53'$	110	Edge of continental shelf.
Marvin	$84^{\circ} 29'$	825	
Do... ..	$84^{\circ} 39'$	580	
Do... ..	$85^{\circ} 23'$	310	
Do... ..	$85^{\circ} 33'$	700	No bottom.
Bartlett	$87^{\circ} 15'$	1,260	Do.
Peary	$89^{\circ} 55'$	1,500	Do.

Peary's Notes on Soundings.

The sounding equipment of the expedition consisted of two reels of specially made piano-wire of 1000 fathoms, each, and three approximately 20-lb. leads, with clam-shell device for grasping samples of the bottom. These reels were arranged to be fitted quickly to the upstanders of a

sledge when making a sounding, and had handles for reeling in the wire and lead.

One of these reels and leads were carried by Bartlett with his advance party, and the other reel and two leads by the main party.

Portions of the wire and the two leads were lost at various times in hauling up, owing, probably, to kinks in the wire.

When the sounding at $85^{\circ} 33'$ was made, 700 fathoms only were left of the sounding wire of the main party, and Bartlett, with the other thousand fathoms, was in advance and inaccessible.

In hauling up the wire from this sounding it parted again, and some 200 fathoms, together with two pickaxe heads and a steel sledge shoe, which had been used to carry it down, were lost.

When Marvin turned back the Captain's 1000 fathoms and the remaining 500 fathoms of the other reel were combined.

When Bartlett made the sounding at $87^{\circ} 15'$ I gave him explicit instructions to use the utmost caution in regard to the wire, in order not to lose any more of it, as I wanted it all for a sounding at the Pole should I succeed in getting there.

Acting upon these instructions, Bartlett ran out 1260 fathoms and then stopped, on account of a small kink in the wire, which he feared would part when the wire was hauled up.

When I made my sounding about five miles from the Pole the wire parted, as had been feared, and the last lead and nearly all of the wire was lost.

The above facts are noted to explain the irregularity of these soundings, which did not get bottom.

The sounding of 310 fathoms at $85^{\circ} 23'$ naturally impressed me at once as surprising, and when Marvin reported the result to me, immediately after taking the sounding, I at once asked him if he was sure that he had the bottom, and he replied that he was, as the fact of this pronounced shoaling from 825 fathoms to 310 impressed him at once, and he made sure that his depth was correct.

Again, when the sounding of 700 fathoms and no bottom was made about ten miles farther north, we both spoke of the peculiar fact of this outlying ridge with deeper channel intervening between it and the continental shelf, and Marvin again said that he was sure of his 310 fathoms reading.

Had it not been for the loss of the last lead and practically all of the wire while making the soundings at the Pole, I should, on the return, have interpolated other soundings.

The profile indicates that a line of 5-mile interval soundings from Cape Columbia to the eighty-sixth parallel might develop a particularly interesting profile of the bottom of the Arctic Ocean.

Tidal Records.

The tidal records consist of practically unbroken series of hourly readings of the height of the tide, taken day and night, at the following places and between the dates specified:—

Station.	Period of observation.	Length of record.
Cape Sheridan.	November 12, 1908, to June 30, 1909 (total loss of record, 31 hours)	Days. 231
Cape Columbia	November 16, 1908, to December 14, 1908	29
Cape Bryant	January 16, 1909, to February 13, 1909	28
Fort Conger	June 10, 1909, to June 25, 1909 (total loss of record, 5 hours)	10

The observations were taken day and night, and besides the regular hourly readings numerous additional readings were generally taken near the times of the high and the low waters.

Commander Peary's observations leave little to be desired in regard to tidal observations between Cape Morris Jesup and Cape Columbia; but there are long stretches of the Arctic coast where nothing is available. This is especially true of the Russian coast and the western and northern portions of the Arctic archipelago.

The results obtained from Commander Peary's records

show that the tides along the northern coasts of Grant Land and Greenland are quite different in many respects from what had been heretofore supposed. For example, his records prove that the tide occurs three hours earlier at Cape Columbia than at Cape Sheridan, and not later, as had been generally assumed.

As already intimated, the full significance of these observations in respect to Arctic geography cannot be seen at this time.

The meteorological records consist of thermograms covering about 180 days, and barograms covering about 260 days.

National Geographic Society's Investigation.

At a meeting of the board of managers of the National Geographic Society, Wednesday morning, October 20, the records and observations and proof of Commander Robert E. Peary that he reached the Pole April 6, 1909, were submitted to the society.

The records and observations were immediately referred to the committee on research, with the direction that the chairman appoint a subcommittee of experts, of which he shall be a member, to examine said records and report on them to the board. Mr. Henry Gannett, chairman of the committee on research, immediately appointed as the other members of the committee Rear-Admiral Colby M. Chester, United States Navy, and O. H. Tittmann, superintendent of the United States Coast and Geodetic Survey.

In due course the board of managers of the National Geographic Society, at a meeting held at Hubbard Memorial Hall, Washington, D.C., November 4, 1909, received the following report:—

The subcommittee to which was referred the task of examining the records of Commander Peary in evidence of his having reached the North Pole beg to report that they have completed their task.

Commander Peary has submitted to this subcommittee his original journal and records of observations, together with all his instruments and apparatus and certain of the most important of the scientific results of his expedition. These have been carefully examined by your subcommittee, and they are unanimously of the opinion that Commander Peary reached the North Pole on April 6, 1909.

They also feel warranted in stating that the organization, planning, and management of the expedition, its complete success, and its scientific results reflect the greatest credit on the ability of Commander Robert E. Peary, and render him worthy of the highest honours that the National Geographic Society can bestow upon him.

HENRY GANNETT.
C. M. CHESTER.
O. H. TITTMANN.

The foregoing report was unanimously approved.

Immediately after this action the following resolutions were unanimously adopted:—

"Whereas Commander Robert E. Peary has reached the North Pole, the goal sought for centuries; and

"Whereas this is the greatest geographical achievement that this society can have opportunity to honour: Therefore

"Resolved, That a special medal be awarded to Commander Peary."

Time Records on Dash to Pole.

Referring to the time occupied by Peary in his last dash to the Pole, Mr. Gilbert H. Grosvenor, director and editor of the National Geographic Society, says:—

"In view of the recent published statement by a Member of Congress doubting the distances travelled by Peary on his last northern sledge journey, I have gone to some trouble to obtain correct figures from the narrative of Peary's last and previous expeditions.

"Anyone who cares to take the time and trouble can verify these figures, and will find the following results:—

"Peary's average distance per march from Cape Columbia to where Bartlett turned back was 12.8 miles. Had it not been for the north wind two days, setting them back, this average would have been $13\frac{1}{2}$ miles. Between two observations taken by Marvin the average of three marches was $16\frac{1}{2}$ miles. Several of the marches were 20 miles.

"His average, from the time Bartlett left him, to the Pole was 26 miles. His average on his return was 25.6 miles.

"For comparison with the above figures, as showing that these averages are not at all excessive, the following facts can be taken from the narrative of the last expedition and previous ones:—

"Peary's last two marches on the return, from Cape Columbia to the *Roosevelt*, were 45 miles each. On this and previous expeditions the journey from Cape Hecla to the *Roosevelt*, a distance of 45 to 50 miles, was made in one march. The distance from Cape Columbia to Hecla was also made on other occasions in one march. The march from the *Roosevelt* to Porter Bay, a distance of 35 miles, was repeatedly made in eight, ten, and twelve hours. MacMillan and Borup, returning from Cape Morris Jesup to the *Roosevelt*, made the distance of 250 miles or more in eight marches, an average of over 31 miles a march. Peary, in one of his earlier expeditions, made the distance from Cape Wilkes to Cape D'Urville, a distance of 65 to 70 miles, in one march. He repeatedly made the march from Cape D'Urville to Cape Fraser, a distance of 40 miles, in one march, and in the winter of 1899-1900 travelled from Etah to a point in Robertson Bay, 60 miles distant, in less than twelve hours.

"On his return from Independence Bay to Bowdoin Bay, Peary averaged 20 miles a day for twenty-five successive marches; 210 miles in seven successive marches (an average of 30 miles a day), making the last march of 40 miles, all these with dogs not driven by Eskimo drivers.

"On more than one occasion in the fall of 1900 Peary's parties went from Lake Hazen to Fort Conger, both by the Bellows route and by the Black Vale route, distances either way of 50 miles overland, in one march. This after the sun had set for the winter.

"In February, 1899, before the sun returned, Peary (with both feet frozen six weeks before) sledged from Conger to Cape D'Urville, a distance of over 200 miles, in eleven marches, in an average temperature of 53° below zero, an average of about 20 miles. In March of 1902 he went from Cape Sabine to Fort Conger, a distance of 250 miles to 300 miles, as travelled, in twelve marches, an average of 21 to 25 miles, and later covered the same distance again in eleven marches, an average of 22 to 27 miles.

"In the history of polar exploration no one has had so much and such long-continued training in ice work as Peary; his speed is the result of long years of practice, resulting in great physical endurance and skill in the use of the sledge."

NOTES.

ELSEWHERE in this issue Prof. Bryan deals with some aspects of the remarkable aeroplane flight from London to Manchester accomplished by M. Paulhan on April 27-28, thereby winning the prize of 10,000*l.* offered by the *Daily Mail* to the aviator who would make this cross-country flight within twenty-four hours. M. Paulhan left London (Hendon) at 5.22 p.m. on April 27, and descended at Lichfield—117 miles distant—at 8.10 p.m., that is, 2h. 48m. later. He left Lichfield at 4.10 a.m. on the following day, and arrived at Manchester at 5.30 a.m., the distance being 69 miles. The total distance covered with the one stop was thus 186 miles. The prize was presented to M. Paulhan at a luncheon given in his honour on Saturday, and a 100-guinea cup was handed to Mr. Grahame-White in recognition of his plucky endeavour to secure the prize for England. At the banquet, the editor of the *Daily Mail*, in expressing regret for the absence of Lord Northcliffe on account of illness, reminded the assembly that it was owing to Lord Northcliffe's personal initiative that the substantial prize won by M. Paulhan was offered for competition. He stated also that, in view of the great importance of aviation to Great Britain, the *Daily Mail* will

immediately offer a further sum of 10,000*l.* for a flight of which the conditions will be announced shortly. Mr. Grahame-White, in acknowledging the toast of his health, said that it is his intention to expend the proceeds of the Royal Aero Club's testimonial to himself upon the necessary organisation for an aeroplane flight from London to Paris "which I have made up my mind to attempt with the least possible delay." Though we have no sympathy with mere record-breaking, such flights as those accomplished across country by M. Paulhan and Mr. Grahame-White, and others now contemplated, provide practical demonstrations of aeroplane performances which will make the British people realise more than anything else the possibilities of aerial navigation. At present the man in the machine counts for everything; and an aeroplane which Prof. Bryan considers to be laterally unstable is so skilfully managed that it rises superior to its imperfections. It is indeed a sign of progress in the management of aeroplanes that, without a trial flight, and about nine hours after his machine arrived at Hendon, M. Paulhan should make a flight of 117 miles across country without a stop. No doubt much yet remains to be done before the best type of construction of aeroplanes can be determined; nevertheless, the flight last week will go down in history as a notable achievement.

It is announced that Mr. P. H. Cowell, F.R.S., chief assistant in the Royal Observatory, Greenwich, has been appointed superintendent of the Nautical Almanac, in succession to Dr. A. M. W. Downing, who has retired.

We have received with regret the announcement of the death, on April 28, of Prof. E. J. L. M. van Beneden, professor of zoology and comparative anatomy in the University of Liège, at sixty-four years of age.

A CONVERSAZIONE, with short lectures and lantern demonstrations, will be held by the Entomological Society in the rooms of the Civil Service Commission, Burlington Gardens, W., on the evening of Friday, May 27. Fellows of the society and others interested requiring further particulars are invited to address all inquiries to the honorary secretary, conversazione committee, 11 Chandos Street, Cavendish Square, W.

THE valuable collections of native African art made by Mr. E. Torday in the southern Belgian Congo are now being classified and arranged by the authorities of the British Museum. The most remarkable specimens in the collection are the wooden portrait statues of past rulers, which throw a new light on savage art in Africa. Next in importance are a splendid carved throne of the paramount chiefs, wooden caskets and cups, and specimens of remarkable textiles resembling velvet, made from the fibre of the upper skin of the palm leaf (*raphia*). This collection was happily made before the almost complete disappearance of native art work due to the importation of cheap European productions.

THE council of the Institution of Civil Engineers has made the following awards for papers during the session 1909-10:—a Telford gold medal to Mr. C. M. Jacobs (New York); a Watt gold medal to Mr. J. D. Watson (Birmingham); a George Stephenson gold medal to Mr. D. A. Matheson (Glasgow); Telford premiums to Messrs. F. C. Buscarlet (Sunderland), A. Hunter (Glasgow), I. C. Barling (Tynemouth), J. Dalziel and J. Sayers (Derby), and J. Shaw (Birkenhead); and the Manby premium to the late Mr. C. W. Hodson (London). The thanks of the council have been conveyed to their colleague, Dr. C. A. Harrison, for the paper contributed by him.

At the annual general meeting of the Institution of Civil Engineers, held on Tuesday, April 26, the result of the ballot for the election of officers was declared as follows:—*President*, Mr. Alexander Siemens; *vice-presidents*, Dr. W. C. Unwin, Mr. R. Elliott-Cooper, Mr. A. G. Lyster, and Mr. C. A. Brereton; *others members of council*, Mr. J. A. F. Aspinall (Liverpool), Mr. B. Hall Blyth (Edinburgh), Mr. J. A. Brodie (Liverpool), Mr. W. B. Bryan, Colonel R. E. B. Crompton, C.B., Mr. Wm. Davidson (Australasia), Mr. E. B. Ellington, Mr. Maurice Fitzmaurice, C.M.G., Mr. J. P. Griffith (Ireland), Sir Robert A. Hadfield (Sheffield), Dr. C. A. Harrison (Newcastle-on-Tyne), Mr. W. Hunter, Mr. G. R. Jebb (Birmingham), Mr. H. E. Jones, Sir Wm. Thomas Lewis, Bart., K.C.V.O. (Aberdare), Mr. H. D. Lumsden (Canada), Sir Thomas Matthews, Hon. C. A. Parsons, C.B. (Wylam-on-Tyne), Mr. A. Ross, Mr. J. W. Shores, C.M.G. (South Africa), Mr. F. J. E. Spring, C.I.E. (India), Mr. J. Strain (Glasgow), Sir Frederick R. Upcott, K.C.V.O., C.S.I., Sir Philip Watts, K.C.B., Mr. W. B. Worthington (Derby), and Mr. A. F. Yarrow (Glasgow).

SCIENTIFIC work in America will benefit largely by the will of the late Prof. Alexander Agassiz. The American Academy of Arts and Sciences receives 10,000*l.*, and the National Academy of Sciences an equal sum. A bequest of 5000*l.* goes to the City of Newport, Rhode Island, for the support of the Coles Laboratory and for use in the maintenance of manual training in the city schools. The principal beneficiary is Harvard University. Prof. Agassiz has left to that institution a valuable collection of books and instruments, as well as a legacy of 20,000*l.* for the general uses of its Museum of Comparative Zoology. Another sum of 20,000*l.* is left to the president and fellows of Harvard for the publication of memoirs of Prof. Agassiz's own expeditions. In addition, a bequest of 2400*l.*, which is to provide a life income to two servants, is to revert to Harvard on the death of these servants and their wives, and the bulk of the estate, now to be divided among the three sons of the deceased, is also to become the property of the University should the family become extinct.

DR. C. B. PLOWRIGHT, whose death was announced in last week's *NATURE*, belonged to the school of mycologists founded by the Rev. M. J. Berkeley, one of the pioneers of modern mycology and the founder of plant pathology. Of this school only three members now remain, one of whom is the veteran Dr. M. C. Cooke. Among the members that assembled annually for the fungus foray, held under the auspices of the celebrated Woolhope Club, Dr. Plowright was always noted for his advanced ideas and his endeavours to elevate mycology from the old Friesian rut in which at the time it was firmly imbedded. His espousal of the heteroecismal theory of the rusts was the cause of much good-natured banter; nevertheless, Dr. Plowright commenced experiments and infections, which were continued for many years, and resulted in the production of the classic work entitled "A Monograph of the British Uredineæ and Ustilagineæ." A second publication of importance was "A Monograph of the British Hypomyces." In addition, more than one hundred papers bearing on systematic mycology and plant pathology have appeared under his name in various publications. He was a constant visitor to the various fungus forays for many years, and was for some time president of the British Mycological Society. His geniality and readiness to remove difficulties from amateur mycologists will doubtless be remembered by many, who will sincerely regret his removal from amongst them.

THE eleventh session of the International Geological Congress will be held in Stockholm on August 18–25, and the executive committee has prepared a very attractive programme both of meetings and excursions. The special problems of which discussion is invited are the classification of the pre-Cambrian system, post-Glacial climatic changes, the iron ore supplies of the world, the geology of the Polar regions, and the sudden appearance of the Cambrian fauna. The excursions are divided into three groups, those before, during, and after the congress. The most extensive of the preliminary excursions will be one to Spitsbergen under the conduct of Baron de Geer; it will last three weeks, and will be devoted to examination of the very varied glacial and stratigraphical geology of Ice Fiord. The cost of the excursion is 50*l.* Most of the other preliminary excursions are in northern Sweden, and include visits to the great overthrust area of Jämtland under the direction of Prof. Högbom, to the iron ore deposits of Lapland, to Lake Tornea to examine its overthrusting and Pleistocene geology, and to the peat deposits of Närke. There will be short excursions during the congress to localities easily accessible from Stockholm. Subsequently there will be excursions of from three to fifteen days to the chief localities of geological interest in southern Sweden, including the Archaean rocks of the south-western coast, the island of Gotland and other Silurian localities, the iron mines of middle Sweden, and the chief Mesozoic localities of Scania. The second session of the Agrogeological Conference will be held in Stockholm simultaneously, and though the two congresses are independent, geologists are invited to join both. In preparation for the discussion on the iron ore resources of the world, an elaborate collection of reports on the iron ore supplies of most countries has been collected from the geological surveys and mining geologists. It has been edited by the general secretary to the congress, Dr. Gunnar Andersson, and is being issued at a price of 3*l.* It consists of two quarto volumes of 1100 pages, with an atlas of forty-two maps and numerous plates. The work has not yet been issued, but from the list of contributions it is obviously a most valuable and authoritative statement as to the available supplies and distribution of iron ore.

THE weather was fairly normal over the British Islands during April, but the conditions were generally far less settled in the northern and western districts than elsewhere. Rain fell with considerable frequency, and at times the measurements were large, especially in those places where thunderstorms occurred. At Greenwich rain fell on seventeen days, yielding a total of 2.65 inches, which is 1.08 inches more than the average of the past sixty-five years; of this amount 1.50 inches fell on April 16, when a sharp thunderstorm was experienced. The mean temperature at Greenwich was 47.5°, which is 0.6° below the average, and there were only seven days with a temperature of 60° or above. Frost occurred in the screen on two nights, but radiation frosts occurred on sixteen nights, the exposed thermometer registering 15.9° on April 3. The sun was shining for 130 hours, which is seventeen hours less than the normal, and there were three days absolutely without sunshine. There were only three days during the month with the temperature in the sun's rays above 120°. In April last year the duration of bright sunshine was 250 hours, and there were twelve days with the solar radiation temperature above 120°, whilst the mean temperature was 49.6°, and the aggregate rainfall 1.64 inches.

IN vol. xxiv. of the *Queensland Geographical Journal* Mr. R. H. Mathews describes certain sacred stones used in burial and other rites by the aborigines of Australia.

One variety, known as Kopai balls, are made of burnt gypsum reduced to powder and moulded into a kind of concrete with ashes and sand. These are placed on the grave, and the spirit is supposed to come out and lick them, becoming in this way conciliated and friendly to the survivors. Another type of stone used in their secret rites is ground down into a blunt point at one end, and marks are cut on the surface with a sharp stone, shell, or piece of bone. The object of these markings is obscure, but they certainly convey some religious or symbolical meaning.

THE Peabody Museum, Harvard University, continues in vol. iv., part iii., of its Proceedings for the current year the studies of the Maya Codices, of which two instalments have already appeared, with an attempt by Drs. Tozzer and Allen to identify the conventionalised animal forms which appear in these remarkable documents. A detailed examination shows that only a small part of the animal life of the country occupied by the Maya-speaking peoples is represented, and while some drawings are fairly accurate, there is much difficulty in identifying other species which the artists intended to represent. Only those forms of animal life are depicted which possessed a mythological significance or were used as offerings to the numerous deities of the Pantheon. The whole scheme is thus purely "religious," and the reproduction of this large series of animal figures will throw much light on the obscure religious system of this remarkable race.

MESSRS. DULAU AND CO. have issued in the series of "Eugenics Laboratory Memoirs" a memoir, by Mr. David Heron, Galton research fellow, on the influence of defective physique and unfavourable home environment on the intelligence of school children. The memoir is based on a limited survey of children in schools under the London County Council, carried on under the direction of the medical officer of the Education Committee, and the characters noted include the sex, age, height, weight, and condition of the teeth of the child, and, for certain schools, the state of nutrition, the condition of the clothing, the degree of cleanliness, the power of hearing, the condition of the cervical glands and of the tonsils, and adenoids. The methods used by Mr. Heron are in several respects novel and noteworthy, and the data based on the measured characters are of interest; but the memoir should serve its most useful purpose in indicating the absolute necessity for clear definition when qualitative characters are to be noted; the classification of the data in the present survey seems in several cases, owing to variations in the personal equation of the observers, to have been so unsatisfactory that little confidence can be placed in the results. So far as they go, these indicate but very slight correlation between intelligence and the other characters observed; but this result is in conflict with that given by the investigations of Dr. Francis Warner in 1888-91 and 1892-4, to which the author does not refer. Dr. Warner's surveys show a high correlation between dulness and malnutrition, and between dulness and development defects, and these conclusions seem the more probable.

ACCORDING to the report for 1909, the Rugby School Natural History Society continues to maintain its record for good work, some of the papers being of a high character, while the illustrations of foreign Lepidoptera are beyond praise. Whether the system of annually making trips for the purpose of obtaining large series of the local Lepidoptera, illustrative of variation, and including as many varieties as can be obtained, is altogether desirable, we will leave our readers to decide for themselves.

"RECORDS OF THE WESTERN AUSTRALIAN MUSEUM AND ART GALLERY" is the title of a new scientific journal started by the director of the museum at Perth, Western Australia. The first number is mainly devoted to an account of the so-called Mammoth Cave (a decidedly bad name for Australia), on the Margaret River, and its contained mammalian remains. Some of the latter are described by Mr. Glauert, and referred in part to existing and in part to extinct species of marsupials and monotremes.

WE have received copies of the two volumes of the *Actes de la Société Helvétique des Sciences Naturelles* for the ninety-second session, 1909. Among the contents of the first volume is a summary of Dr. Fritz Sarasin's "Geschichte der Tierwelt von Ceylon," the full text of which we have received for review in another and later serial. In another article Dr. M. Bikli gives an illustrated account of the physiography and plant-life of Greenland, a country the name of which the author believes to be derived from the contrast between the barren coastline and the green carpet frequently clothing the slopes of the more inland fjords. A special feature of the country is, indeed, the abundant dwarf vegetation clothing almost all the elevated ground except the mountains, this being illustrated by a photograph taken a short distance inland on Disco Island, while other photographs show how this plant-growth has in the course of years covered boulders and slabs of rocks. A particularly interesting picture shows the rounded shores and islands of a typical glacier-landscape at the mouth of one of the fjords.

DISCUSSING the action of light upon the green parts of plants in *Naturwissenschaftliche Wochenschrift* (April 3), Dr. Th. Löhr directs attention to the investigations of Senn upon the changes in form and position of the chromatophores. According to this observer, the green colouring matter occurs in the shape of drops or grains, the grana, invested by a distinct protoplasmic layer and lying in the general stroma of protoplasm. Under favourable conditions of light the chromatophores are polygonal, but when subjected to strong or weak light they contract to a globular form. Reference is also made to the hypothesis advanced by Stahl that the colour of the chromatophores is regulated so as to avoid absorption of heat rays and undue transpiration. The latter part of the article deals with the conclusions of Wiesner regarding the light requirements of plants, and Haberlandt's explanation of light perceptivity.

THE second "Masters lecture" on the production of horticultural varieties was delivered by Prof. H. de Vries before the Royal Horticultural Society, and occupies the first place in the Journal (vol. xxxv., part iii.). He recognises varieties of two types, those which are constant at their first appearance and others which are continually sporting; the latter can only be fixed by "working up." As an example of his method, he relates his experience in trying to obtain the wholly peloric variety of *Linaria vulgaris*. For eight years he cultivated the ordinary species, treating it in various ways and excluding always the possibility of crossing with allied forms; during this period, inflorescences with occasional peloric (hemi-peloria) flowers were produced, and eventually plants producing all peloric flowers appeared in the cultures. He notes that seed was obtained from some of these wholly peloric flowers. In his book he states that the seed came only partially true, but by further cultivation and selection he reduced the "reverts" to a small percentage.

It has not been the custom to issue an annual report on insect pests in the West Indies, but a summary is pub-

lished in No. 201 of the *Agricultural News* of the more serious occurrences of pests during 1909. In only one district, a comparatively small area in Barbados, was any trouble experienced from the sugar-cane root-borer (*Diaprepes abbreviatus*); the larger moth-borer (*Castnia ticus*) was, however, reported from British Guiana. The cotton-worm (*Aletia argillacea*), which was very abundant during the season 1908-9, has given very little trouble during the present season, nor have any other cotton pests been reported. Scale insects continue to attack limes, but no severe outbreak has occurred during the year; parasitic fungi are known to occur on these insects, and probably aid in keeping them in check. The scarabee, or jacks, of the sweet potato (*Cryptorhynchus batatae*) has proved serious in Barbados, and cannot yet be controlled; new methods of treatment are therefore being devised. Another insect about which further information is required is a small moth, the larva of which lives in the heads of ripening sorghum, and causes much damage.

The sand-dunes of the Libyan Desert have been studied by Mr. H. J. Ll. Beadnell during a residence of three

and proves to be 15 or 16 metres a year. The finest material from the northern sandstones is probably recovered in the district of alluvial loams south of Kharga oasis.

IN connection with Prof. Silvanus P. Thompson's recent experiments on the physiological effects of an alternating magnetic field on the human body, Mr. A. A. C. Swinton, in a letter which appears in the *Electrician* for April 22, directs attention to several simpler methods of producing the same effects which have been known and used by medical men for some years. If the current from an ordinary magneto machine be passed from the hand to a wet sponge held on the temple behind the eye, a faint flicker will be seen, which increases in frequency as the speed of the machine is increased. If the current is sent through the head in other directions a metallic taste is produced in the mouth. By making the arms and body into the secondary of a coil of many turns carrying a high-frequency current, a small incandescent lamp the terminals of which are in contact with the two hands may be made to light up.

A Belt of Dunes in Kharga Oasis, looking south or downstream. From the *Geographical Journal*.

years in Kharga oasis, some 300 miles south of Cairo (*Geographical Journal*, vol. xxxv., April, p. 379). Even where superposed on irregular sands, the dunes show a remarkable linear grouping from north to south. The dunes of Abu Moharik thus start west of Cairo, and thence form a belt 6 or 7 kilometres wide and 650 kilometres in length. The author traces the sand to the rocks of post-Middle-Eocene age that border the Mediterranean, and not to the Nubian Sandstone of the southern region. Between these two regions lies the tableland of Eocene limestone, grains from which may supply more than 7 per cent. of calcium carbonate to the dunes piled up in the oasis of Kharga. The growth and movement of crescentic dunes or barchans have been especially observed. By saturating the concave side of a barchan with water, it became possible to cut a section in it, showing a bedded structure formed by sand carried over from the windward side. Mr. Beadnell urges that this justifies the older view of the formation of the steep convex face, as against that of excavation by scour suggested by Dr. Cornish. Dr. Cornish, however, in the discussion on the paper, attributes the stratification to sliding following upon scour. Steep as the inner face seems to the eye, Mr. Beadnell shows that its slope cannot exceed 33° . The average rate of progression of dunes in the Libyan Desert, from north to south, is now for the first time measured over two years,

and more complex disturbances. magnetic storms are not instantaneous over the whole earth, but in general travel to the east, occasionally to the west, with a speed of about 7000 miles per minute, which may be reduced considerably in the case of some of the larger

FROM a paper by Dr. L. A. Bauer in the March number of *Terrestrial Magnetism and Atmospheric Electricity*, it appears that a more detailed examination of the records of the magnetic storm which accompanied the eruption of Mont Pelée on May 8, 1902, has led him to the conclusion that the storm was not instantaneous over the whole earth, but that it originated about 14° west of Mont Pelée and travelled eastward with a velocity of about 7000 miles per minute round the entire globe. This result raised in Dr. Bauer's mind the further question whether magnetic storms in general are instantaneous over the whole earth, and an examination of the records of the disturbances of January 26, 1903, and of the seventeen cases tabulated by Mr. Ellis in his Royal Society paper, has led him to the further result that mag-

netic storms are not instantaneous over the whole earth, but in general travel to the east, occasionally to the west, with a speed of about 7000 miles per minute, which may be reduced considerably in the case of some of the larger and more complex disturbances.

MR. ARTHUR MORLEY contributes a useful article on the strength of materials under combined stresses in *Engineering* for April 29. Undoubtedly recent experiments on combined stresses have furnished interesting information on the behaviour of materials under static loads, but some hasty applications of this information are very unfortunate. A static determination of the tenacity of a material is easily made, and may serve as a useful index of quality, but it is well known that a simple stress of about one-quarter to one-third of this amount will be sufficient to cause fracture if frequently reversed in direction. What the conditions of failure may be under combined stresses which fluctuate are, in the absence of experimental evidence, at present unknown; but a safe load may as well be proportional to the static tenacity as to the static shear stress at elastic failure, and it is much too soon to speak of the entire revision of formulæ and practice affected by accepted theories, or to hope that controversy concerning the design of crank-shafts is ended. Rather it would be correct to say that only the fringe of the question has been touched.

A PAPER on the effects of sewage and sewage gases on Portland cement concrete was read at the Concrete Institute on April 21 by Mr. Sidney H. Chambers, surveyor to the Hampton Urban District Council, and appears in the *Builder* for April 30. Mr. Chambers has had special opportunities for studying this problem during the past five or six years, and has come to the conclusion that the gases in solution in sewage, and those expelled from it, arising from its decomposition, do act injuriously upon Portland cement concrete, even when the concrete is constituted of sound and good materials. However, little danger from erosion need be feared provided one or other of the following factors be absent:—(a) a high degree of putrescence of the sewage; (b) a moistened surface, which held or absorbed the putrid gases; (c) the presence of a free air supply. In one chamber under the author's observation, as the level of the liquid fell it left the concrete wetted with a liquid containing sulphuretted hydrogen in solution. This wet surface was then exposed to the action of the air supply, which oxidised the sulphuretted hydrogen with the production of sulphur and sulphuric acid, and led to the decomposition of the concrete, the lime being converted finally into sulphate of lime. The exact nature of the intermediate compounds cannot be stated, but it is probable that the active agent is sulphurous acid, as cement is insoluble in sulphuric acid. The decomposed concrete was washed away at the next rising of the liquid, thus exposing a fresh surface to the action. The continuation of this cycle led to the formation of grooves at the varying liquid-level.

MESSRS. SWAN SONNENSCHN AND CO. will publish in the course of the next fortnight a volume to be entitled "The Signs and Symbols of Primordial Man," in which Dr. Albert Churchward explains the evolution of religious doctrines from the eschatology of the ancient Egyptians.

A CLEARANCE catalogue of a miscellaneous collection of books, including works on America, Africa, &c., various domestic animals, and general natural history and literature, has just been issued by Messrs. John Wheldon and Co., Great Queen Street, Kingsway, W.C. The same firm announces the publication of a work, to be issued in twenty-five quarterly parts, on "South American Ornithology: a Manual of the Birds of Continental South America, from the Isthmus of Panama to the Straits of Magellan," edited by Mr. H. Kirke Swann.

MM. GAUTHIER-VILLARS, of Paris, have issued in their "Savants du Jour" series a monograph, by M. Ernest Lebon, dealing with Prof. Gaston Darboux and his work. The book opens with a biography of the distinguished mathematician and a list of the many distinctions conferred upon him. The remaining six sections are concerned with Prof. Darboux's contributions to mathematical science, and contain several appreciations of them by French men of science. It may be noted that Prof. Darboux's writings number 419. The volume, which costs 7 francs, contains an excellent portrait of Prof. Darboux.

We have received from Messrs. Newton and Co. an advance proof of the first portion of their new catalogue concerned with "Apps-Newton Induction Coils, X-Ray, High-frequency, Static, and other Electrical Apparatus for Medical Work." An introductory section, which precedes the price-list, provides the general medical practitioner with the information needed to enable a beginning to be made in the use of electrical methods in his practice. The catalogue serves, incidentally, to show with what powerful aids recent developments in electrical science have provided present-day physicians and surgeons. The contents of the

list, arranged as they are so as to make reference easy, will prove of great interest, not only to medical men, but also to electricians.

MESSRS. KEGAN PAUL, TRENCH, TRÜBNER AND CO., LTD., have published an eighteenth edition of the late Mr. Winwood Reade's "The Martyrdom of Man." Reade, who died in 1875, in his thirty-sixth year, said of this book of his that in commencing it he intended "to prove that Negroland or Inner Africa is not cut off from the main-stream of events as writers of philosophical history have always maintained, but that it is connected, by means of Islam, with the lands of the East, and also that it has, by means of the slave trade, powerfully influenced the moral history of Europe, and the political history of the United States. But I was gradually led from the history of Africa into writing the history of the world."

OUR ASTRONOMICAL COLUMN.

HALLEY'S COMET.—Attempts to observe Halley's comet, with binoculars or naked eye, during the past week have shown that it is by no means an easy object, especially for town-dwellers. By getting out of the town on its eastern side, thereby leaving the inevitable pall of smoky haze behind the observer, the chance of seeing the comet would be enhanced; otherwise the dawn becomes too bright ere the comet rises above the haze bordering the horizon. As shown in the following table, the conditions with regard to sunrise are now slightly more favourable, but the interval between comet-rise and sunrise again begins to decrease after May 6, and, on this account, observations will become increasingly difficult:—

		Comet rises a.m.	Sun rises a.m.
May 6	...	2.20	4.26
" 9	...	2.19	4.21
" 12	...	2.18	4.16
" 15	...	2.37	4.11
" 18	...	3.30	4.7

Despite the unfavourable conditions, several observers have reported seeing the comet with binoculars. Thus Mr. W. B. Tripp writes that he saw it plainly, from Isleworth, with a binocular field-glass, from 3.0 to 3.30 a.m. on May 3; to the naked eye it was a very faint object south of γ Pegasi. In addition to a bright nucleus, there appeared to be an appreciable, though short, tail, of which Mr. Tripp sends a rough sketch. Other naked-eye observations have also been recorded. Sir Robert Ball, telegraphing to the *Times* on May 3, said:—"Halley's comet was observed at Cambridge at 3 this morning. The stellar nucleus was between the second and third magnitude, and the tail was 20 minutes long."

The rapid approach to the earth should make observations easier, the distances, in millions of miles, for the next few days being as follows:—May 6, 56; May 10, 41; May 14, 27; May 18, 16; May 20, 14.3. After May 20 the comet will recede from us at about the same rate as it is now approaching us, attaining a distance of about 42 million miles on May 30.

Some interesting articles dealing with comets in general, and Halley's in particular, appear in No. 1926 of *La Nature* (April 23), which is wholly devoted to the subject. M. Jean Mascart discourses on the historical importance of Halley's comet; M. Rudaux discusses the nature of comets and their orbits, referring to many famous examples; and M. Touchet contributes a description of comet 1910a. All the articles are profusely illustrated with interesting diagrams and photographs.

Another interesting article, in which Dr. H. N. Russell discusses the conditions of the present apparition, is published in the *Scientific American* for April 16. He points out that the present apparition is a favourable one, and discusses the phenomena which may be observed. One of the illustrations is a reproduction of Prof. Frost's objective-prism spectrum of January 14, in which the cyanogen band is an outstanding feature. Dr. Russell makes some

interesting speculations as to the density of the comet, and suggests that golf balls, sown at the rate of two or three per cubic mile, would probably represent fairly well the degree of rarefaction obtaining in the head at the time its cross-section was 12,500 miles.

In No. 4404 of the *Astronomische Nachrichten* Herr J. Holetschek discusses the length of the comet's tail at different apparitions, *apropos* of the question whether the tail, on May 19, will extend far enough to envelop the earth. In 1759, when the earth passed through the plane of the comet's orbit on May 14, the tail exhibited large fluctuations in apparent length; on May 5 it was recorded as nearly 47° long, but on May 14 the recorded length was but 19° . Herr Holetschek gives the following values for the length at various apparitions, the first being a mean value, the second the largest value recorded; the unit is the earth's distance from the sun:—1456, 0.20, 0.39; 1531, 0.14, 0.17; 1607, 0.06, 0.12; 1682, 0.10, 0.22; 1759, 0.08, ??; 1835, 0.08, 0.17; in each case the first value is probably the length of the most brilliant, easily seen, part of the tail. For the tail to reach to the earth on May 20 its length must be 0.15 on this scale. Some amount of discussion has appeared in the daily Press as to the probability of its attaining the requisite length, and, to a representative of the *Daily Mail*, Mr. Crommelin suggested that the chances are about even; but there is no method of determining the probable length at any particular time, for comets' tails are so very uncertain in their behaviour.

THE VELOCITY OF THE SOLAR SYSTEM IN SPACE.—The results of a new determination of the velocity of the solar system in space are published by Prof. Stroobant as an extract from the *Bulletin de l'Académie roy. de Belgique* (No. 1, pp. 39-51, 1910). After discussing previous solutions of the problem, he takes Newcomb's later value for the apex ($A=277.5^\circ=18h. 30m.; D+35^\circ$), and, from the more recent determinations of radial velocities of stars, calculates the displacement of the sun in that direction.

From the discussion of the velocities of forty-nine stars situated near the assumed apex, Prof. Stroobant derives 18.75 km. as the velocity of translation of our system, and from fifteen stars surrounding the anti-apex he derives 21.55 km. per sec. Combining these results, he finds that, in regard to stars visible to the naked eye, the solar system is travelling towards the assumed apex with a velocity of 19.40 km. per second. This value is a little less than that (19.89 ± 1.52 km.) derived by Campbell taking the apex obtained by himself, and is much greater than that (16.7 km.) found by Kapteyn; it represents an annual displacement of 4.10 astronomical units. Prof. Stroobant tabulates the stars discussed by him, giving their positions, magnitudes, spectral types, &c., and shows that stars of different types give different values for the velocity of the solar system; thus twenty stars of the Orion type give a mean value of 22.5 km., and appear to constitute an individual system in the stellar universe.

STAR COLOURS.—In a paper which appears in No. 3, vol. xxxi., of the *Astrophysical Journal* (April, p. 234), Prof. Louis Bell discusses the reputed colours of the comets in double stars in relation to the known facts concerning the colours of stars and their spectra.

It is a fact, established by many investigations, that among the reported colours of double stars there are bizarre tints which are not met with among isolated stars. That this is not due to any physical connection between the comets is shown by the fact that it appears as strongly in the case of optical doubles as in the case of binary systems. The suggestion that these tints are merely subjective effects of contrast is generally countered by the statement that they are not always complementary, but Prof. Bell shows that this statement is not conclusive.

From a discussion of the spectra of a number of doubles, and from a number of experiments on artificial stars, he shows, fairly conclusively, that the reported tints are produced physiologically, and have no determined objective existence. As an example of the evidence deduced from the study of spectral type, he mentions 59 Serpentis, where the primary type i. is yellow and the secondary type ii. is blue; a type ii. star of a bright blue colour is unknown among isolated stars, and logically improbable. His experiments show that with artificial stars of unequal magnitudes, such as are found among double stars,

"dazzle tints" and "fatigue" effects probably account for the curious associations of colours met with in the records of the colours of multiple stars and star-clusters.

THE FORMATION OF SATURN'S RING SYSTEM.—In No. 4403 of the *Astronomische Nachrichten* Prof. Lowell discusses the causes which have produced the present conformation of Saturn's system of rings. He points out that commensurability of period between perturbing and perturbed masses is a greater factor in determining their loci than is the more direct effect of attraction, and shows that in the case of Saturn's system the rings have their present conformations in accordance with this principle. Thus Prof. Lowell shows that, despite its smaller mass, Mimas has been the chief fashioner of the rings, aided by Enceladus and Tethys, in this order. Not only do the older divisions of the rings show this commensurability of period with the satellites, but newly discovered divisions occur at such distances as would give commensurability the greatest effect.

THE WATER PROBLEM.

THE discussion on the constitution of water which took place under the auspices of the Faraday Society on April 26 was remarkable for the presence of two distinguished foreign visitors, Prof. Walden, of Riga, and Prof. Guye, of Geneva, the former having travelled specially from Riga in order to be present, whilst the latter was able to arrange a necessary visit to London in such a way as to enable him to present his paper in person. Contributions to the discussion were also received from Mr. Sutherland, of Melbourne, and from Prof. Nernst.

Prof. Walker, of Edinburgh, occupied the chair, and in opening the discussion remarked on the extreme complexity of the problem of ascertaining the real nature of this commonest of all solvents, and on the great progress that had been made in recent years in the accumulation of quantitative data for its solution.

Prof. Walden's paper, "Is Water an Electrolyte?" included a number of observations that had been made in order to determine whether water, when dissolved in a medium possessing powerful ionising properties, might not itself become an electrolyte. To secure an adequate answer to this question, it was considered necessary to make use (amongst others) of media of which the specific inductive capacity was greater than that of water. The liquids selected were hydrogen cyanide, HCN; formamide, H.CO.NH₂; nitrosodimethylamine, (CH₃)₂N.NO; formic acid, H.CO.OH; and sulphuric acid, the first two solvents being characterised by a specific inductive capacity greater than 84, the value for water. In passing, it may be noted that Prof. Walden's discovery of the use of formamide as a solvent represents a "find" of extraordinary importance which, even if it stood alone, would form an adequate recompense for the labour involved in his masterly survey of the wide field of organic liquids; this solvent appears to reproduce nearly all the valuable qualities of water, including its convenient freezing point and boiling point and its powerful ionising properties, but will mix freely with important groups of compounds which do not dissolve to any marked extent in water.

Hydrogen cyanide, which with its high specific inductive capacity and great fluidity provides ideal conditions for electrolysis, was found when used as a solvent for water to give molecular conductivities of the order of 0.009 as contrasted with 300 for a salt such as potassium iodide; the low molecular conductivity of the water dissolved in hydrogen cyanide finds a parallel, however, in the low conductivity of hydrogen cyanide dissolved in water. Formamide, with a similar specific inductive capacity, but much smaller fluidity, gave for the molecular conductivity of water values (about 0.016) slightly higher than in the case of hydrogen cyanide. In the case of formic and sulphuric acids the specific inductive capacity is lower than that of water, sulphuric acid being further handicapped by its extraordinary viscosity, but both solvents gave increased values for the molecular conductivity of water, namely, about 0.17 in formic acid, but rising in the case of sulphuric acid as high as 74. From these observations it is clear that the conductivity attributed to the water does not

depend on the physical qualities of the solvent, but on some chemical relationship between solvent and solute. It was suggested by the author that water, acting as an amphoteric electrolyte, could form a salt when mixed either with a strong acid or with a strong base, and that the high conductivity of mixtures of sulphuric acid and water, and the slight conductivity of mixtures of formic acid and water, were due neither to free acid nor to free water, but to the presence of an oxonium sulphate or formate in the liquid. The absence of conducting power in mixtures of water with hydrogen cyanide or formamide was attributed to the weakness of their acidic and basic qualities and the impossibility of combining them with water to form a salt-like electrolyte.

Prof. Guye, in a paper "On the nature of molecular associations in the special case of water," referred to a new formula by which the coefficient of association of a liquid might be deduced from its molecular surface energy, and showed that in the case of water at the boiling point it gave the factor 1.96—a value considerably lower than that (2.66) deduced by Ramsay and Shields, but agreeing closely with a value (1.98) deduced by Walden by another method. He also described the results of a calculation whereby the degree of association of liquid water could be calculated from the degree of association of steam on the assumption that the law of mass-action held good in both cases; and that the value of the constant remained the same throughout. Taking the figure 1.089 given by Bose for the association-factor of steam, the value 1.99 deduced for water was shown to agree satisfactorily with those derived by the other methods referred to above.

The values given by Prof. Guye for the coefficient of association of water at 100° were, in the subsequent discussion, referred to by Mr. Bousfield, who pointed out that (if correct) they would render untenable Sutherland's theory that liquid water is a binary mixture of trihydrol and dihydrol, since even at 100° it would be necessary to assume the presence of considerable amounts of monohydrol in order to reduce the (average) association-factor below 2.

The paper by Mr. W. R. Bousfield and Dr. T. M. Lowry, on "Liquid Water a Ternary Mixture. Solution-volumes in Aqueous Solutions," was an extension to other solutes of some curious observations made five years previously in the case of aqueous solutions of caustic soda. The solution-volumes of the soda were found to vary largely with the concentration and with the temperature, the most remarkable feature of the variations being the occurrence of a maximum of solution-volume at about 60° C. in liquids of all concentrations. The gradual conversion of the ordinary, slightly concave, expansion curve into a strongly convex curve had now been traced through a series of solutes—chloral hydrate, sugar, acetic acid, silver nitrate, potassium, sodium, calcium and lithium chlorides. The curves for caustic soda were shown to be intermediate between those for sodium and calcium chlorides, and to form one member of a series of progressively changing types. The drooping of the ends of the curves was shown to depend on the occurrence during the preparation of the solutions of a contraction resulting from the formation of hydrates. Such a contraction indicates that water is increased in density by combining with a solute; in order to give definiteness to this conception, the suggestion was made that the density of combined water is similar to that of its denser constituent (dihydrol) in the free state, and that the contraction on dissolution is due mainly to the conversion into hydrate of lighter constituents present in the liquid. As this contraction in the case of lithium chloride solutions increases both above and below 40°, it follows that a lighter form of water is produced, not only by cooling, but also by heating it. The presence of three constituents in the liquid (ice, water and steam, or trihydrol, dihydrol and monohydrol) is indeed absolutely necessary in order to account for the complex changes of volume that have been observed in water and in the solutions prepared from it.

Mr. Sutherland's paper "On the constitution of water" had been circulated before the meeting, and owing to lack of time was taken as read. His suggestion that the hexagonal symmetry of ice crystals may be taken as evidence in favour of the "trihydrol" formula will now receive more serious consideration than would have been the case a few years ago; although his method of deducing the relative sizes

of the atoms differs from that made use of by Barlow and Pope, and his method of "packing" is not the "closest" possible, there is no doubt that the general scheme of the arrangement is sound, and that the argument from crystal structure to chemical constitution may now be accepted as both legitimate and useful. Unlike the previous authors, Mr. Sutherland considers that monohydrol does not exist in liquid water, but is present in all salts containing water of crystallisation. He attributes to it a density (1.31 in the solid and 1.26 in the liquid state) considerably greater than that of dihydrol (1.13 and 1.09) or of trihydrol (0.92 and 0.88), and in an appendix gives values for a number of its other physical properties.

Prof. Nernst's paper on the specific heat of ice, water and steam was read by Dr. Wilsmore. The survey covered the whole field from -200° to the highest temperatures, but attention was directed specially to minima in the specific heat of water vapour under moderate pressures and of liquid water at moderate temperatures; both minima were attributed to the dissociation of complex molecules. The question of specific heats was also dealt with in a note on the specific heat of water of crystallisation by Mr. F. P. Sexton, of Truro, which was read by Dr. J. A. Harker. In the case of copper sulphate the first four molecules of combined water were found to have a specific heat 0.499, whilst the fifth molecule gave the value 0.508. Mr. Bousfield pointed out that the value 0.5 also held good for the combined water in solutions of potassium chloride, the heat capacities of which could be calculated correctly by assuming them to be mixtures of free water, hydrate-water, and salt. Dr. Senter pointed out that the values now given agreed well with the view, in support of which much evidence was available, that in compounds such as copper sulphate four molecules of water were definitely associated with the metallic atom, the remainder being perhaps attached to the molecule as a whole.

Early in the evening Mr. H. B. Baker showed a remarkable experiment on the influence of purification in retarding the action of water on sodium amalgam, the underlying idea being that if water could by purification be rendered non-conducting it might also be rendered chemically inactive. Similar experiments on the inactivity of highly purified nitric acid were described by Mr. Veley.

A complimentary dinner, the first in the history of the Faraday Society, was given in honour of its foreign guests, Profs. Walden and Guye, on Wednesday, April 27, under the chairmanship of the president, Mr. James Swinburne, F.R.S. The English guests included Sir William Ramsay, Sir William Tilden, Sir Joseph Larmor, Prof. H. B. Dixon, Prof. Divers, and Dr. Chree. In responding to the toast of the guests of the evening, Prof. Walden referred to the scientific relationship between Russia and Great Britain, remarking, incidentally, that the first Russian chemist was an Englishman, sent by Queen Elizabeth to Russia in the sixteenth century. Prof. Guye dwelt on the debt which chemists all over the world owed to Faraday, and gave an interesting account of Faraday's visit to Geneva when he accompanied Sir Humphry Davy on his tour through Europe.

T. M. L.

RECENT ADDITIONS TO IDEAS REGARDING THE INTERNAL STRUCTURE OF THE EARTH.¹

BEYOND the superficial observations made by geologists, not extending more than about one two-hundredth of the radius below the surface, even by indirect means, we are dependent on mathematicians for our ideas regarding the physical state of the earth's interior; these ideas are based on extrapolation from physical constants obtained in the laboratory, and their variety extends to the number of possible permutations and combinations of the three physical states of matter—solid, liquid, and gaseous. Halley's conception of a core and shell rotating at different speeds has been revived by Sir F. J. Evans (1878) and by the distinguished founder of this series of lectures to explain the secular variations of magnetism. The Laplacian hypothesis, based on Clairault's theorem, is now

¹ Abstract of the Wilde lecture delivered to the Manchester Literary and Philosophical Society on March 22, by Sir Thomas H. Holland, K.C.I.E., F.R.S.

being superseded in many minds by Chamberlin's planetesimal theory, after having inspired petrologists with a vain hope of finding traces of the primeval slaggy crust among the Archæan gneisses. Astronomers prefer a solid globe, but on grounds different from those assumed by Hopkins and at first accepted by Lord Kelvin. Arrhenius concludes in favour of a gaseous core, like that postulated by Ritter, but of larger dimensions than the gaseous core suggested by Dr. Wiede.

Theories regarding the processes of consolidation, the gradient of pressure, and the deep-seated rise in temperature are equally varied. Until this year all agreed in assuming the earth's interior to be hot, but Prof. Schwarz now prefers to think it is cold. So long as radio-active bodies were unknown the apparent reserves of heat-energy offered the world a short life; but its actuarial value has now been increased almost indefinitely by the discovery of radium in embarrassingly large quantities, and Prof. Joly warns us that, instead of peaceful cooling, the present "age" may end in catastrophic heating.

The nearest approach to actual observation regarding the deep-seated parts of the globe is recorded by the seismograph as interpreted by R. D. Oldham, who aptly compares the seismograph with the spectroscope as an instrument for examining inaccessible objects. The first and second phases of long-distance seismographic records, which are due to waves passing through the earth by approximately chordal paths, show a reduction in velocity when there is a sufficient distance between the origin of the shock and the recording instrument for the assumed chordal paths to pass through the inner two-fifths of the earth's core, while the distortional waves are apparently dispersed by refraction when the origin of the earthquake and the recording instrument are separated by about 140° . The records, which are confessedly too few to be regarded as conclusive, suggest that the central core differs in physical characters from the outer three-fifths and the superficial crust. Similarly, the vibrations that pass under the great oceanic depressions indicate elastic conditions differing from those under the continental plateaux, the difference being apparent to a depth of about one-quarter the earth's radius. This last conclusion might be correlated with the variation in the chemical composition in the sub-oceanic crust caused by selective denudation of the kind indicated by Sir John Murray in 1899, and by Chamberlin's theory regarding the origin of the oceanic depressions.

The recent discussions and new data obtained by geodesists and geologists to check Dutton's theory of isostasy have revived interest in the deep-seated parts of the superficial crust. The remarkable work recently done in India by Burrard and Lenox-Conyngham, when correlated with the results of the Geological Survey, are especially important in showing the truth and the limitations of isostasy. Burrard's results indicate that the Himalayan heights are partly compensated by deficiencies of subterranean gravity, and that greater loads are maintained by the rigidity of the geologically stable crust of the peninsula than in the folded parts of the extra-peninsular region. The deficiency of gravity under the outer and sub-Himalaya is, however, equally pronounced in the plains near the southern foot of the range; but at a distance of about 150 miles from the foot of the mountains there is a subterranean band of high gravity parallel to the alluvium-filled Gangetic valley, as well as to the four Himalayan zones—the foot-hills, composed of Tertiary strata; the outer Himalaya, of much older, unfossiliferous sediments; the crystalline range of snow-covered peaks; and the Tibetan highlands of fossiliferous, marine strata.

Soon after Dutton published his theory of isostasy, R. S. Woodward pointed out that, if the highlands continued to rise in consequence of the reduction in their load by erosion, and the depressions continued to sink under the growing weight of accumulating sediment, the process should continue indefinitely, and mountain ranges would thus never be worn down, while new folds in undisturbed areas would never arise; but the geological history of India shows why and how this process may result in "isostatic suicide." For ages before the end of the Mesozoic era the rivers of Gondwanaland, which stretched away as a great continent to the south and west, poured

their loads of silt into the Eurasian ocean, of which the southern shore-line approached the line now occupied by the Himalayan snow-covered peaks. With the loading down of the northern littoral of Gondwanaland, the northern part of the continent became stretched, and normal faults were developed with a general east to west trend.

Some of the faults of this kind occurring in the Central Provinces were shown by J. G. Medlicott, so long ago as 1860, to be pre-Gondwana (that is, pre-Carboniferous) in age, others were formed before the Upper Gondwana (Lower Mesozoic) strata were formed, while the latest affected the younger Gondwana beds, and became channels for the Upper Cretaceous basalts. The general trend of the Cretaceous dykes in this part of India, and the prevalence of normal faults further east at about the same latitude, shown in various geological maps published by later members of the Geological Survey, indicate the nature and direction of the tension produced by the unloading of Gondwanaland and the simultaneous depression of the adjoining ocean bed. The process reached its climax towards the end of Cretaceous times, when the basaltic magma below welled out and flooded more than 200,000 square miles to a depth of nearly a mile.

Presumably the tension marked by faults in Central India existed also in areas further north, where the records are now buried under the Gangetic alluvium, and the band of high gravity detected by Burrard's plumb-line and pendulum is probably due to concealed batholiths of basic and ultra-basic magma, which were injected into the region of tension after the manner described by Prof. R. A. Daly.¹ Then followed the production of a geosyncline parallel to the northern shore-line of the old Gondwana continent and parallel to the subsequent folds of the Himalayan range, which are now being thrust over towards the region of deficient gravity between the visible mountain range and the concealed band of basic batholiths.

The data in this area are in substantial agreement with Daly's idea of a persistent sub-crustal gabbroid magma, which, though possibly only in a state of potential fusion under regions of normal pressure-gradient, may become fluid in localities of protracted erosion and gradual rise of the northern shore-line of the old Gondwana continent and agree, in general, with those analysed by Hayford and others in America in showing that isostasy can be detected only when the visible masses over wide areas are concerned; further data of this kind will permit of the determination of the minimum loads that can be maintained by the crust in old stable land surfaces as compared with the apparently smaller loads maintained in recently folded regions. If the sequence of events in India has been correctly traced, it should be possible to indicate areas on the earth which are in danger of basaltic floodings and of later folding movements. In South America, for instance, the north-flowing tributaries of the Amazon and the Araguaya are possibly developing conditions on the old land surface of Brazil similar to those that on Gondwanaland preceded the outburst of the Deccan Trap in Cretaceous times.

THE HULA, OR FOLK-DRAMA OF HAWAII.

THE Hula, or national folk-drama of Hawaii, has already been casually described by the Rev. W. Ellis in his "Polynesian Researches," and has been noticed in the "Travels" of Captain Cook; but it was left to Dr. N. B. Emerson to undertake a detailed investigation of the unwritten literature of the island, and to make a collection of the songs sung in these performances. The results of this study have been published in Bulletin No. 38 of the American Bureau of Ethnology. We may congratulate this institution on having now, for the first time, under the authority of a special Act of Congress, extended its operations beyond the bounds of the American continent.

The Hula is a special form of folk-drama, dealing in a series of impassioned lyrics with many phases of the national mythology and traditions. The poetry is of a highly romantic and sensuous type, including themes connected with human love and life, and the processes of nature,

¹ "Abysmal Injection as a Causal Condition and as an Effect of Mountain-building," by R. A. Daly (*Amer. Journ. Sci.*, xxi., 1906, pp. 207-13).

the mysteries of the spirit world, described by a series of metaphors and personifications. Much of it is of very ancient date, and is hardly intelligible even to the best native scholars at the present day. In studying the translations and analysis of Dr. Emerson, we cannot avoid the suspicion that much is vague and uncertain, and that the interpretations may sometimes ascribe to these apparently meaningless songs a significance which reflects modern romantic conceptions alien to the spirit of the early singers. Throughout the whole drama the themes are essentially religious. The chief deity invoked is Laka, the impersonation of the powers of vegetation, who is addressed in special hymns and worshipped at an altar adorned with leaves and flowers of those plants which are believed to be specially acceptable to the goddess, because they are the forms in which she prefers to manifest herself. With her are invoked the spirits of the wood, which resemble the fairies of Europe, Pele, the goddess of the volcano, and her sister, Kapo, who, like the Mother goddesses in other parts of the world, assumes a dual form—benevolent as a sylvan deity, chthonic or lewd, the latter phase being only occasional.

As Mr. A. Lang has pointed out, the mysteries of Greece

Woman playing on the Nose-flute (Ohe-hano-ihu).

can best be interpreted on the analogy of rites among savage or semi-savage races. The Hula accordingly presents notable resemblances to the Greek Eleusinia and similar celebrations. The performers are carefully selected; they must observe stringent purity tabus, sexual license being prohibited; they are kept in a special enclosure, which they must never leave except with muffled heads, and they must engage in no conversation beyond its limits; above all things, they must avoid contact with a corpse. As the Greek hierophant proclaimed, "Ye mystae, to the sea!" in Hawaii the performers rush into the ocean, going and returning in a state of nudity; there is a pass-word of admission, a prayer at the beginning and end of each performance, and a special supplication for the removal of tabu; a ritual dress, modelled on the primitive fig-leaf. Finally, the central act of the rite is a form of sacrament. A cooked pig is brought into the assembly, and the hierophant, acting as carver, "selects the typical parts—snout, ear-tips, tail, feet, portions of the vital organs, especially the brain (*lolo*). This last it is which gives its name to the ceremony. He sets an equal portion before each novice. Each one must eat all that is laid before him. It is a

mystical rite, a sacrament; as he eats he consciously partakes of the virtue of the goddess that is transmitted to himself."

The Hula assumes various forms. A special type is assigned to each instrument—the drum, the gourd rattle, the bamboo rattle, a kind of xylophone, pebble castanets, a hollow bamboo beaten on the ground, a jew's harp, and that remarkable instrument the nose-flute. Others include the use of marionettes, or mimetic delineations of animals, as the shark and dog dances.

On the whole, this elaborate study of a primitive folk drama is interesting from many points of view—as a description of savage music recorded in the recognised notation; as throwing fresh light on the problem of the mysteries; as a new conception of folk-poetry, with its sensuous, enigmatic lyrics. Lastly, it throws novel light on the interpretation of the popular mythology and traditions. If we cannot always accept Dr. Emerson's interpretations of the materials which he has collected, we can admire the industry and insight which appear throughout this volume.

PIGMENTATION AND CANCER.

DOES the absence of skin pigment predispose white men to cancer? This question has been answered in the affirmative in a paper¹ which has attracted some attention. The author, Dr. Watkins-Pitchford, adduces instances of the inverse ratio obtaining between the degree of pigmentation of the skin and of the body cavity, and explains that the external and internal pigmentations protect the tissues from excessive "irradiation" by actinic rays, of which the influence is assumed to be highly inimical to the life of the individual. More weight would have attached to his observations, in whatever bearing they have upon cancer, had the thickness of the body wall been considered in relation to the degree of internal pigmentation and the slight penetrating powers of many of the rays loosely called actinic.

"White man is of all animals the most liable to cancer" forms the postulate from which the author elaborates his views. This is an old dogma which is by no means universally accepted as true, and for certain individual organs is now proven to be false. For example, cancer of the mamma is probably as frequent in Indian hospitals as it is in London, and it is as common in the mouse as it is in the human female. It certainly occurs in the native African negress more frequently than was formerly supposed. However, the author brings this first postulate into line with his second, "the absence of effective pigmentation, or other form of external protection, in white man is the primary cause of his liability to cancer"; the same holds for domesticated animals. The liability to cancer should therefore be found increasing in proportion as pigmentation is decreasing, and the true albino of any species man included, should display the greatest liability of all. A table is given to illustrate the scale of liability of black, brown, red, yellow, and white races of man by estimations of "probable" cancer death-rates for Zulus, Tamils, Red Indians, Chinese, Italians, English, Dutch, and Swedes. The figures can be definitely stated to be worthless for purposes of comparison. Those for the Chinese in the United States are meant to show the intermediate incidence of cancer in the yellow race; but why not have chosen the Japanese, who have relatively excellent national statistics showing more than 25,000 deaths annually, and who admit that this number is far short of the total, which would represent a death-rate probably not less than in England? The Italian figures presumably represent "brown" man, but the Italian national statistics are among the worst in Europe, and cannot be compared with English statistics. The table merely gives a list of increasingly worthless figures and correspondingly untrustworthy records of the occurrence of cancer. The argument would, however, break down for another reason—by its failure to explain the frequency of cancer in the negroes of America as contrasted with its real or apparent infrequency in Africa.

¹ "Light, Pigmentation and New-growth, being an Essay on the Genesis of Cancer." By Dr. Wilfred Watkins-Pitchford. Pp. 130. Read at the South African Medical Congress, Durban, August 2, 1909.

The general application of an inverse relation between degree of pigmentation and liability to cancer cannot be maintained, and it fails equally when applied to explain the varying incidence of the disease in different anatomical sites of the body. For carcinoma of the breast, the argument is much as follows. The woman of the white variety of mankind stands erect with her mammae projecting, and fully exposed to direct solar irradiation; she has no pigment or hair to aid her delicate, translucent skin in protecting the glandular epithelium lying immediately beneath the surface. She covers her bosom with a single garment—the flimsiest of white silk blouses. The man, in addition to wearing shirt and underclothing, protects his chest from irradiation by coat and waistcoat of dense cloth and of dark colour. Hence there are 100 cases of cancer of the breast in the woman to one in the man. The differences between the male and female, and between the mammary glands in the two sexes, are not of the subordinate importance assigned to them in determining the onset of cancer. They are of primordial importance, since the difference between the male and female obtains for all species liable to carcinoma mammae.

The frequency of this form of cancer in the woman requires to be considered, almost certainly, from totally different points of view. Not only do the sites of predilection vary from one class of vertebrate to another, but, if the Mammalia themselves be considered, some species are very liable to cancer of certain organs from which others, even nearly allied, are relatively or altogether exempt, as illustrated, e.g., by the variations in the frequency with which the mamma is attacked. The liability of the woman is merely a peculiarity shared, e.g., with the female of the mouse and dog, whereas in other domesticated mammals, e.g. in the cow, cancer of the mamma is practically unknown. Equal degrees of "irradiation" will not harmonise the parallel liability of the woman and the female wild mouse to cancer of the mamma, nor will differences in "irradiation" explain the exemption of the cow and the proneness of the tame albino and the wild grey mouse to this form of the disease.

These specific differences in liability depend in part, at any rate, on something more than external conditions. Under very divergent conditions, as regards habits (exposure to daylight), environment, and food, the incidence of cancer may be parallel, as in the case of the tame and wild mouse. Therefore innate fundamental tendencies of much biological import cannot be dismissed by assuming that cancer occurs in the mamma of dogs because the abdomen is "irradiated" through sitting up when "bagging," or in consequence of a too great fondness for lying before an open fire. Nor can the biological significance of the sites of predilection for cancer of the rectum and uterus in mankind be explained by their corresponding with the sites on which a full bladder focusses actinic rays! The assumption that organs which are dark red or brown in colour are less liable to cancer than organs of a lighter colour will not explain why primary carcinoma of the liver is more frequently recorded in cattle than in other domesticated mammals.

A real and grave increase in cancer is asserted to have occurred during the past fifty years, and the attempts to allay tendencies to public panic by soothing assurances to the contrary are stated to be a praiseworthy policy, but intentionally misleading. This is rather a grave charge to bring, without substantiation, against investigators who have as much claim to be taken seriously as has Dr. Watkins-Pitchford in his explanation of the increase he alleges, viz. that there has been a decline in the use of woollen garments during the past fifty years, a change in the colour of the clothing worn, and that black broadcloth and black silk have ceased to be the clothing of respectable society, except the clergy, who enjoy a "privilege of cloth," and with it a low cancer death-rate.

In short, the prevention of cancer is represented as a matter of effective protection against solar irradiation, to which white man, having lost his pigmented skin, exposes himself both blindly and nakedly; but, we pause to ask, How is it, then, that the black-coated mouse is as liable to cancer as is the albino? We wonder if the difference in the recorded frequency of cancer in black and white man is the result of imperfect opportunities for observing

the disease in the former, and of the attainment of the cancer-age by a smaller relative number of individuals. We remember that the black man and woman are by no means exempt from cancer, and we regret that the drudgery of putting their opinions to a sufficient test is not undertaken personally by a large army of arm-chair speculators who essay to write on the nature, cause, prevention, and cure of cancer. This punishment should certainly be theirs.

E. F. B.

CHEST DEVELOPMENT IN BOYS IN NEW SOUTH WALES.

THE New South Wales branch of the British Science Guild has just circulated a report in which it states that a special sub-committee investigated a number of points in connection with the physical development of boys in New South Wales, and compared the results with those of other countries. It was found (1) that the average girth of English boys round the chest is roughly 3·6 inches more than that of boys in New South Wales at seventeen years of age; (2) Tasmanian boys have always measured rather more than New South Wales boys round the chest, and at the late age of sixteen or seventeen years they come approximately to the English average; (3) the chest growth of the New South Wales boy is at all ages much less than that of the Washington boy, viz. at nine years nearly 1 inch, at ten years more than 1 inch, between thirteen and fifteen years 1½ inches or more; (4) as a result of this the lung capacity of New South Wales boys averages at all ages much less than that of the American boys, and the deficiency varies from 500 c.c. at nine years of age to 625 c.c. or more at seventeen years.

The committee found it difficult to give a complete estimate of the causes of this devitalising condition, the factors at its disposal being too indeterminate, but the suggestion is offered that the habit of the young Australian of leaning against lamp-posts and door-posts, or the difficulty with which he can be got to walk for an outing so long as there is a conveyance to be had, or his inveterate custom of supporting the games of cricket and football by leaning across a fence or resting his form upon a shaded bench while he bets upon the odds or barracks more or less enthusiastically, have to be considered in this connection.

The executive council of the Guild at Sydney passed the following recommendations:—(1) that the attention of the Government and municipal councils be drawn to the supreme importance of providing areas specially set apart and adapted for the purpose of healthy games, it being understood that such areas should be left bare of trees and flowers, save on borders, and should be provided with running tracks and facilities for cricket, football, lacrosse, basket-ball, and similar games; (2) that as the principle of taxing the unimproved value of land is a direct discouragement to schools to provide such areas, representation should accordingly be made to the Government and to municipal councils to allow some substantial concessions to all *bona fide* schools providing adequate playgrounds, such playgrounds being, like parks, really a guarantee of the people's health.

THE ADMINISTRATION OF ANÆSTHETICS.

THE report recently presented to Parliament concerning deaths resulting from the administration of anæsthetics (Cd. 5111, price 1d.) touches upon a matter of grave public interest, in which expert medical opinion and questions of pure science and the common sense of the intelligent "man in the street" alike contribute. We may say at once that the report appears to us to be of high value; it recognises a danger that for many years past has weighed very seriously upon the minds of those who know the danger, namely, of sudden death during the administration of chloroform, and it ends by recommending towards the remedy of this danger that a small standing committee or commission should be appointed to deal with the subject under the control of the Home Office.

The body of the report, although offering, no doubt, points open to criticism by individual authorities, is, on the

whole, unexceptionable as an expression of the resultant opinion, received from many different sources. It is recognised at the outset that a "certain number" of deaths are due to preventable causes, and that a "certain number" of deaths are inevitable, which obviously signifies that the actual numbers of preventable and inevitable deaths are quite undetermined. One of the first services to be expected from a standing committee of experts would be information as to the relative proportions between these two classes of deaths. Idiosyncrasy as a factor cannot be eliminated. Anæsthetics, like all other poisonous drugs, act differently on different constitutions. Alcohol in known quantity does not necessarily produce identical effects upon different persons, but, as regards chloroform, ether, and other poisons, before we are entitled to appeal to idiosyncrasy we require to know what quantity of any one of these poisons may have been actually administered. Such information might usefully be acquired at small cost by a standing committee of the Home Office, and made available to the medical profession and to the intelligent laity in a convenient form.

The use of anæsthetics "of longer duration," inclusive, presumably, of chloroform, for the purposes of minor surgery, including dentistry, is considered in paragraphs 9 and 10 of the report. Although evidence was offered on behalf of the Incorporated Society of Extractors and Adaptors of Teeth to the effect that there had been 1,249,167 administrations of general anæsthetics by members of the society with only one fatal accident, the committee is of opinion that the administration of those anæsthetics the effect of which is of prolonged duration should be confined to qualified medical men.

The report is almost precisely on lines recommended by the General Medical Council in that it urges the need of legislation; that it recognises the necessity of limiting the administration of general anæsthetics to qualified medical and dental practitioners, and of prohibiting single-handed anæsthetising and operating.

There is no doubt that this report may prove to be the initial point leading to the acquisition of much useful knowledge and to greatly increased safety in the increasing number of cases where, thanks to Lord Lister and to the system of aseptic surgery, operations are possible, and anæsthetics therefore required. In the words of the report, there is need yet for much careful clinical observation, controlled, if necessary, by physiological experiments.

METRIC MEASURES.

THE Decimal Association has recently issued a circular on the progress of the metric system of weights and measures in this country, and also two papers written by Mr. Aldred F. Barker, director of textile industries at the Bradford Technical College, advocating the adoption of the metric system in the textile trade. It appears from the circular that the total number of metric weights and measures verified in the United Kingdom during the year ended March 31, 1909, was 8797. As this was the first year in which the obligation upon local authorities to distinguish between metric and imperial weights and measures in their returns to the Board of Trade was enforced, comparisons of this total with the totals for previous years, as furnished in the returns, would necessarily be misleading; but it is evident that the metric system is making steady headway here. Of the weights and measures verified and stamped in this country during the year in question, 1 in 1280 belonged to that system. Opponents of the metric system have an axiom to the effect that, whatever its merits, its compulsory introduction would be absolutely disastrous to the great textile industry. Mr. Barker's papers form a highly technical refutation of this axiom. He shows that the metric system could be adopted by the industry with a minimum of inconvenience, and that it would afford a more methodical and practical basis for those mysterious lists and tables which are to the textile trade what the Nautical Almanac is to the astronomer.

Mr. L. J. Spencer, of the Mineral Department, British Museum, has contributed to the March number of the *Mineralogical Magazine* an interesting paper on the weight

of the "Cullinan" diamond, and on the value of the carat weight. He directs attention to the discordant values given by various authorities for the weight of the "Cullinan" diamond expressed in carats, and points out that the adoption of an international standard carat would be the best means of preventing such discrepancies in estimations of the weights of precious stones. The "metric carat" of 200 milligrams, the adoption of which was advocated by the International Conference on Weights and Measures in 1907 as a universal standard, has met with considerable support abroad, but diamond dealers in this country are not at present disposed to abandon their time-honoured but diverse-valued carat of about $3\frac{1}{2}$ troy or avoirdupois grains, the various equivalents adopted for which by different firms do not appear to cause much inconvenience to the trade. In these circumstances, only the exclusive adoption of the metric carat by all the more important foreign States would render official action possible towards its legal recognition or compulsory adoption in the United Kingdom.

FUNGAL STUDIES.

MR. C. L. MOORE has followed up his studies of the Myxomycetes of Pictou County in Nova Scotia, by a short account of some Nova Scotian aquatic fungi referred to the species *Saprolegnia*, *Achyla*, *Aphanomyces*, *Leptomitrus*, and *Sapromyces*. The paper, which is published in the *Transactions of the Nova Scotian Institute of Science* (vol. xii., part iii.), contains figures and descriptions of the antheridia and oogonia for most of the species.

An important contribution to the literature on the Mycetozoa is provided by the list of species from Ceylon compiled by Mr. T. Petch, which is published in the *Annals of the Royal Botanic Gardens, Peradeniya* (vol. iv., part vi.). The list enumerates 102 species, the majority of which are also found in Europe; *Alwisia bombarda* and *Erionema aureum* are two tropical species recorded from the wet country. The commonest species are *Didymium effusum*, *Physarella mirabilis*, and *Hemitrichia clavata*. *Physarella* may be said to invade the laboratory, where it develops on logs kept for growing other fungi. Mr. Petch notes that there is a greater tendency for the plasmodium to wander than in Europe, which he ascribes to the greater rainfall and humidity. *Stemonitis herbatica*, *Physarella*, and *Didymium effusum* have been gathered from the crowns of palm trees, 20 feet from the ground; *Perichaena chrysosperma* frequently ascends to a height of 50 feet on Bombax trees.

Mr. Petch has also prepared a second part of his revisions of Ceylon fungi, which appears in the same number of the *Annals*. As a result of the examination of fresh specimens, a number of specific names have been reduced to synonyms. It is noted that certain characters generally regarded as specific may sometimes be mere variations due to weather. Thus the white gills of *Lepiota Zeylanica* in showery weather pass through a yellow stage before changing to red, whereas in fine weather the yellow stage is not evident. Again, the stipe of *Lepiota pyrhaea*, which ordinarily bears an annulus and scales, appears smooth and ringless when grown in a saturated atmosphere. With reference to the genus *Auricularia*, the author offers several reasons for recognising two species *Hirneola polytricha* and *Auricularia tremellosa*, both distinct from the common European species *Auricularia auricula judae*.

The October (1909) number (vol. cxviii., part viii.) of the *Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften*, Vienna, is entirely devoted to botany. Prof. von Höhnelt contributes a further set of notes on Javanese fungi. He creates a new genus, *Treubiomyces*, for a fungus (Nectriaceæ) collected on leaves of *Ficus elastica* which bears rough patches of clustered hyphæ surmounted by long hairs. Another fungus, *Limaculina samoensis* taken on the same host, is characterised by a perithecium raised on an under layer of hyphæ, the *subiculum*, which bears short round cells and stellate spores. In the same number Dr. P. Fröschel communicates a short paper on the latent period in heliotropic experiments, in which he

confirms the results of Blaauw that the light of a mercury vapour lamp or direct sunlight acting for a period of 1/2000th second is sufficient to produce a stimulus. Mr. F. Kölbl, describing his experiments on the heliotropic sensibility of woody plants, notes that shrubs are more sensitive than trees.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Honorary degrees will be conferred this term upon Sir Oliver Lodge, F.R.S., principal of the University of Birmingham, and Prof. W. H. Perkin, F.R.S., professor of organic chemistry in the Victoria University of Manchester.

Mr. K. J. J. Mackenzie has been appointed university lecturer in agriculture for five years as from January 1, 1910.

Dr. T. Percy Nunn, vice-principal of the London Day Training College, will give a lecture on psychology and some problems of education on Friday, May 13, at Gonville and Caius College. The lecture will be open to all interested in the subject.

OXFORD.—The Romanes lecture for 1910 will be delivered in the Sheldonian Theatre on Wednesday, May 18, at 2.30 p.m., by the Hon. Theodore Roosevelt, ex-President of the United States of America. The subject chosen by Mr. Roosevelt is "Biological Analogies in History." Lord Curzon of Kedleston, Chancellor of the University, will preside.

The first Halley lecture, established "in honour and memory of Edmund Halley (sometimes Savilian professor of geometry in the University and Astronomer Royal) in connection with his important contributions to cometary astronomy and to our knowledge of the magnetism of the earth," will be delivered on Tuesday, May 10, at 5.30 p.m., in the University Museum, by the founder, Dr. Henry Wilde, F.R.S. The title of the lecture is "On Celestial Ejectamenta."

DR. E. J. GODDARD, Linnean Macleay fellow in zoology, Sydney, has been appointed by the council of Stellenbosch College, South Africa, to the chair of zoology and geology in succession to Prof. R. Broom.

THE thirty-seventh annual dinner of old students of the Royal School of Mines will be held on Thursday, May 26, at the Hotel Cecil. The chair will be taken by Sir Thomas H. Holland, K.C.I.E., F.R.S.

A COURSE of eight lectures on "The Chief Animal and Vegetable Pigments" will be delivered in the Physiological Institute (University College) of the University of London on Fridays during May and June, commencing on Friday, May 6, by Dr. S. B. Schryver. The lectures are open to all students of the University, and also to all qualified medical men and other persons who are specially admitted.

IN an article in the current number of the *Oxford and Cambridge Review*, Mr. John C. V. Bevan, formerly Rhodes scholar and fellow of University College, Oxford, combats a statement which has been circulated that there is no return to the countries which send Rhodes scholars to Oxford. It appears that, of eighty-two Americans, eighty-one have returned home, while one has accepted a university appointment in England. Of fifteen Germans, fourteen have returned to the Fatherland, and one has gone to America. Seventy-eight colonials have completed their tenure as Rhodes scholars; fifty-one have already returned to their colonies; twelve are completing a further course of study before they return; three have obtained appointments in India; two in colonies other than their own; two in foreign countries; one is temporarily engaged in parochial work in this country; four have accepted teaching posts in English universities, but are hoping to secure professorial appointments in their own colonies; three only have decided definitely to settle in England.

A REPORT as to the disposal of the balance of the grant to university colleges of 100,000l. for 1909-10, and as to changes in the list of participating colleges, has been sent to the Treasury by the advisory committee on the grants. The report, together with Treasury Minutes thereon, has

been printed and circulated as a Parliamentary Paper (110). The committee has already recommended the payment to the recognised colleges of general grants for the year 1909-10 on the same basis as in the two preceding years, and it now recommends the payment of further grants to thirteen colleges, varying in amount from 2000l. to Victoria University, Manchester, to 500l. to University College, Reading. The committee has had under consideration whether any new colleges should be added to the list of those which participate in the Treasury grants. Special attention has been given to the claims of Hartley College, Southampton; Royal Albert Memorial College, Exeter; East London College; and Birkbeck College, London. The committee recommends in regard to Hartley College, Southampton, that it shall not remain permanently on the list of university colleges in receipt of Treasury grants, and that its grant, reduced to 1500l., shall be continued for the year ending March 31, 1911, but no longer. The committee has felt unable to recommend the award of a Treasury grant to the Royal Albert Memorial College, Exeter, and Birkbeck College. It recommends, however, that the East London College be awarded a grant subject to conditions set forth in the report, and will consider at what amount the grant for the quinquennium beginning with the year 1910-11 shall be fixed. The Treasury has concurred in the committee's recommendations, and will give effect to them.

Two fellowships, to be known as the "A.K. Travelling Fellowships," are to be established in the British Isles by M. Albert Kahn, of Paris, for the purpose of providing selected persons with *bourses de voyage* to enable them to travel in foreign countries. Each fellowship is to be of the value of 660l. This sum is to be expended by each fellow as to 600l. in defraying his travelling expenses, and as to 60l. in the purchase of books and souvenirs. The only condition which each fellow is required to fulfil is that he shall, at the expiration of his fellowship, prepare a report containing his impression of the countries he has visited. It is the desire of the founder that these travels shall be used as an opportunity of acquiring knowledge and experience which will be of use to the fellows in their future careers as teachers, scholars, or investigators. M. Kahn has arranged that his intentions shall be carried out by a board of trustees, consisting, in the first instance, of the Lord Chancellor, the Lord Chief Justice, the Speaker of the House of Commons, the principal of the University of London, Lord Avebury as nominee of the founder, and a sixth person to be elected by the other trustees. From an article in the *Times* it appears that the trust is to be associated permanently with the University of London, and this has been carried into effect by the principal of that University being appointed as one of the trustees. He will also act as the honorary secretary to the trust, and the office through which the trust will be administered will be in the University building. The trustees have been instructed to invite nominations from the Vice-Chancellor or other executive head of each of the universities in the United Kingdom, from the president of the Royal Society, and from the president of the British Academy, although they are not required to confine their election to the persons so nominated.

LAST September Dr. A. D. Waller, F.R.S., delivered an address to the University of California, and the substance of it is published in the current issue of *Science Progress* as an article entitled "The University of London and an Imperial Institute of Science." Dr. Waller directed attention to the immediate future of the University and to some of the first principles that determine the healthy university in the healthy community. Incidentally, he pointed out that it is upon the combination between teaching and research, and not upon their separation, that the intellectual welfare of a community and of an individual depends. The best guide to any district of knowledge is the man who has been there himself as an explorer or as a pioneer. Discussing university research fellowships, he maintains that no condition of life is more enviable than that of a keen-brained man during the best ten years of intellectual life, from, say, the age of twenty-five to that of thirty-five, in receipt of a salary of 200l. for teaching during half the week and of a fellowship of 200l. for "researching" during the other half. Under such conditions of life the return

in teaching power will repay the outlay in money, and that from among the workers thus supported the exceptional man will be far more likely to emerge than is the case now. The practical measures by which it is possible to give effect to this dual principle in London are such as would at the same time constitute an intercollegiate bond of union formed by the university between its colleges, schools, and institutions through its faculties and boards of studies. The formation of this bond of union should consist in the foundation of an Imperial Institute of Science and Learning, of which the present Imperial Institute building should be the home and headquarters, and its *personnel* select panels of university research fellows. Such panels should consist of professors, recognised and probationary teachers, and other distinguished persons in London, in the United Kingdom, and in His Majesty's Dominions beyond the Seas, selected and nominated by boards of the faculties appointed by the university.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 28.—Sir Archibald Geikie, K.C.B., president, in the chair.—R. B. **Sangster**: The rotatory character of some terrestrial magnetic disturbances at Greenwich and on their diurnal distribution. The paper commences with an investigation of the changes in direction of the line of total magnetic force at Greenwich on 1903 October 12d. 18h. to 23h., when a considerable magnetic disturbance was in evidence. Measurements of the published registers of all three force components were made at equivalent time intervals of about five minutes, whence is obtained a diagram showing the variation of the force component perpendicular to the line of total force. The diagram shows there was an almost wholly rotatory motion of the transverse disturbance vector, the trace consisting of six distinct convolutions varying greatly in size, but consistent in anticlockwise progression. Several other disturbances during epoch 1900-7 are examined in detail, and it is shown that a right- or left-handed rotatory character in the motion of the disturbance vector was of fairly frequent occurrence, while change from left to right not uncommonly occurred about midnight. It was also found that the same direction of rotation often persisted for several hours, and tables of the diurnal distribution of right- and left-hand rotatory disturbance are furnished to show that those of right-hand character were entirely absent during the hours 4 p.m. to 9 p.m., while, meantime, the left-handed rotations were very prevalent, and reached a notable maximum at 8 p.m. Other points in the diurnal distribution are noted, including the more decided effect resulting from a seasonal grouping of the seventy disturbed days dealt with.—D. Orson **Wood**: The liberation of helium from minerals by the action of heat. Experiments were made to determine how the volume of helium liberated from radio-active minerals by the action of heat depends on the temperature, and on the time for which that temperature is maintained, in particular with the view of the future use of heat to release all the helium contained in minerals not easily treated by chemical methods. The minerals experimented on were monazite and thorinite, the one comparatively poor and the other very rich in helium. The ground minerals were heated, *in vacuo*, in tubes of Jena glass or quartz, by an electric heater consisting of a single coil of nickel wire, to temperatures up to 1200° C., which were measured by a Pt resistance thermometer or a Pt Pt-Rh thermocouple. The gas released was purified by drawing it through KOH and P₂O₅ tubes, and finally by Na-K electrodes. The volume was measured in a modified McLeod gauge (described by Prof. Strutt, *Proceedings*, vol. lxxx.) specially constructed for the measurement of volumes over a large range—1 c.c. to 1 c.mm. Curves are given to show the volume of helium liberated with time at constant temperatures (250°–1000° C.), and also the percentage of the total content obtainable after prolonged heating at the different temperatures. The way in which the gas must be supposed to be retained within the mineral to accord with the results obtained is discussed, and it is concluded (1) that heat may be used for the complete liberation of the gas if a sufficiently high temperature (about 900° C.) is

reached, and (2) that the results are in agreement with the supposition that a small proportion of the gas is diffused through the mineral and that the remainder is concentrated in very minute cavities within it.—Prof. Swale **Vincent**: The chromophil tissues and the adrenal medulla. The author gives an account of the gross anatomy and histology of the chromophil tissues in mammals, and especially in the dog. Descriptions and drawings of the groups of cells in the sympathetic ganglia and of the chromophil bodies in other regions are furnished, and comparisons are made between their structure and that of the adrenal medulla. An extract of the abdominal chromophil body of the dog has precisely the same powerful effect upon the blood pressure as an extract made from the medulla of the adrenal. There seems no reason why one cannot admit the hypothesis that all the chromophil cells have an internal secretion, though this process is more completely elaborated in the larger chromophil bodies and in the adrenal medulla.

Royal Anthropological Institute, April 12.—Sir Herbert Risley, K.C.I.E., president, in the chair.—S. Hazzledine **Warren**: Charcoal burning in Epping Forest. The industry was carried on near Chingford in 1908 and 1909 but has since been given up. The structure of the burners' hut was quite on prehistoric lines. The technical terms used by the burners are also survivals, many of them being Anglo-Saxon or French.—N. F. **Roberts** and H. C. **Collyer**: Additional notes on the British camp at Wallington. The authors described the excavations made when buildings were being erected on the site of the camp, no vestige of which was apparent until the ditch of the camp was cut through in the course of digging foundations, the whole area having at some time been levelled for cultivation. Numerous objects were exhibited which had been recovered from the ditch, including stone implements, mealing stones, loom weights, spindle whorls, and large quantities of pottery, including drinking cups and cooking pots, some of which contained charred grain. Some traces of bronze were found, including a bronze fibula, pointing to the date of the camp having been of early Iron age, possibly about 50 B.C. Some of the stone implements were considered to be of foreign manufacture, and although most of the pottery was very coarse, and probably made locally, a portion of it was evidently imported from Gaul. Particular attention was directed to some perforated tiles, which had apparently been used as "grids," one actually having been found lying near a cooking pot upon a hearth at the bottom of the ditch. Similar tiles had not previously been found in Great Britain. An amber bead showed probable intercourse with Scandinavia. In the ditch itself there was no trace of Roman or Romano-British pottery, although a small quantity of such ware was found in the humus which lay above the original land surface, and which had been washed or carried down by the plough from the higher ground. The authors considered that the camp had been destroyed or abandoned about the time of the Roman entry into London. The camp, which covered several acres, had apparently held a considerable population, which practised weaving and the potter's art, cultivated grain, and possessed, or at all events consumed, the ox and horse, the bones of which were associated with those of boar and wolf or dog.

Royal Meteorological Society, April 20.—Mr. H. Mellish, president, in the chair.—R. G. K. **Lempfert** and R. **Corless**: Line squalls and associated phenomena. A line squall is usually associated with the displacement of an air current moving from south-west by a colder current from north-west. The authors investigated the phenomena associated with several well-marked line squalls, and showed by maps with isochronous lines the direction of front and the rate of advance of the various storms across the country.

Linnean Society, April 21.—Dr. D. H. Scott, F.R.S., president, in the chair.—Miss M. G. **Sykes**: The anatomy of *Welwitschia mirabilis* in the seedling and adult stages. The development of the ridges bearing inflorescences has been studied. On the whole, the investigation has served further to confirm the impression of the aberrant nature of the plant; it may, indeed, be described as an "adult seedling."—Prof. P. **Stein**: Die von Mr. Hugh Scott im

uli 1908-März 1909 auf den Seychellen gesammelten Anthomyiidae, mit den Gattungen Rhinia und Idiella.—Dr. Malcolm Burr: The Dermaptera of the Seychelles.—Dr. J. J. Tesch: The Pteropoda and Heteropoda collected by the Percy Sladen Trust Expedition in the Indian Ocean.—Dr. G. Enderlein: Die pilmücken Fauna der Seychellen.

Mathematical Society, April 28.—Sir W. D. Niven, resident, in the chair.—Dr. W. F. Sheppard: The accuracy of interpolation by finite differences (second paper).—G. H. Hardy: Theorems connected with Maclaurin's test or the convergence of series.—Lieut.-Colonel A. Cunningham: Two notes on the theory of numbers, (i) the factorisation of $2^n + 1$; (2) the indivisibility of $2^n - 2$ by p^2 , being prime.

PARIS.

Academy of Sciences, April 18.—M. Émile Picard in the chair.—The perpetual secretary announced the death of Julius Kühn, correspondent for the section of rural economy.—Arthur R. Hinks: The solar parallax deduced from micrometric observations of Eros made in 1900 and 1901. The final result of the micrometric observations is $\pi = 8.806'' \pm 0.004''$. The results obtained by the method of passages are less exact.—M. Giacobini: Halley's comet. The comet was observed on April 17 at the Paris Observatory. Its present magnitude is between 2 and 2.5. The head of the comet is a circular nebulosity $30''$ to $35''$ in diameter, with a strong central nucleus, and no tail could be distinguished.—M. Titzélica: A new class of surfaces.—A. Blondel: The linear functional equation.—A. Potot: The mode of action of driving wheels.—C. E. Guye and H. Schapper: The internal friction of metals at low temperatures. The metals examined were copper, zinc, gold, nickel, palladium, and platinum, and the temperatures ranged from $+100^\circ$ C. to -195° C.—M. Menneret: The movements of a liquid in a tube. The damping of the oscillations of a liquid column in a U-tube follows two laws, according to the nature of the damping. Similar results are found in the uniform flow of a liquid in a rectilinear tube.—L. Bloch: Ionisation by the pulverisation of liquids.—MM. de Broglie and Brizard: Ionisation by bubbling and chemical reactions.—Louis Dunoyer: Concerning the formation of the kathode rays. In the production of the kathode rays the nature of the kathode is usually regarded as unimportant. An experiment is described in which the ordinary conditions of working are followed, and in which the nature of the kathode directly affects the phenomena obtained.—H. Baubigny: The constitution of the dithionates and sulphites. Dithionous acid is regarded as $\text{HO}_2\text{S}-\text{SO}_2\text{H}$, and sulphurous acid as H_2SO_3 , the evidence on which these formulæ are based being given.—E. Fournéau: The alkaloid of *Pseudocinchona africana* and its saponification by alkalies. The alkaloid of *Pseudocinchona* resembles yohimbine, and a comparative study of the two bases has therefore been made.—Marcel Guerbet: The constitution of the alcohols resulting from the condensation of the secondary alcohols, with their sodium derivatives. The oxidation products of the condensation product from capryl alcohol have been examined, and lead to the view that the alcohol is

—A. Borg: The action of silver oxide upon elaterine. The chief product of the reaction is a quinone, named elaterido-quinone, acetic acid being also formed.—E. Léger: Aloinose, a sugar from aloin.—Léon Brunel: Cyclohexanetriols and their derivatives.—L. Blaringhem and Paul Viguié: A new species of shepherd's purse (*Capsella Viguiéri*) produced by mutation.—Silvanus P. Thompson: The physiological effects produced by an alternating magnetic field. On placing the head inside a bobbin carrying an alternating current (field 1400 C.G.S. units) and closing the eyes, the effect of a feeble vacillating light is produced, the period of the fluctuation not being well defined.—A. d'Arsonval: Remarks on the preceding note by Silvanus P. Thompson. The phenomena noted have been known to physiologists since 1893.—Ch. Dhéré and M. Gorgolewski: A method of preparing a serum very free from electrolytes by electrical dialysis. By electrical dialysis the conductivity of the serum was reduced to one-twelfth of its original amount. The purified serum was

very readily precipitated by the addition of small amounts of alcohol; the temperature of coagulation was much lower for the purified product.—E. Bataillon: Complete embryogenesis produced in Amphibia by the puncture of the virgin egg. The eggs of *Rana fusca* were punctured with a short stylet of glass, manganin, or platinum, the size of the hole being from 0.03 to 0.08 mm. Segmentation started in the treated eggs as rapidly as in eggs impregnated in the ordinary way. A dozen free larvæ resulted from nine sets of operations.—J. Bridé and L. Nègre: The nature of the parasite of epizootic lymphangitis. The experiments described favour the hypothesis of the blastomycelian nature of the parasite.—E. Loené, R. Debré, and G. Simon: The presence of virulent germs in the atmosphere of hospital wards. Diphtheria bacilli were proved to be present in the air of the diphtheria wards.—F. Carrigou: A rapid and certain method for recognising in a mineral water the presence of metalloids and metals.

April 25.—M. Émile Picard in the chair.—H. Deslandres: The distribution of the filaments in the upper layer of the solar atmosphere. The observations taken at the Meudon Observatory now include photographs of the upper layer for twenty rotations with the calcium line and fourteen with hydrogen. The observations are discussed in detail, and four diagrams given showing the filaments on May 20, June 15, November 27, 1909, and April 11, 1910. The observations may throw light on the distribution and special variations of the protuberances, at the present time not regarded as connected with any other solar phenomena.—A. Haller and A. Lassieur: Study of by-products from cocoa-nut oil. The composition of essence of cocoa. In the purification of commercial cocoa-nut oil by treatment with superheated steam a distillate is obtained smelling strongly of oil of rue. From this mixture a ketone, $\text{C}_{11}\text{H}_{22}\text{O}$, has been isolated. The oxime and semicarbazone are described, and the oxidation products studied. The ketone was shown to be normal methylonyl ketone. Methylheptylketone was also obtained from the fractions of the crude oil.—C. Eg. Bertrand and F. Cornaille: The characteristics of the botryopterid leaf trace.—Ch. André: The effect produced on hailstorms by the hail cannon. A statistical study of the effect of hail cannon. Comparing the damage done by hail over the years 1901 to 1908, and the number of hail cannon installed during that time, the conclusion is drawn that no practical service is rendered by the cannon.—P. Lowell: A new method of planetary photography employed at the Lowell Observatory at Flagstaff, Arizona. The method was devised by Lampland, and improved by E. C. Slipher. A special screen is used in association with suitable plates, so that the yellow rays near the D lines are the only ones to act on the plate. Details of the results obtained with Jupiter and Saturn are given.—C. Russyan: The integration of a system of partial differential equations of the first order by the generalised method of Jacobi.—Joseph Marty: The existence of singular solutions for certain equations of Fredholm.—Michel Fekete: The series of Dirichlet.—M. Ouyvet: An application of birational transformations.—H. Vergne: The canonical changes of variables.—B. Galitzine: The precision of apparatus serving to study the vibration of buildings. In the immediate neighbourhood of a Diesel motor the vertical vibrations predominate, but in a building some distance away both the vertical and horizontal movements are of the same order of magnitude. The vibrations are greater in the higher storeys of a building than in the lower.—U. Schoop: A new principle of depositing metals. The fused metal is turned into a fine dust and projected on to the surface to be covered by means of an indifferent gas, hydrogen or nitrogen, under high pressure. A sort of metallic fog is produced, which, in spite of the high temperature of the fused metal, has usually a temperature of between 10° C. and 60° C. Tin, lead, copper, and aluminium alloy, all of which are very fluid when fused, can be deposited on wood, glass, metal, and other surfaces, the thickness of the deposit being completely under control.—C. Chéneveau: A simple arrangement for measuring a magnetic field. A differential manometer containing a paramagnetic liquid (an aqueous solution containing 30 per cent. of manganese sulphate) and a diamagnetic liquid of approximately the same density not miscible with the first

(a mixture of benzene and carbon tetrachloride) is placed in the magnetic field the strength of which is to be measured. The boundary meniscus of the two fluids is displaced in the field and is brought back to the original position fixed by a cross-wire in a microscope by the compression of an air bulb. The pressure required to do this is measured on a separate differential manometer. A field of 2800 units gave a reading in the manometer of 65 mm.—**P. Vaillant**: A law of Stefan relating to evaporation.—**H. Ollivier**: The spontaneous re-magnetisation of iron.—**P. Pascal**: The measurement of the magnetic susceptibilities of solid bodies. The solid is placed in a thin glass tube in the magnetic field suspended from the arm of a sensitive balance. By replacing the solid by water a formula is derived giving the magnetic susceptibility independent of the nature and dimensions of the apparatus.—**M. Pariselle**: The ethyl ether of allylcarbinol. This substance has been obtained by the interaction of allylmagnesium bromide and monochlor-methyl-ethyl ether. The products obtained by the addition of bromine and hypochlorous acid have been studied.—**Mlle. Pauline Lucas**: The action of organomagnesium derivatives on the trialkylacetophenones.—**Marcel Delépine**: The essence from *Crithmum maritimum*.—**J. Bertheaume**: The chlorplatinate and periodides of dimethylamine and trimethylamine: their use for the separation of these bases. Determinations of the solubilities of the chlorplatinate of these two bases showed that the differences were too slight to be used as a basis of separation. The method of separation proposed by Weiss, based on the differences of solubility of the periodides, proved to be equally unsatisfactory.—**H. Aguihon**: The influence of the reaction of the medium on the formation of melanines by diastatic oxidation.—**J. Chevalier**: Variation in the amount of sparteine in the plant according to the period of its vegetation.—**Léon Marret**: The presence of Alpine plants at low altitudes in the central Valais.—**J. Beauverie**: The Ambrosia of *Tomicus dispar*.—**H. Colin and J. de Ruzf**: The absorption of barium by plants. The barium absorbed by plants was found to be localised in the roots.—**Gabriel Vallet**: The sterilisation of large quantities of water by means of the ultra-violet rays. A water polluted with coli bacilli was exposed to ultra-violet light produced by the expenditure of 0.4 kilowatt-hour in a quartz mercury vapour lamp. The water was passed at the rate of 10 cubic metres per hour, and the conditions for complete sterilisation are laid down.—**E. Sauvage**: The abdominal part of the great sympathetic in Saurians.—**A. Ricco**: The eruption of Etna of March 28, 1910.—**L. Joleaud**: The evolution of Quaternary hydrography in the Constantine region, Algeria.—**Albert Nodon**: Researches on the ionisation of the hot spring of the thermal waters of Hammam-Salahin, near Biskra.

DIARY OF SOCIETIES.

THURSDAY, MAY 5.

ROYAL SOCIETY, at 4.30.—The Development of Trypanosomes in Tsetse Flies: Col. Sir D. Bruce, C.B., F.R.S., Captains A. E. Hamerton and H. R. Bateman, R.A.M.C., and Captain F. P. Mackie, I.M.S.—On the Weight of Precipitate obtainable in Precipitin Interactions: Dr. H. G. Chapman.—The Absorption of Gases by Charcoal: Miss I. F. Homfray.

ROYAL INSTITUTION, at 3.—Blackfeet Indians in North America: Walter McClintock.

RÖNTGEN SOCIETY, at 8.15.—Quantitative Measurements of the Conversion of Kathode Rays into Röntgen Rays by Antikathodes of Different Metals: J. H. Gardiner.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—A Telephone Relay: S. G. Brown.

LINNEAN SOCIETY, at 8.—Eight Months' Entomological Collecting in the Seychelles Islands: Hugh Scott.—The Anatomy of *Tipula maxima*: J. M. Brown.

FRIDAY, MAY 6.

ROYAL INSTITUTION, at 9.—Auto-inoculation: Sir Almroth E. Wright, F.R.S.

GEOLOGISTS' ASSOCIATION, at 8.—The History of the Study of Fossils: Dr. A. Smith Woodward, F.R.S.

SATURDAY, MAY 7.

ROYAL INSTITUTION, at 3.—The World of Plants before the Appearance of Flowers: Dr. D. H. Scott, F.R.S.

MONDAY, MAY 9.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Land of the Incas: Sir Clements R. Markham, K.C.B., F.R.S.

VICTORIA INSTITUTE, at 4.30.—Annual Address. Halley's Comet: Dr. A. C. D. Crommelin.

TUESDAY, MAY 10.

ROYAL INSTITUTION, at 3.—The Mechanism of the Human Voice: Prof. F. W. Mott, F.R.S.

WEDNESDAY, MAY 11.

ROYAL SOCIETY OF ARTS, at 8.—The Restoration and Discoveries at the Guildhall, London: S. Perks.

GEOLOGICAL SOCIETY, at 8.—Dedolomitization in the Marble of Port Shepstone, Natal: Dr. F. H. Hatch and R. H. Rastall.—Recumbent Folds in the Highland Schists: E. B. Bailey.

THURSDAY, MAY 12.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: The Influence of Bacterial Endotoxins on Phagocytosis (Preliminary Report): Leonard S. Dudgeon, P. N. Fanton, and H. A. F. Wilson.—The Origin of Osmotic Effects. III. The Function of Hormones in Stimulating Enzymic Change in relation to Narcosis and the Phenomena of Degenerative and Regenerative Change in Living Structures: Prof. H. E. Armstrong, F.R.S., and E. Frankland Armstrong.—On the Direction of Motion of an Electron ejected from an Atom by Ultra-violet Light: Dr. R. D. Kleeman.

ROYAL INSTITUTION, at 3.—Blackfeet Indians in North America: Walter McClintock.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Street Lighting by Modern Electric Lamps: H. T. Harrison.

MATHEMATICAL SOCIETY, at 5.30.

FRIDAY, MAY 13.

ROYAL INSTITUTION, at 9.—Radio-activity as a Kinetic Theory of a Fourth State of Matter: Prof. W. H. Bragg, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.—Mollusca of the Porcupine Expedition, Part IV.: E. A. Sykes.—The Genus *Cremnobates*, Swainson: C. Hedley and H. Suter.—Notes on Polyplacophora, chiefly Australasian, Part II.: T. Iredale.—Notes on and additions to the Terrestrial Molluscan Fauna of Southern Abyssinia: H. B. Preston.

SATURDAY, MAY 14.

ROYAL INSTITUTION, at 3.—The World of Plants before the Appearance of Flowers: Dr. D. H. Scott, F.R.S.

THURSDAY, MAY 12, 1910.

THE DEATH OF THE KING.

KING EDWARD THE SEVENTH is no more. An Empire is in mourning. The death of the King has come with a suddenness which has stunned his people, who, however, have already given no uncertain signs of the deep love and respect they entertained for a ruler who always strove to do his duty. Her Majesty the Queen-Mother and the other members of the Royal Family know full well that they are not the only mourners, and that the sympathy of millions in the widest Empire the world has known, and others outside it, is extended to them in their personal loss.

We can answer for it that the grief of the leaders and students of science in the realm is as deep as that of any of their fellow citizens. They do not forget that the late King was the son of the Prince Consort, one of the highest products of the German university system, in which science always finds a place, through whose influence the importance to this nation of the study and fostering of science and art was first recognised, and whose early death, it has been said, was more harmful to Britain than the loss of a great campaign. With such a wise father it is not to be wondered at that the late King began his university studies by attending Playfair's lectures on chemistry (in 1861) when he was twenty years of age. For this reason, again, it is not to be wondered at that among the innumerable public duties the King performed since, as Prince of Wales, he opened the great railway bridge across the St. Lawrence at Montreal, many of those in which he exhibited the keenest interest have had to do with the opening or extension of institutions connected with science.

If there were anything like a complete organisation of science in England, we may be certain the King's interest in it, great as it was, would have been greater still. The organisation of science means a scientific department of the State; this means a Minister of Science in the immediate entourage of the sovereign.

How much we might have gained, great though the late King's work in this direction has been, we can gather from what has been accomplished by the King's actions in scientific

matters on which he was kept informed and interested, not by a Minister of State, but by the eminent representatives of medical science attached to his person.

Since the late King's accession to the throne it may be said that the enormous expansion and amelioration of everything that has to do with the healing of sickness and the lessening of all the ills which follow on it are mainly due to his unceasing efforts to secure a better organisation of hospitals and of the nursing staff throughout the land.

In the various addresses which the late King delivered during a period of forty years before his accession to the throne, and since, on the occasions of the calling into being of new English colleges and universities, and on other similar functions, the note of the importance of the advancement of science to the nation was almost invariably struck. On one of the last public appearances of this nature, that of laying the first stone of the new buildings of the Imperial College of Science and Technology, in July of last year, the King said:—"In recent years the supreme importance of higher scientific education has, I am happy to say, been fully recognised in England; and as time goes on I feel more and more convinced that the prosperity, even the very safety and existence, of our country depend on the quality of the scientific and technical training of those who are to guide and control our industries." This and other similar utterances have shown that in the late King science had a firm friend, and that his action for good would have been greater still if representatives of science were to be found among the King's ministers.

Although it is incumbent upon us to refer chiefly to the late King's activities and marks of sympathy in scientific directions, we must at the same time point out his vast services to the nation in other, almost innumerable, ways. An ardent apostle of peace, the whole world was his debtor; and not science alone has gained by his anxiety to foster the arts of peace by honouring those engaged in their pursuit.

In past times only national services in war were distinguished by the sovereign's mark of approval; King Edward did not hesitate to confer marks of honour upon the most eminent representatives of science, art, literature, commerce and industry. We owe to him the foundation of the Order of Merit, the highest

and rarest distinction for State service which now exists, and it is an honour to the few men who hold it that a woman, Miss Nightingale, belongs to the Order.

With regard to his present Majesty, King George the Fifth, to judge of what he has done as Prince of Wales, we may feel sure that there will be no falling off from the strenuous life of public duty exhibited by his father and grandfather.

We are informed by those who have had the privilege of conversing with him that, as one of the effects of his education as a naval officer, for the education of a naval officer must be scientific, he is fully in sympathy with those who insist upon the importance of science as one of the foundations of the greatness of a nation. It was this interest in science which caused him to regret deeply his inability to accept the presidency of the British Association at its meeting in South Africa. State duties had called him to India at that time.

King George is unapproached as a traveller, among crowned heads, whether of his own or of previous time. The new sovereign has probably seen more of the Empire than has been traversed by any single person among all his subjects. After the Australian Commonwealth was inaugurated, the King and Queen journeyed fifty thousand miles by land and water. They returned to Canada for the great tercentenary pageant at Quebec and the consecration of the battlefields, and meanwhile, in 1905, they had put a girdle round the globe again and traversed India from the Khyber to the Ganges, and from the Himalayas to the temples of the South. It has been well said that not one of his subjects realises better than the King how little is known of England by those that only England know, or how inseparably the whole life and fortunes of this island are knitted up with the destinies of the outer Empire. That many of the national shortcomings to which it is our duty to refer from time to time are fully known to his present Majesty is proved by his famous warning, uttered after all his journeyings, "Wake up, England."

In the midst of the nation's grief at a loss so great and so sudden that there has not been time to realise it, comfort may be found in the assurance which we possess that in the future, as in the past, the illustrious Royal Family

will guard the best interests of our Empire. They will thus retain the affection and respect of a grateful people, whose hearts now go out to them in profound sympathy with their sorrows.

EDITOR.

THE NEW "ORIGIN OF SPECIES."

The Mutation Theory. Experiments and Observations on the Origin of Species in the Vegetable Kingdom. By Hugo de Vries, Professor of Botany at Amsterdam. Translated by Prof. J. B. Farmer and A. D. Darbishire. Vol. i., *The Origin of Species by Mutation*. Pp. xv+582. (London: Kegan Paul and Co., Ltd., 1910.) Price 18s. net.

THE two smaller books by Prof. de Vries written in English have already put us in possession of a clear account of his theory of the origin of species by discontinuous variation. The publication of a translation (of which this is the first volume) of his larger "*Die Mutationstheorie*" will be valuable to students as containing the detailed arguments upon which it is based.

De Vries has long been known as a distinguished physiologist who has the advantage of a sound training as a physicist. Now a physicist, in attacking a problem, endeavours to get it into the simplest form which admits of experiment and measurement. Having obtained a "law" which fits his results, he proceeds to test its application to more complicated phenomena. But "life" is a complex which at present defies analysis, and the naturalist is therefore obliged to survey organised nature as a whole, and to endeavour to extract from its observation principles of general application. In this way organic evolution has been arrived at, for it is now generally admitted to find its securest basis in the evidence afforded by palæontology of the succession of living forms in the past history of the earth. It might also, though less convincingly, find it in the facts of geographical distribution. Darwin did not invent evolution, but he made it immensely more acceptable, first by breaking down the old belief in the constancy of species, and, secondly, by giving, in "selection," a mechanical explanation of how they came into existence.

To this de Vries raises the same objection as Huxley, though on different grounds, that "we do not observe actual specific changes in nature" ("*Plant Breeding*," p. 4). His object is to overcome this difficulty. He agrees (p. 207) that

"we have a doctrine of descent resting on a morphological foundation. The time has come to erect one on an experimental basis."

In this he believes he has succeeded. Every-

one must admire the patience and enthusiasm which he has brought to the task, and if the naturalist must be permitted to criticise the result from his point of view, he cannot but approve the scrupulously fair and instructive way in which de Vries has published every detail of his research.

In order to do justice to the theory which de Vries has founded on his observations, it is necessary to attach some precise meaning to the technical terms used. Darwin was nothing if not a naturalist. It is impossible to read de Vries's pages without feeling that he is not quite at his ease with the naturalist's technique. On p. 21 I find, for example, the following statement:—

"It is most remarkable that in the 'Index Kewensis,' which was published at Darwin's expense after his death, no distinction is drawn between varieties and synonyms."

I do not suppose it was intended, but this might be construed to mean that the work as executed failed to carry out Darwin's intention. That this would be the reverse of the fact I can state with confidence, as the plan was discussed and settled between Mr. Darwin and myself in his own house. What he told me he wanted was to be able to trace to its source any specific name that he met with. This the "Index" does, and it is an incalculable boon to those who use it. But its purpose is merely bibliographical, and it was not intended to express any opinion as to the validity of the species which it catalogues; nor was there ever any suggestion that it should catalogue varietal names.

It would be quite possible for a discussion of de Vries's theory to evaporate into a mere logomachy, a mere dispute as to the meaning of words. That I hope to avoid, but if I fail, he himself will have to share the blame. The word "mutability," which is peculiarly de Vries's property, and, indeed, contains the kernel of his theory, is an example. So far as I can find, it does not occur in Darwin's writings. Yet on p. 202 I find the following summary of the Darwinian theory:—

"Mutability may take place in almost all directions; and it is natural selection which operates in one direction during long geological periods";

and that there may be no mistake, he adds that this "obviously represents the view of Darwin." This is emphasised on p. 198, where "species-forming variability" and "mutability" are treated as synonyms. But de Vries's whole contention is that, in the ordinary acceptance of the terms, they are profoundly different. This is apparent from the following passage in the author's "Plant Breeding" (pp. 5-6), a book which, I confess, seems to me to be written with more precision than the larger one.

"The phenomena that follow Quetelet's law are now considered as one group, which is called fluctuating variability or fluctuation, since the individual qualities fluctuate around their average. The processes by which new qualities are produced must be studied separately. Under the assumption that these processes are neither slow nor invisible, but consist in leaps and jumps such as are popularly indicated by the name of sports, they are now called mutations,

and the great subdivision of the phenomena of variability is designated, in consequence thereof, as mutability."

Now there is no want of precision about this statement. It of course assumes the very point which has to be proved, that "fluctuating variability" does not produce "new qualities"; but that is another story.

De Vries has elsewhere employed the words continuous and discontinuous, as descriptive of the two processes. Unfortunately, Bateson used these at the same time in a different sense, and this has added another pitfall to the discussion of the subject. At first sight we seem to have a sharp distinction between the theories of Darwin and of de Vries, the one accounting for the origin of species by the accumulation of small variations, the other by "sports." If we take, as an example of the latter, the production of the nectarine from the peach, there can be no doubt that the leap may be considerable. While the occurrence of sports is undeniable, de Vries appears to draw a distinction between the part attributed to them by Darwin and Wallace in the production of species (pp. 12 and 39). Wallace regards them "as absolutely without significance" (p. 40). But Darwin, with more caution, doubts whether they "are ever permanently propagated in a state of nature" ("Origin," fifth edition, p. 49), and this is practically the same thing. De Vries himself is led gradually to minimise their magnitude. He finds (p. 53) "sports" "not a happy" term, and prefers "jerky variability" where "jerks" may only induce quite small changes." Later on he finds (p. 55) that "many mutations are smaller than the differences between extreme variants." He quotes Galton's polyhedron which, when disturbed, "oscillates round its position of equilibrium" (fluctuation), and finally "comes to lie on a new side" (mutation). But when the faces are very small, the illustration is obviously not helpful; when the variation is very small, the distinction between the two kinds is inappreciable.

To meet this difficulty, de Vries sets up other criteria. These he has drawn from a mass of experimental work for which it is impossible to conceal one's admiration, and is a positive addition to our knowledge. But it is, of course, permissible to draw from it somewhat different conclusions. "Mutants" arise without transitional forms (p. 248). It appears, however (p. 504), that such do occur, but simultaneously, and not before; the mutants, therefore, are artificially selected from a varying population. But they possess from the first absolute stability; this is an extremely interesting point; it is, of course, implied that they were self-fertilised, and that the conditions were unchanged. It is, however, to be noticed that it was not universally the case, as three of the mutants studied "proved to be inconstant," and some actually reverted to the original parent (p. 508). Such mutants he calls "elementary species," a term for which he invokes (p. 57) the authority of Darwin, who, however, only said that "varieties are incipient species," a very different thing.

It follows that "specific characters are absolutely

independent of selection" (p. 90); "by natural selection species are not *created* [no one ever thought they were], but eliminated" (p. 199). Selection "now has served its time as an argument for the 'Theory of Descent'" (p. 29). It was, indeed, finally disposed of by Lord Salisbury (p. 70), a fact which would have more weight if he had not ludicrously misapprehended the Darwinian theory.

The utility of specific characters (p. 65) and adaptation necessarily go by the board as well. Desert plants are not adapted to desert life. "They endure the desert, but only with difficulty" ("Plant Breeding," p. 350); "the spurs of the orchids . . . have not been originated in the way in which plants are now using them" (*l.c.*, p. 352). It must be admitted that all this is perfectly consistent, and follows logically from the conception of the species as an arbitrary result, "independent of the environment," and for which "we can as yet assign no cause" (p. 130). This makes a pretty complete sweep of the Darwinian theory, and practically takes us back to the position of Linnæus, who was content to suppose that species were created. It must, however, be put to de Vries's credit that he makes an heroic attempt to save Darwin himself from the wreck by claiming him as at heart a mutationist (p. 87) who "only by the pressure of criticism" (p. 39) gave up the true faith. There is a little irony in the fact that, as the critic was apparently Fleeming Jenkin (p. 37), the mischief was the work of a physicist. The attempt, though generous, is scarcely convincing, and so Darwin goes, and with him goes the splendid and fertile field of biological research for which he opened to us the door. Its place is taken by the procession of arbitrary mutants which have nothing to tell us because they have nothing to say. It is a rather dreary outlook, only mitigated by the "hope that we may be able to gain some control over the formation of species" (p. 186). Yet when I turn to Darwin and read "We have no evidence of the appearance, or at least of the continued procreation, under nature, of abrupt modifications of structure" ("Variation," ii., p. 414), I pluck up a little conviction of something that seems more full-bodied than a mere echo of Fleeming Jenkin. It may be remarked, however, that the celebrated argument of the latter has never been refuted.

I do not know whether to take comfort from the fact that if Darwin fares badly, Lamarck fares worse.

"Specific characters are never 'acquired'; and there is no need for taking 'acquired characters' into consideration in the whole domain of comparative biology and the theory of descent" (pp. 130-1).

That gets a troublesome question out of the way, at any rate. To finish clearing the ground, a last dictum:—"No theory of the origin of species can have any bearing at all on this subject" [sociology] (p. 159). "Man is immutable albeit highly variable" (p. 156), a reservation with little satisfaction, as de Vries will allow no stability to racial variation.

It may be asked, on what are these sweeping conclusions based? Bateson inferred the discontinuity of variation from the observed discontinuity of species. De Vries apparently does not accept this, but for once

adopts the obvious Darwinian explanation, "Sub-species become species by the extinction of intermediate forms" (p. 186). His own theory is based on the prolonged study of a single species of unknown and suspect history. It is, perhaps, one of the most remarkable cases in science of generalisation from a single instance, and that highly dubious.

He commences the account of his experimental work by remarking (p. 217):—

"The chief obstacle in the way of . . . investigating the origin of species is our complete ignorance of the conditions under which the process takes place." To test it, he "brought over one hundred species into cultivation" from the neighbourhood of Amsterdam. "Only one of these turned out to be what I really wanted." He does not tell us in what respect they failed, but concludes that mutability occurs "relatively rarely." It seems, therefore, to be open to the same kind of objection as has been urged against natural selection, that it "will generally act," as Darwin said, "very slowly, only at long intervals of time" ("Origin," sixth edition, p. 85). I think it is clear that what baffled de Vries was specific stability. It takes a somewhat prolonged subjection to cultural, *i.e.* changed, conditions to break this down. I have given numerous instances in these pages of extremely stable species which ultimately broke down. I have watched the process at Kew in *Primula obconica*, which now produces flowers two inches across. The process was described by Vilmorin half a century ago:—"The fixed character of the species being once broken, the desired variation will sooner or later appear" (Darwin, "Variation," ii., p. 262). I cannot doubt, therefore, that if de Vries had had patience, every one of his hundred species would have become plastic in his hands.

He, then, has been obliged to rest his theory on a single case, that of *Oenothera lamarckiana*. There is no evidence that this is a "natural species." It made its appearance in the Paris Jardin des Plantes, and, as pointed out by Lock and Boulenger, de Vries's results are open to the interpretation of being simply due to "Mendelian disjunction."

But, waiving this point, there is a graver difficulty. De Vries insists (p. 130) that his mutations are "independent of the environment." A moment's reflection will show the disadvantage under which his theory rests in this respect compared with that of Darwin, which provides a means of automatic and continuous equilibrium, and remorselessly eliminates whatever fails to adjust itself to it. De Vries admits (p. 199) that his mutations must submit themselves to selection; but they are so handicapped at the start that they can rarely have much chance, and this is confirmed by the inability of sports to hold their own in nature. Even *Oenothera lamarckiana*, whatever it may do under cultivation, does not appear to be able to produce permanent varieties under natural conditions.

Two other lines of argument require brief examination. De Vries points to the familiar little crucifer, *Draba verna*, which is now in flower everywhere, as a case of natural mutation. Jordan collected from

different countries some two hundred forms, differing often in extremely minute characters, but which he and other observers found to be stable in cultivation. Most systematists regard them as mere varieties. But species are only the stable forms of diverging races, the connecting links between which have disappeared. A naturalist will unite in one species in the Linnean sense, as in the case of *Draba verna*, a range of forms where it is conceivable that the differences could be bridged by continuous variation. Darwin thought that such forms might be stable, as, indeed, they appear to be. They may, in fact, be regarded as adjusted to slight differences in the environment, a view which derives some confirmation from the fact, which I confess surprised me, that de Vries finds only one of the two hundred forms of *Draba verna* in the neighbourhood of Amsterdam. This view would, of course, be rejected by de Vries, who looks upon them by analogy as mutants. The Darwinian explanation equally rests on an analogy, the production of the races of cultivated plants by artificial selection.

De Vries feels the force of this, and it is therefore essential to his case to break down the analogy. He admits (p. x) that "the process of selection has enabled us to produce improved races." But he draws a curious distinction between horticultural and agricultural methods. "In horticulture, varieties arise by mutations. . . . In agriculture, the highly improved races arise gradually through selection" (p. 82). For my part I am quite prepared to admit that mutation has had some share in the production of the latter; and as to the former, de Vries quotes my own observations on *Cyclamen latifolium*, where there can be no doubt that the existing race is the result of continued selection. The distinction, in fact, cannot be sustained.

De Vries objects to any argument drawn from cultivated races. We know little usually of their origin (pp. 13, 14), and this is true; they are often of hybrid origin (p. 75), which is equally true; both objections, it may be noticed, have been urged against his own *Oenothera*; finally, "improved races" (unless arising by mutation) lack stability (p. 120). This has been fully discussed by Darwin, and both he and Sir Joseph Hooker insist "on what little evidence this belief rests" ("Variation," ii., p. 32). Such races are the result of artificial selection, and are only stable under artificial cultural conditions. If these are withdrawn a new adjustment has to be sought, and, as Wallace has pointed out, in the face of competition for which they are in no way fitted. As Darwin says, "to assert that we could not breed our . . . esculent vegetables, for an unlimited number of generations, would be opposed to all experience" ("Origin," fifth edition, p. 16). The fact is accepted in the law courts, and if a pea such as Veitch's Perfection did not come true from seed, the purchaser would have a cause of action against the vendor.

De Vries states (p. 124) that "fruit-trees grown from seed quickly revert to the original type." This is too extreme a statement. The measure of truth in it is easily accounted for. Stability can be obtained in races where seminal reproduction can be quickly re-

peated. But a generation of fruit trees approximates to that of mankind, and though, theoretically, stability might be obtained, it would require a Methuselah to do it.

De Vries prefaced the first edition of this book by remarking that "The origin of species has so far been the object of comparative study only." It must always be to his credit that he has been the first to submit it to experiment. If the results seem so far inconclusive, the method, in the long run, must be fruitful. Darwin deliberately relied on continuous variation, de Vries relies on discontinuous. It must be obvious that the former has been a potent solvent of a wide range of biological problems where de Vries leaves us without an answer; and he frankly admits that on the fundamental principle we are as much in the dark as ever. For mutations, "we can as yet assign no cause" (p. 130), though (p. 207) he suggests that "the opportunity for the appearance of mutations is at once given" by change of environment. Beyond this we are no wiser as regards one kind of variation than as regards the other. We are evidently a long way from that "control of the mutative process" which "will, it is hoped, place in our hands the power of originating permanently improved species" (p. x).

W. T. THISELTON-DYER.

PHYSICAL SCIENCE IN THE TIME OF NERO.

Physical Science in the Time of Nero; being a Translation of the "Quæstiones Naturales" of Seneca. By J. Clarke, with notes on the treatise by Sir Archibald Geikie, K.C.B., P.R.S. Pp. liv+368. (London: Macmillan and Co., Ltd., 1910.) Price 10s. net.

THE genius of the Roman people was mainly for action, conquest, and organisation. In the realms of thought they made but few original advances, here showing a striking contrast to the Greeks, whose progress in civilisation some few centuries previously had been intellectual rather than material, and made in art, philosophy, and speculation as to the deeper problems of life and nature. Of course, western nations owe, and have owed, an immense debt to the intellectual advances made by the Greeks, and there seems little danger that this debt will ever be underestimated. But there is reason to fear that full justice may not be done to the scientific progress made by the Romans; and Mr. Clarke's admirable translation of Seneca's "Quæstiones Naturales" comes very opportunely to illustrate its extent.

As Mr. Clarke points out in his introduction, Lucius Annæus Seneca was an exceptionally able man of many aptitudes—rhetorician, advocate, philosopher, author, politician, and for fifteen years tutor first and latterly also *âme damnée* to that monster of iniquity, the Emperor Nero. During his lifetime Seneca must have been best known for his eminence as a politician; during the many years when he was out of imperial favour, and had no share in politics, he devoted himself to philosophy, science, and authorship. As a philosopher he illustrates the eclecticism

of the Stoics, particularly in ethics. It was in ethics that his deepest interest lay. Even in a physical treatise like the "*Quæstiones Naturales*," he often breaks off a scientific discussion in order to improve the occasion by an outburst of orthodox morality à la Mr. Barlow, in which he chastens the excesses of the fashionable society of his day with a gusto that vividly recalls the sermons of a modern fashionable preacher, and with all the energy of an itinerant tub-thumper. In fact, so pure is his puritanism, so moral the morality of his denunciations, that one is almost tempted to disbelieve the known facts of his biography. But if his Stoicism is thus perhaps suspect, no similar accusation can be brought against his honesty as a man of science. "There is considerable internal evidence in the '*Quæstiones Naturales*,'" says his translator, "that his pursuit of such studies was in part an outcome of the true scientific spirit, and that he possessed in no ordinary degree the scientific imagination." He was also an eclectic in his views about the material world, believing it to be built up out of the four elements—fire, air, earth, and water—of Empedocles, Plato, and Aristotle. But he rejected the fifth Aristotelian element, *œvria*, the immaterial *quinta essentia* so misconceived by mediæval philosophers, and he did not hesitate to part company with the Stoics whenever he felt inclined to disagree with their views. Of training as a man of science Seneca had none, for none was available in his day.

No doubt the "*Quæstiones Naturales*," or "Physical Inquiries," were written about and after the year 60 A.D., not long before Seneca's suicide was ordered by Nero; they are in a semi-epistolary style, and dedicated to his friend Lucilius. Their text has suffered much in the process of transmission through the ages; none of the MSS. is earlier than the twelfth century, and much ingenuity has been exercised by their editors (most recently by Prof. Gercke, of Breslau) in rearranging the various portions of the work into the order and form in which Seneca may be supposed to have left them. Originally the work consisted of eight books, two of which, probably ii. and iii., have now become fused into the present book iv. Most of it is taken up with meteorological questions, and consists of discussions as to the nature of meteors, the rainbow, thunder and lightning, winds and the atmosphere, snow, hail, and rain. One book is devoted to the forms of water, another to earthquakes, a third to comets. Seneca's general method is to state what is known or asserted about the phenomenon he is describing, and to give a critical discussion of the explanations—for it is chiefly in the explanations that he is interested—has received, and, finally, to state and establish his own view about its causation.

The science of the ancients rarely advanced beyond the rudimentary stages for two main reasons. The first is the difficulty they always had in understanding that accurate observation and reasoned experiment were either necessary or desirable. The second is the facility with which their nimble minds sought refuge from this hard world of facts in speculation. To them

a theory was as good as a fact, and a theory weighted with the authority of some great philosopher was better than many facts. The chief merit of Seneca as a man of science lies in his recognition of the importance of observation, and of the use of common sense in the interpretation of the observed facts of nature. It is true that many of his observations were faulty, many of his explanations were based on false analogy, many of his arguments are illogical or even ridiculous when viewed in the light of modern knowledge; but in these matters he merely suffered from the disabilities of his age, and his shortcomings are not to be too hardly judged.

The style of the "*Quæstiones Naturales*" is that of the polished orator and rhetorician. Seneca addresses Lucilius directly, and in the heat of argument he often sets up and argues with scientific men of straw whose duty is to advance views foredoomed to demolition. The text, as we have seen, is full of uncertainties and corruptions, but it has been very happily treated by its translator. The English version is most readable, and gives a first-rate reproduction of the varied style; the oratorical questions, the irony, the sarcasm, the occasional poetic afflatus, with which Seneca animated what might have been in other hands a heavy didactic exegesis. Mr. Clarke's skill as a translator is particularly evident in the success with which he has broken up into reasonable fragments the often long and involved sentences of the Latin original. Again, Seneca's habit was to employ important words—"aer" and "spiritus," for example—in several different senses, and, conversely, to express a single idea, such as that of the atmosphere, by a variety of different words in different contexts. The translator appears to be singularly successful in conveying what was Seneca's real meaning in these numerous and difficult passages. In conclusion, it may be added that Sir Archibald Geikie's valuable notes, which take the form of a running commentary on the seven books, and are given at the end of the translation, are of great assistance in the appreciation of Seneca's attainments and limitations. They are written from the point of view of modern science, and do much to show how and why he so often fell into scientific error. The book is well got up and indexed, and may be cordially recommended to all who are interested in Seneca, in the art of translation, or in the history of science. A. J. J.-B.

THE STUDY OF IMMUNITY AND ITS PRACTICAL APPLICATIONS.

Immunity and Specific Therapy. By Dr. W. d'Este Emery. Pp. xiv+448. (London: H. K. Lewis, 1909.) Price 12s. 6d. net.

THE amount of literature bearing on immunity and on the specific therapy of infective diseases which has appeared during the last few years is so great that it is difficult, even for the "specialist," to keep pace with its production. Reviews and summaries on the subject are therefore very needful, and the publication of Dr. Emery's work is opportune.

The book surveys almost the whole field relating to immunity—microbial toxins, antitoxins, bacterio-

lysis, agglutinins, precipitins, phagocytosis, and immunity to bacteria—and though perhaps somewhat more full of detail than the needs of the medical practitioner require, will be of great value to the pathologist and bacteriologist. The subject is dealt with critically and judicially, the various hypotheses are presented to the reader, and divergent views are stated fairly.

The opening chapter of the book gives a good general account of the essentials of immunity. One point we are glad to see the author brings out, viz. the ill effects to the patient of prolonged anæsthesia in surgical operations. It does not seem always to be appreciated that the power of recovery of a patient is, to say the least, jeopardised when anæsthesia is prolonged beyond a certain time.

The account of the interactions between toxin and antitoxin (chapter iv.) contains a clear statement of the hypotheses of Ehrlich, Arrhenius and Madsen, and Bordet, and is concluded with the judicial summary that

"No theory is absolutely sufficient to explain all the phenomena, and soon after each new one is adduced the supporters of the older ones bring forward evidence which renders it untenable. The probability is, at the time of writing, that Ehrlich's views are generally held, and are open to the fewest objections. They are complicated, it is true, and have had to undergo constant modifications as new facts have arisen; but the facts themselves are complicated. Yet it must be confessed that there are some grave objections to its acceptance in its present form, and it may become yet more involved before it can be fully accepted as a complete explanation" (p. 91).

The summary of Ehrlich's "side-chain" hypothesis of the formation of antitoxin (chapter v.) is excellent. Incidentally the definition of a "proteid" is dealt with, and it is suggested as a logical outcome of Ehrlich's hypothesis that proteids might be defined as substances which, when injected into suitable animals, give rise to the production of antibodies; this would then include the toxins, enzymes, &c., substances which do not give the proteid reactions as usually accepted by chemists. At the time of writing, Ford's work on the production of antibody by what is apparently a carbohydrate derived from poisonous fungi had probably not appeared, but, nevertheless, with this possible exception it does appear to be true that all anti-bodies are the result of the action of proteid or proteid-like substances. In the chapter on phagocytosis, opsonins, opsonic determinations, and vaccine treatment are naturally considered at some length. The divergent views on the nature of opsonin are well summarised; the author considers that there appears to be no sufficient evidence for the existence of thermostable opsonin apart from amoceptor, and that if thermolabile opsonin is not complement, complements may play the part of opsonins. The vaccine treatment of infective diseases is dealt with somewhat fully, and the opinion is expressed that "of the practical success of this treatment in certain diseases there can be no doubt," particularly in diseases due to acute infections with staphylococci, pneumococci, *B. coli*, and some other organisms; but as regards tuberculosis only a

moderate degree of success has been obtained by the author.

Dr. Emery evidently holds the opinion that determinations of the opsonic index are not essential for the control of dosage in vaccine treatment. He points out that a patient with a low opsonic index may improve under treatment, fresh lesions may appear when the index is high, and the index may rise greatly just before death, and says:—

"The more carefully the opsonic index is considered, the more certain will it appear that a high index is not an indication of immunity; it neither proves that the lesion is undergoing cure, nor that a fresh infection will not occur. . . . Nor is a low index any proof of lack of immunity, since patients may improve remarkably during a prolonged negative phase" (p. 280).

A chapter is devoted to the colloidal theory of antibodies and its bearing on such phenomena as agglutination and the interactions between toxin and antitoxin, and gives a good account of this difficult subject.

A final chapter deals briefly with the practical applications of immunity research in the treatment of infective diseases.

The book contains a glossary of terms, a useful bibliography, and is well and sufficiently illustrated. A number of small verbal errors somewhat mar the text, but a sheet of "errata" correcting most of them has recently been issued. We can recommend the book as an excellent summary of the voluminous literature on a difficult subject.

R. T. HEWLETT.

THE CARBONISATION OF COAL.

Modern Coking Practice, including the Analysis of Materials and Products. By T. H. Byrom and J. E. Christopher. Pp. xi+156. (London: Crosby Lockwood and Son, 1910.) Price 8s. 6d. net.

IN the preface to this handbook the authors point out that

"The subject of coke manufacture is of rapidly increasing interest and significance, embracing as it does the recovery of valuable bye-products in which scientific control is of the first importance."

This declaration, taken in conjunction with the fact that one of the authors is a Fellow of the Institute of Chemistry, awakens the hope in the reader's mind that at length the technical library has been enriched by a work which might rank with Simmersbach's "Grundlagen der Koks-Chemie," and afford substantial aid to those studying the economic principles of coal distillation, which is one of the most important questions of the present century.

This expectation, however, is doomed to disappointment, as the reader soon finds that the title of the book should have been "Modern Coke-oven Construction and Practice," that all discussion as to the effect of temperature and mass on the distillation of coal and the products yielded is avoided, and that whilst the change in structure from the beehive coke-oven to the modern recovery plant is well dealt with, and the manufacture of sulphate of ammonia receives full attention, yet the subject of tar is dismissed in one page.

In speaking of tar fuel, on p. 5, the authors say:—

"The modern tendency, however, is to distil the tar first, and recover its many valuable constituents such as benzene, naphtha, carbolic acid, naphthalene, creosote, and also the tar colours discovered by Perkin."

This looseness of expression might lead some to believe that the coal-tar colours were a distillate from tar.

A few pages further on solid fuels are subdivided into organic and inorganic, the latter consisting of sulphur, silicon, phosphorus, and aluminium, the latter being credited with giving a heat quite equal to that produced in electric furnaces, a statement which will be doubted by the users of "Thermit."

In the chapters devoted to the construction of the modern form of bye-product recovery coke-oven, the authors are at their best, and this portion is well illustrated with many reproductions of photographs from existing plants, as well as elaborate sections and plans, yet the same fault is to be found as in other parts of the book, that is, the principles which govern the various stages in the process of carbonisation, and the chemical changes taking place during the operations, are ignored, whilst details of mechanical interest only are elaborated.

In the preface the reader is told that the book embodies a series of lectures delivered at a technical college to a class of men engaged on coke-ovens, and, interesting as they must have been to the audience, it cannot be too strongly impressed upon those delivering lectures of this kind that, unless there is given a foundation of scientific facts and theory upon which the practical man can build and evolve original ideas, the value of such lectures must be enormously lessened.

Not only is the theory of carbonisation neglected, but the coke produced during the process of gas manufacture is hardly mentioned, although the gas coke produced in the United Kingdom more than doubles in quantity that made in bye-product recovery plants, the beehive coke-oven, with its wicked waste of tar and sulphate of ammonia, still being the most favoured means of squandering our already depleted coal-measures.

At the present time there is a great opening for an author who, with scientific knowledge of the subject, can gather together the work of Stein, Flack, Richters, Muck, Parry, Thörner, Lunge, Knublauch, and others on the carbonisation of coal, and weave into tangible shape the lines upon which economy of coal, abolition of smoke, increase of manurial ammonium compounds, and enhanced values for our tar products can be obtained.

THE HUMAN CENTRAL NERVOUS SYSTEM.

Voordrachten over den Bouw van het centrale Zenuwstelsel—een Voorbereiding tot de Kliniek der Zenuwziekten. Door Prof. J. W. Langelaan. Pp. vi+485, and 309 text-figures. (Amsterdam: A. Versluys, 1910.)

THIS consists of the course of instruction on the embryology and anatomy of the human nervous system given in Leyden in the sessions 1907-8 and

1908-9 put into the form of a book, which is illustrated with an excellent series of photographs of sections and drawings by Heer G. Koster. It is quite a revelation to find what soft effects of light and shade the artist has obtained with pen and ink, without sacrificing accuracy and clearness, in the production of these admirable illustrations.

The book is subdivided into four sections, dealing respectively with (A) the development of the human central nervous system (pp. 1-98); (B) the nature and histogenesis of the nervous tissues (pp. 99-137); (C) the form of the various parts of the central nervous system (pp. 138-286); and (D) the structure of the central nervous system (pp. 287-485).

The most distinctive section of the book is part A. Part B contains a good and impartial summary of the present state of our knowledge concerning the mode of development and the nature of nerve-fibres and cells, and supplies the reader with a good bibliography. Although parts C and D, on the whole, are excellent accounts of the subjects of which they treat, they present no special features which the student cannot find elsewhere in text-books written in languages more generally understood than Dutch is. Moreover, the text of these sections is not so "up-to-date," nor is the bibliography so satisfactory as those of the early sections.

Section A is a model of the manner in which embryology should be taught to medical students.

It begins with a clear account of the early stages of development of the primate embryo, leading up to the formation of the nervous system, and then describes the history of the further growth and differentiation of the brain and spinal cord in human embryos. Most books on embryology are rendered confusing to the student by the introduction of descriptions of what happens in the chick or the developing rabbit, with tags of miscellaneous information concerning the embryos of other vertebrates, and the plea is urged in support of such a mode of procedure that it is the comparative method. But the use of data culled from comparative anatomy in works on human anatomy can be justified only when they help to elucidate the latter or explain some general principle which cannot be appreciated from the mere study of one vertebrate; unless the information directly serves one of these two purposes it is worse than useless to insert it. One of the great merits of Prof. Langelaan's work is that it gives a straightforward account of the human brain and its development; and no comparative data are inserted in the embryological section except to explain stages in human development which are not known from direct observation of human material; and then he is careful to rely almost exclusively on information obtained from the study of the mammals most nearly related to man that supply the desired facts.

A considerable part of the embryological section of the work is based upon the author's own researches, which are already familiar to readers of *Brain* (1908) and the *Anatomischer Anzeiger* (1908); and this fact gives section A the freshness which springs from first-hand knowledge, in contradistinction to the staleness of conventional errors which

mar all mere compilations, however conscientiously they may have been done.

Although there are a good many errors, both of commission and omission, in this book, and many statements which we cannot endorse, the work is, on the whole, the best elementary text-book on the anatomy of the human nervous system, and it certainly contains the most useful account of the development of the human brain that has appeared in a student's text-book. If it were not for the difficulty of language the book would appeal to a large class of students and medical men. G. E. S.

OUR BOOK SHELF.

The Miners' Guide. By F. P. Mennell. Pp. viii + 196. (London: Gerrards, Ltd., 1909.) Price 4s. net.

THIS little book aims at being a guide to the prospector, and should largely attain its object. It is neither lengthy nor profound, but sketches, lightly, those principles of geology it is desirable that the prospector should be acquainted with.

In discussing the source of metals in lodes the author appears to lean strongly to the theory of lateral secretion, and is at some pains to show how large a quantity of metal may be contained in the rocks of a mineral district, even when barely perceptible traces of its existence can be detected by analysis. He is a firm believer in the underground circulation of meteoric waters as a means of dissolving and concentrating these metals in lodes and other deposits, and seems to doubt the existence of a bary-sphere.

The description, in chapter iii., of the characters of ore bodies is all too short, and chapter iv., which is devoted to prospecting, might also be expanded with advantage; but this is supplemented later by a review of the occurrence of, and prospecting for, gold, silver, platinum, the base metals, and other useful minerals and precious stones. An important feature of this portion of the book is a general account of the uses of the different minerals, and the conditions necessary to be observed in preparing them for the market. Prices and production also receive some attention, and the more important localities are cited. Chapter xi. deals with sampling, and in the space available gives a good description of the operations that must be undertaken, and the methods of computation that must be adopted, to ascertain the average value of a lode sampled. The following statement, however, "As a guide to the possibilities of undeveloped ground, geological knowledge is often worth any amount of sampling, but the miner can only judge from his own experience what scientific knowledge enables the geologist to gauge by the help of theories founded on other people's experience as well as his own," seems to assume a dangerous position and to tend to a reliance on theory, rather than actual testing, to determine the value of any mineral deposit.

The working notes are necessarily fragmentary, dealing as they do with alluvial working, including dredging; lode mining; methods of crushing, cyaniding, &c., in one short chapter. The book, however, contains many useful hints, and is one that should certainly appeal to the prospector in far lands.

The Coccidæ of Ceylon. By E. Ernest Green. Part iv., with 39 plates. Pp. 251 + 344; plates xciv.-cxxxii. (London: Dulau and Co., 1909.)

THE work before us well illustrates the enormous recent development of our knowledge of entomology, for when Mr. Kirby published his "Catalogue of the Described Hemiptera Heteroptera and Homoptera of Ceylon," in the *Journal of the Linnean Society*

(Zoology, vol. xxiv., 1891), he was only able to enumerate seven species of Coccidæ from the island—*Lecanium mangiferae*, Green (1889); *L. coffeae*, Walk. (1852); *L. viride*, Green (1889); *L. nigrum*, Nietn. (1861); *Pseudococcus adonidum*, Linn. (1758); *Coccus (?) floriger*, Walk. (1858), and *C. laniger*, Kirby (1891).

Shortly afterwards, however, Mr. Green took up the systematic study of the Coccidæ in earnest, with such good results that he soon accumulated materials for a monograph of the Coccidæ of Ceylon. At first he estimated that it would probably run to four parts, containing thirty plates each; but now he finds that "the present (fourth) part contains many additional plates, which (with the several supplementary plates) bring the total number up to 135, or fifteen more than the number promised to my subscribers. For the completion of the monograph it will be necessary to bring out a fifth part, of double size, containing from fifty to sixty plates." Even so, considering the rapidity with which material accumulates, we should not be surprised if a further extension, or a speedy supplementary part, may not be found necessary.

But, however this may be, part iv. contains the conclusion of the subfamily Lecaniinæ, with nine genera and nineteen species; and the new subfamily Asterolecaniinae, with six genera, 24 species, and two varieties.

The work is based almost entirely on Mr. Green's personal observations, and a large proportion of the species described and figured are new. We have nothing but praise for the text and letterpress of this monograph of a family of insects which is important both as destructive to vegetation and, in some instances (as in the cochineal insect), as yielding products of considerable commercial value.

Colonsay, one of the Hebrides. Its Plants: their Local Names and Uses. Legends, Ruins, and Place-names. Gaelic Names of Birds, Fishes, &c. Climate, Geological Formation, &c. By Murdoch McNeill. Pp. viii + 216. (Edinburgh: David Douglas, 1910.) Price 2s. 6d. net.

THE main purpose of the author is to publish a list of plants collected during some years' stay on the island, to which he has added general notes on the history, geology, and fauna. The author has been a keen observer of the birds, both migratory and native; among the former are the barnacle goose, pintail duck, and wild swan, while eider-duck and cormorants live on the outlying reefs or unfrequented coast, and guillemots, buzzards, and kestrel nest on the northern shores. In the same localities with the eider-duck are found shoals of seal, both the large grey and common species.

A chapter is devoted to the description of the woods, lochs, and pastures. The lochs are the most interesting botanically. The white water-lily, the common reed, and bottle sedge are the most conspicuous plants in the shallows; species of *Potamogeton* and *Callitriche autumnalis* are abundant in the deeper waters. The enumeration of flowering plants and ferns amounts to 567 species, but this number includes garden escapes. The author has been fortunate in obtaining the cooperation of special authorities on certain genera. Mr. A. Bennet has identified a dozen species of *Potamogeton*, and a similar number of Rubi are given on the authority of Rev. W. M. Rogers. Among the more typical and rare plants are *Spergularia rupestris*, *Lobelia Dortmanni*, *Sedum roseum*, *Myosotis repens* and *Ligusticum scoticum*.

The book is pleasantly written, and contains a considerable amount of observational matter scattered through its pages. The Gaelic names and quotations will only be appreciated by a limited number of readers.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Stability and Efficiency of Kites.

IN NATURE of March 17 Mr. Dines suggests that the instability of kites may be due to changes in the relation of the weight to the velocity of the wind, or to deformation of the kite by excessive pressure, or that there is a critical velocity at which the forms of the stream-lines become so altered that instability results.

My own experience leads to the opinion that deformation by a strong wind is practically the only important cause of instability. At the Blue Hill Observatory, where the conditions for experimenting are unusually severe, the Clayton modification of the Hargrave kite is the only one that can be employed. In this form the longitudinal sticks are continuous from one cell to the other, and the lateral sticks form the front and rear edges of the cells which prevent the fluttering of the cloth unavoidable in kites the rigidity of which depends upon the tension of the covering. The Clayton-Hargrave kite is rigid, but there is no strain or tension anywhere except when flying, and it has proved itself to be sufficiently stable. Relief from sudden and excessive strain is necessary, and to secure this the bridle is made elastic, so that in strong winds the angle of inclination becomes smaller. Thus equipped, the kite is not uniformly efficient in strong winds, for, as the angle of inclination becomes smaller, the pressure of the wind upon the edges of the cells becomes relatively greater, and the altitude is reduced. A normal altitude of 55° to 60° may be lowered to 40° by an increase of wind of 15 to 25 metres per second. If the front cell of the kite is equipped with rigid curved lifting surfaces the efficiency is greatly increased, the mean altitude exceeding 60° , and the loss due to increase of wind is unimportant in velocities up to 25 metres per second.

Some of the lightest of these kites have flown in the strongest winds encountered while experimenting, the velocity in some instances having exceeded 30 metres per second. An interesting example of this kind occurred on April 14 during the international ascension. Two kites, weighing 600 and 850 grams per square metre, and having lifting surfaces of 11 and 7 square metres, respectively, were employed to lift the line. The outer section of the line was 1500 metres of wire having a tensile strength of 140 kilograms, and the next was 2500 metres long, having a tensile strength of 180 kilograms. The large light kite was placed at the outer end of the line, and the other at the junction of the two sections. At a height of 2000 metres, with 3500 metres of line out, two gusts of wind resembling thunder-squalls were encountered, the mean velocity for twenty minutes exceeding 30 metres per second, and the maximum reaching 33. The strain on the line at the ground did not exceed 90 kilograms, and, allowing for the weight of the line, probably did not exceed 110 at the second kite. The pull of the larger kite in a 10-metre wind is usually about 45 kilograms, and that of the smaller about 35, and, allowing for the pressure of the wind on the line, this, apparently, was not greatly exceeded. The large kite will fly in a wind of 5 metres per second, and was perfectly steady in a velocity of 33 metres per second. The pressures corresponding to these velocities are, respectively, 2 and 80 kilograms per square metre of surface exposed normally; hence it seems improbable that a well-made kite could become unstable through disproportionate weight or some unusual property of a high wind. It should be said that the velocities given are "true" velocities, and not to be compared with those from the large Robinson anemometers, in which the factor 3 is employed. The maximum velocity referred to, expressed in English units, becomes 74 miles per hour "true" velocity, 90 when reduced to the U.S. Weather Bureau standard, or about 100 miles per hour when reduced to

the same scale as the Kew pattern when the factor 3 is employed.

In 1900, while comparing different wires for use as kite-lines, I found that, theoretically, the larger wires were the more efficient, although slightly weaker, weight for weight, than the smaller. The reason for this is that the pressure of the wind is more effective upon the small wires than on the large. A No. 10 wire weighing 2.16 kilograms per 1000 metres usually breaks at 85 kilograms. Its diameter is 0.61 mm., and the surface presented to the wind is 1 square metre for each 1650 metres of length. If we wish to double the strength of our line we employ a wire 0.93 mm. in diameter, weighing 5 kilograms per 1000 metres of length. The cross-section, however, has increased only one-half, the surface presented to the wind being 1 square metre for each 1100 metres of length.

An opportunity to secure experimental data did not present itself until January, 1908. Since then, in conducting the monthly kite ascensions at Blue Hill, I have employed small kites flown with small wires, and large kites flown with large wires, to determine the relative efficiency of the two systems. The results show very conclusively that the system of large kites and large wires is the more efficient, not only for the sizes experimented with, but very probably for much larger sizes. The lifting surface of the kites employed has varied from 3 to 13 square metres, and the line has been made up of pieces of wire varying from No. 10, of 85 kilograms, to No. 21, of 235 kilograms, tensile strength.

The opinion, held by many, that large kites are inferior to small kites in meteorological work is not sustained by these experiments. The Clayton-Hargrave kite when built with three sections can be made stronger for the same weight than when made with two or four sections. The increase of weight as the size increases is unimportant in meteorological experiments, for kites with lifting surfaces exceeding 15 square metres need not weigh more than 650 grams per square metre. The ability of these larger kites to withstand high winds apparently is greater than that of small kites, for the large and heavy sticks necessary in the framework, like the large wires, present relatively a smaller cross-section to the wind for a proportionate weight and strength.

Increased stability may be secured by placing two diverging vertical planes in the rear cell of a kite. If these planes are adjustable, the kite may be caused to fly on either side of the mean direction of the wind, or any errors of flight may be corrected.

The entire question of stability appears to be one of eliminating unequal strains and unnecessary resistances.

F. P. FERGUSON.

Hyde Park, Mass., U.S.A., April 20.

I AM much interested in Mr. Fergusson's letter, and his long experience with kites, about double my own, makes me very diffident about expressing an opinion contrary to his.

Doubtless deformation is a very fruitful source of instability, but after carrying out some thousand kite ascents from a steamer and on land, I am of opinion that it is not the only cause. However, my position is that we do not know with certainty the cause of instability, and it is very desirable at the present time that we should know beyond dispute.

I agree with Mr. Fergusson as to the advantages of large kites; they are more stable than small ones, and, as he has shown, since the wind resistance on the wire is the one serious obstacle to reaching great heights, it is obviously desirable to make that resistance small in proportion to the other forces. But there are practical objections. Large kites and thick wire require a stronger and more expensive outfit, and more assistance at starting and landing; also, should an accident occur, the risk of its being serious is far greater.

I do not agree with Mr. Fergusson that the Clayton-Hargrave kite is the only one that can be used when the wind is strong. The conditions in England in the winter are probably more severe than at Blue Hill, and have been particularly severe during the last winter. Nevertheless, the strength of the wind has on no occasion prevented our

flying a kite with non-rigid edges at Pyrton Hill, and we have been fortunate in breaking only one kite in landing it, and in not failing once since last October to bring back the kite to the starting point without accident; also Mr. Cody's kite, which has non-rigid edges, will certainly fly in a strong wind.

Mr. Fergusson states that a kite of 7 square metres surface will exert a pull of 35 kilograms in a wind of 10 metres per second. In English units this is equivalent to 1 lb. per sq. foot of sail area in a wind of $22\frac{1}{2}$ miles per hour. If the whole area were exposed normally to the wind, the pressure or pull would be 53 kilograms, and hence, remembering that the back sails are partially sheltered by the front, and that the angle of incidence is only about 15 degrees, 35 km. seems a very high value. The pull of a diamond-shaped box kite of 7 metres sail area in the same wind is certainly below 15 km. It would be interesting if Mr. Fergusson would tell us how the wind at the kite is measured at Blue Hill. I do not think any anemometer placed in the kite can be trustworthy—one might as well place one close to the roof of a house amongst a set of chimney stacks—and if an anemometer is placed on the wire there is the difficulty of avoiding oscillation and of correct orientation.

I am glad to be able to state that we do not now officially publish in England values of wind velocity based on the factor 3 for the Kew pattern Robinson cups, but on the factor 2.2. This reduces what would have been called 100 to 73; but the values quoted by me in my letter of March 17 are entirely independent of the Robinson anemometer. For reasons fully given in a recent publication of the Meteorological Office (M.O. 202) those values are doubtful, but the evidence is in favour of their being too low rather than too high.

I should like to take this opportunity of replying to Mr. Gold's criticism of the method of measuring wind velocities on a kite in England, namely, by measuring the tension of a piece of cotton carrying a light sphere at the far end, away from, and out of the influence of, the kite (NATURE, April 21). It is true that the surface of the cotton exposed to the wind is comparable with that of the sphere, but the force is for all practical purposes a normal one, since the tangential component is admitted by all to be very small. It follows that the tension of the cotton, neglecting its weight, is the same throughout, just as in the case of the string stretched on a smooth curve given in text-books on mechanics, and hence the tension measured is the tension of the cotton where it is tied to the sphere, and is independent of the length.

W. H. DINES.

A Difference in the Photoelectric Effect caused by Incident and Divergent Light.

RECENT investigations have shown that the ionisation produced by the secondary rays arising from a thin metal plate traversed normally by a primary beam of Röntgen or γ rays is greater on the emergent than on the incident side. The present experiments were made to see if a similar effect could be detected with ultra-violet light.

Thin films of platinum were prepared by sputtering from a platinum kathode on to quartz plates 1 mm. thick. These could be mounted in the centre of two similar brass cylinders so that their planes were perpendicular to the axes of the cylinders. A narrow beam of ultra-violet light from an arc passed down the axis of the two cylinders normally to the plates. The saturation current from the illuminated plates to the cylinders could be measured. The plates could also be turned so that the film side was either away from (position A) or towards the light (position B).

In every experiment two similar plates were used; one was used as a standard to determine the strength of the ultra-violet light, and its position, whether A or B, was unchanged. The other plate was compared with this for each of the two positions alternately. By referring each measurement to the standard plate, the otherwise troublesome variations of the arc were rendered harmless. Unless the films were very thick it was always found that position A gave rise to a relatively greater photoelectric current

than position B, although it was penalised by having to pass through the thickness of the quartz plate.

When no allowance is made for the absorption by the quartz, a very thin film gives 12 per cent. more photoelectric current for the emergent than for the incident light. When the absorption of the quartz is allowed for the difference is increased to 16 per cent.

These results have been confirmed by reversing the direction of the light without altering the position of the plates, and other experiments have been made to ensure that they do not arise from scattered light or other defects in the apparatus. The ratio of the emergent to the incident effect has been determined for a series of films of varying thickness.

This investigation was suggested to me by Prof. O. W. Richardson, and the experiments have been carried out under his direction.

OTTO STUHLMAN, JUN.

Palmer Laboratory, Princeton, N.J., April 26.

A Link in the Evolution of the Bees.

THE ligula or "tongue" of the bees presents two main types, one broad, obtuse, and often emarginate, the other pointed, acute, frequently much elongated. The obtuse-tongued bees have been considered to be the more primitive, and there is no doubt that the most advanced types are long-tongued. The difference between the two groups has seemed so important that at one time (Trans. American Entomological Soc., xxix., p. 185) I entertained the idea that they had no common bee-ancestry, but were derived from different groups of wasps.

Frederick Smith, in 1853, described a new genus of bees from Australia under the name *Meroglossa*. This was based on a male from Port Essington, which had many of the characters of the obtuse-tongued *Prosopis*, but had a pointed, dagger-like tongue. Ashmead, in 1899, placed it in the same group as *Prosopis*, in spite of the tongue; in 1905 (Trans. Amer. Ent. Soc., xxxi., p. 318) I gave an account of Smith's type, remarking that it was "not unlike some *Prosopis*." In 1905 I described a number of Australian species supposed to belong to *Prosopis*, but remarked of one of them (*P. turneriana*) that the mouth-parts did not seem to agree with the genus. I had at that time no material for dissection, but Dr. R. C. L. Perkins had such material, and discovered that several had acute tongues. In Proc. Hawaiian Entom. Soc., October, 1908, he founded the genus *Palaeorhiza* for my *P. perviridis*, with the following interesting remarks:—

"*Palaeorhiza* is evidently represented by many species in Australia. Several have been described as belonging to the genus *Prosopis*, in spite of the fact that the most superficial examination shows that these insects have an acute lanceolate tongue. Hitherto no connecting-link between the blunt-tongued and acute-tongued bees has been recorded, but in *Palaeorhiza* we have a form which, except for the structure of the tongue, would be assigned to the section of *Obtusilingues*. It will therefore be obvious that this section and the *Acutilingues* can no longer be maintained as of great importance, since *Palaeorhiza* must always be associated with *Prosopis*, as the male genital characters, and all other ones, save the lingual, clearly show."

Nevertheless, he proposes for *Palaeorhiza* a distinct family, *Palaeorhizidae*, at the same time suggesting that it should be *Meroglossidae* if *Meroglossa* is allied.

In the course of going over the splendid collection of Australian bees formed by Mr. Rowland E. Turner, now the property of the British Museum, I have been able to examine the structure of a number of species of *Palaeorhiza*. In the first place, I find that *Palaeorhiza* and *Meroglossa* are substantially the same genus; but the truly astonishing thing is that the females have broad, obtuse tongues like *Prosopis*, while the males have sharp, dagger-like tongues! I first discovered this in *P. penetrata*, subsp. *percrassa* (properly *Meroglossa penetrata percrassa*), a black insect with the face of the male canaliculate, much in the manner of the original type of *Meroglossa*. My natural thought was that there must be two species, in spite of every appearance to the contrary. I next took

the undoubted sexes of *Meroglossa parallela* (Ckll.), a metallic insect related to the type of *Palaeorhiza*, and these showed exactly the same thing. I then looked at a new species (*Palaeorhiza* or *Meroglossa melanura*), with a honey-coloured abdomen black at apex, the mesothorax striped with yellow and black, and the base of the metathorax finely longitudinally fluted. In this the sexes were associated without a doubt, and the difference in the tongues was as in the others. Still others were examined, all with the same result. It appears that the female in this genus lacks, or fails to develop, the determiner which represents the pointed apex of the tongue. Another peculiar character, a comb on the first two joints of the maxillary palpi, is common to both sexes of *Meroglossa*.

Another generic name for Australian bees must fall. The study of additional material shows that my *Prosopistemon* is not valid; its type-species must be known as *Prosopis serotina*.

The extraordinary *Pachyprosopis mirabilis* of Perkins, described from N. Queensland, without further data, was taken by Mr. Turner at Mackay in May, 1900.

Fluorescent Absorption.

IN NATURE of January 6 Mr. Burke criticises the conclusions which I drew from my experiments proving that fluorescent absorption does not exist (*Phil. Mag.*, 1909).

The method which I devised was a direct one, and free from all sources of error. I cannot see any point in Mr. Burke's criticism; I used a scheme for making the source of light and the fluorescing absorbing cell intermittent, throwing the flashes either "out-of-step" or "in-step" at will. If the flashes were out-of-step, the light from the source traversed the absorbing cell while it was not fluorescing. This flash entered the eye, and was immediately followed by the flash of fluorescent light from the cell, the source being in darkness during its emission. The total amount of light, or the sum of the two sets of flashes, was the same whether they were "in-step" or "out-of-step," showing that the absorbing power of the cell was not increased by its fluorescence. Mr. Burke now appears to stand alone as a champion of fluorescent absorption, for Nichols and Merritt have recently repeated their work with improved apparatus and methods (one of them being a modification of my stroboscopic method), and have failed to find any trace of the phenomenon.

R. W. WOOD.

Johns Hopkins University, April 28.

Centre of Gravity of Annual Rainfall.

MR. WATT'S *nil admirari* attitude towards the C.G. of annual rainfall is unfortunate, for, notwithstanding his disclaimer in the first sentence, I find that his statement in the last sentence of his letter in NATURE of April 28 is another *a priori* shot! In the Mysore rainfall annual reports of the last fifteen years I have given diagrams of the monthly rainfall of the eight districts as percentages of the yearly totals, but they are not simple, or similar, or symmetrical. Yet year after year there is a close agreement in the C.G., or date round which each year's rainfall balances. *Verb. sat, sap.*

Impure Manganese Di-oxide.

A FEW weeks ago I had occasion to order a quantity of manganese di-oxide for general lecture and laboratory experiments, and we duly received the same from a well-known firm the name of which it would be invidious to mention. Although in colour the manganese di-oxide was normal, we soon found that its chemical properties were very erratic. When mixed with potassium chlorate and heated gently, the mass inflamed inside the flask, and a reaction proceeded with explosive violence, resulting in the formation of clouds of smoky gas relatively poor in oxygen.

When warmed with concentrated hydrochloric acid the action was unusually vigorous, and an inferior grade of chlorine was evolved possessed of a curious odour resembling that of euchlorine. The black colour of the powder rapidly disappeared, yielding a yellow solution, and a white, insoluble residue, which, from its voluminous appearance, suggested silica.

One of my senior students, Mr. William Davison, thereupon analysed the di-oxide, and obtained the following results:—

	Per cent.
Manganese di-oxide	60.06
Antimonious oxide	33.64
Silica	2.20
Ferric oxide	3.00
Arsenious oxide	trace
Sulphur	trace
Moisture	1.05
	99.95

That this was a case of wilful adulteration I do not suppose for a moment; but it seems desirable to direct the attention of teachers and others to the possibility of such a common and cheap article as manganese di-oxide being sold, not only in an impure form, but in one which it is positively dangerous to use with potassium chlorate for such a simple and universal experiment as the preparation of oxygen.

J. NEWTON FRIEND.

The Technical College, Darlington, May 6.

BRITISH NEW GUINEA.

COLONEL MACKAY was chairman of a Royal Commission appointed to proceed from Australia to inquire into the present conditions of the territory now known as British New Guinea. As such, he proceeded along the south coast of the island to its eastern extremity, then visited the D'Entrecasteaux and other groups in the offing, subsequently proceeding along the north coast to Buna Bay. Here he left the sea and struck inland to visit the Yodda Goldfield, returning overland to Port Moresby. This was the most arduous and interesting part of his journey, for the Owen Stanley Mountains, which here reach about 7000 feet, had to be crossed. Apparently the range really consisted of a series of more or less parallel ridges, up and down which the party was scrambling for seventeen days, camping during much of the time in tropical rain forest.

It is the record of the above trip which "Across Papua" presents to us in pleasantly written form. The expedition was not in any way a scientific one, but the author shows that he has considerable powers of observation. He notes "the absence of stone on the higher ridges, and the extreme narrowness of their root-strewn, moss-carpeted crests. How also, as we approached the higher altitudes, lichen and moss gradually enveloped the timber until they covered limbs and leaves alike; but what impressed me most was the serene calm that reigned over all, for I heard no crash of fierce or fearful animal, no sound of human voice, no song of radiant bird in all that kingdom of mist and sunshine, of sparkling dew-gems, and immemorial silence."

The truth of this traveller's description we know well, but what wealth it suggests to the tropical naturalist—the enormous variety of plants which make up such a forest, each with its peculiar insects, many lizards and frogs showing quite peculiar adaptations to their damp environment, peculiar land shells on every ridge. The natives live on the lower slopes, but seem to be less cannibal and of better stock than

1 "Across Papua." Being an Account of a Voyage Round, and a March Across, the Territory of Papua with the Royal Commission. By Colonel Kenneth Mackay, C.B. Pp. xvi+192. (London: Witherby and Co.) Price 7s. 6d. net.

those of the coast. Here would be an unique chance. At present the country is untouched, but in a dozen years it may well be opened up, and if gold be found all would fall before the axe.

Colonel Mackay's observations suggest much work, too, for the ethnologist. The Yodda Goldfields have brought to light red pottery with designs, and stone bowls with patterns on their rims, indicating that the country was once occupied by a race superior to the present Papuans. The latter, too, even on the coast, are interesting enough, but they are fast getting spoilt by the missionaries and traders. Those of the hills near "the gardens of the ghosts" are still untouched, making mummies of their dead, for whom they have a supreme respect. The splay-footed people near Cape Nelson should also be well worth a visit.

It is rightly pointed out that no tropical country can remain long undeveloped, owing to the teeming millions of the overcrowded East, and British New Guinea, to be secure, must be opened up. Coco-nuts, coffee, cocoa, and rubber will probably in a generation cover most of the available land, while gold may

ried on by some of the more energetic of the county committees. A few of the experiments deal with animals but by far the greater number with crops, presumably because the expense is less; they serve a variety of useful purposes, arousing an interest in practical agriculture, showing the farmer (if, indeed, he needs showing) that artificial manures will give increases in crop, and, finally, they may furnish very useful material for the county agricultural lecturers.

Field experiments are perhaps the most difficult of all experiments to interpret. The growth of plants is influenced by so many factors—temperature, water supply, food supply, &c.—that small variations in the conditions may lead to marked differences in result. The soil is a very complex mixture and not uncommonly shows some variation even within the limits of a single field. Even if the soil itself is tolerably uniform a slope may introduce irregularities. The influence of a tree or hedge makes itself felt for some distance, while the effect of the previous treatment of the ground is often very great. Of course, if the intention is mainly to get up an interest in agricul-

tural trials these considerations are of little moment, but they assume great importance where it is desired to give definite information about the effect of manures on the crops. A perusal of the reports before us leaves a rather mixed impression. There has been a vast amount of work done, and much industry and energy have been displayed, but it is not always clear that the experimenters have grasped the first principles of the art of making experiments. In no case is the experimental error indicated, nor can we find it has been ascertained; indeed, so far as we know, it is only at Rothamsted that the determination is made, and there, where all the conditions are favourable and the workers thoroughly competent, it amounts to 10 per cent.

In the Sussex experiments a number of plots were laid out on each of twenty farms and received various combinations of artificial manures. As the experiments have only gone on for one year it is impossible to draw any definite conclusion, so great is the disturbing effect of season. In the discussion all the results have been averaged, in spite of the fact that the soil varied from a chalk loam in some centres to a heavy clay probably destitute of chalk in others. It is, of course, not legitimate to take an average of incomparable quantities, and we suggest that more useful results would be obtained by arranging the soils into strictly comparable groups.

The Northumberland experiments have gone on for a longer time and averages for several years are given, so that the effect of season is more or less eliminated. They are well known as illustrating the value of basic slag in improving poor clay pastures. On the light soils potash has been found very effective. A more detailed study could be made if the

Native Trading Vessels of Port Moresby. From "Across Papua."

cause still more rapid growth. The book before us will doubtless assist this development, as the conditions and climate are shown to be by no means worse than those of Ceylon or the Straits not many years ago. Perhaps this is the aim of the book, but we confess that we desire the more solid observations of a trained naturalist. Unfortunately, such have not always the brightness and sense of humour possessed by Colonel Mackay. J. S. G.

SOME RECENT AGRICULTURAL FIELD TRIALS.¹

SINCE the application of the "whisky" money to agricultural education in Great Britain a considerable amount of experimental work has been carried

¹ West of Scotland Agricultural College, Reports on Experiments; Durham County Council Education Committee, Report of Dairy Investigations; Northumberland Education Committee, Guide to Experiments for 1909; East Sussex Education Committee, Experiments on Meadow Hay; Agricultural Students' Gazette, Experiments on Pasture; Journal of the Department of Agriculture and Technical Instruction for Ireland.

error of the experiment was known. Thus we are informed that the most effective slags are those in which a high percentage of the phosphates present dissolves in citric acid. On looking at the figures, however, we find that the extreme difference in yield is little more than 10 per cent., which is probably well within the experimental error.

Percentage of phosphoric acid soluble

in 2% citric acid	93.1 ... 74.2 ... 66.1
Hay obtained, in cwt.	9½ ... 9½ ... 8

Again, one of the conclusions drawn from the rotation experiments is that sulphate of ammonia has had distinctly exhausting results except on the crop to which it was applied. The fall in yield, however, is only 7 per cent. In neither case is the conclusion justified by the evidence.

Among the West of Scotland reports is one in which the new nitrogen manures, cyanamide and basic calcium nitrate, are shown to have given valuable returns. Most of the reports deal with different varieties of oats and potatoes. General conclusions cannot be drawn since we are told "that the character of the seasons was found to affect the relative as well as the absolute productiveness of the oat varieties in an astonishing degree." A number of measurements of the straw and grain of these different varieties are recorded, and a good deal of other information has been collected. In the experiments on the manuring of potatoes it generally happened that the best and most profitable crops were obtained after applying ten tons of farmyard manure per acre along with a complete dressing of superphosphate, sulphate of potash, and sulphate of ammonia, a result agreeing with others obtained elsewhere.

The Cirencester experiments on pasture have been going on for eighteen years or more, and show some interesting results worth working up in greater detail, since they differ in several ways from those obtained at Rothamsted. Thus superphosphates alone gave better results than no manure and also encouraged clover; the plot receiving sodium nitrate alone was poor, tufted, and worse than the plot receiving ammonium sulphate alone; *Ustilago* was most prevalent on the plot receiving kainit alone.

The Irish experiments on winter milk production and winter rearing of calves were made to see if either of these schemes would pay. At present Ireland places but little butter on the market during winter, with the result that the summer trade suffers. It is considered that higher prices would be realised in summer if the winter trade could be developed. Satisfactory financial results were obtained. The reports derive considerable interest from the tables of costs, a welcome though rather unusual feature in experiments of this sort.

The Durham dairy investigations were intended to settle certain practical points such as the feeding of concentrated food on pasture and the relative value of moderate and heavy rations for milch cows. It was shown that an increase in food caused an increase, but not a proportionate increase, in milk yield, a result in accordance with Holtmark's very complete investigations in Norway. Brewers' grains were, as usual, found to increase milk production, but no attempts were made to ascertain whether, as is sometimes asserted, they have any physiological action. This is all the more unfortunate since in a second series of experiments the materials for this study seem to have been at hand, the increase in milk yield amounting in the two experiments only to 0.7 per cent. and 3.3 per cent. There is nothing to indicate the magnitude of the experimental error, but as only five cows were taken in each set it cannot have been less than the quantities recorded. The only legitimate

conclusion is that brewers' grains in this particular instance failed to produce their usual effect. Here it is just the experiment that the trained investigator would have welcomed in order to follow up the subject. But the author of the bulletin not only misses the opportunity, but draws the wholly unwarrantable conclusion that a moderate allowance of 20 lb. of brewers' grains per day has the effect "of increasing, at all events for a certain period, the daily yield of milk."

We have directed attention to these defects because they recur not infrequently in the work carried on in the counties. Unfortunately some of our agricultural experimenters have a habit of ignoring or explaining away an unexpected result. If only they would learn that to follow up an unexpected result is the beginning of wisdom in research work, we might make much greater progress in agricultural science than we are doing now. Of course, it may be urged that the object of the experiment is simply to arouse interest or to demonstrate some well-ascertained fact, so that a scientific method is not necessary. Even if the experiments have served the purpose for which they were intended it is nevertheless much to be desired that the experimenters should realise their opportunities and make more than they are doing out of their work.

THE TOTAL SOLAR ECLIPSE, MAY 9, 1910

UNFORTUNATELY, the news to hand regarding the observation of this eclipse, visible in Tasmania, tells us that all the observing parties experienced unfavourable weather conditions. According to the *Times* of May 10, a Reuter telegram from Hobart (Tasmania), dated the previous day, states, "The observation of the total eclipse of the sun from Bruny Island has failed, owing to dense cloud and rain. Mr. Baracchi, the Victorian Government astronomer, reports that the darkness during the period of totality might be compared with that of a starlit night."

A cablegram from Mr. McClean, dated May 10, shows that this party also met with no success, on account of bad weather. The message was as follows:—"Eclipse invisible, steady rain all day. Only two fine days last fortnight. Terrific gales and thunder frequent."

While it is most disappointing that no observation of this eclipse have been secured, yet it was rather anticipated that such would be the case, owing to the unfavourable time of the year for satisfactory weather conditions. Nevertheless, Mr. McClean deserves high praise for getting a party together, with a fine outfit of instruments, and going so far to make the attempt to secure observations. While he returns on the *Orvieta*, which leaves Melbourne on May 1, he has made arrangements to leave all his instruments out there so that he can pick them up for the total eclipse of next year. This eclipse will be visible from some of the islands in the western Pacific but it is not yet settled which particular one will form the basis of operations.

The last mail from Australia has brought some details as to the station which Mr. McClean is just leaving and the preparations he made, and it is hoped that these will be published in a subsequent number of *NATURE*.

W. J. S. LOCKYER.

PROF. E. F. W. PFLÜGER.

THE name of Pflüger has been made known to many generations of students as belonging to some inhuman agency by which, to their confusion and vexation, an edict was enacted known as "Pflüger's law." To how many of those students has the human picture ever been presented of the untiring

young *privat-docent*, working alone in his single room night after night for two years without an interruption until, in 1859, he published his accumulated results in a bulky volume, "*Untersuchungen ueber der Physiologie des Elektrotonus*," Berlin, 1859?

By the side of this picture of the active young searcher in the 'fifties of last century might be placed a picture of the no less active learner of the 'nineties who, at the age of seventy, with forty years of service behind him as professor of physiology in the University of Bonn, and with no worldly reward in front of him of money or position or of fame, day by day and month by month carried out with his own hand the mechanical *minutiae* of daily quantitative estimation of nitrogen necessary to satisfy his mind as to the balance sheet of nitrogen of a dog under physiological conditions strictly supervised by himself, and, as is shown by the 131 volumes of Pflüger's *Archiv*, of which the first volume appeared in 1868 and the 131st in 1910. His faithful service to physiology continued for ten years longer, to the fifty-first year of his ordinary professorship, to the eighty-first year of his life.

Eduard Friedrich Wilhelm Pflüger, born in 1829, a pupil of Johannes Müller, is the last of the great German school of physiological and biological workers—Haeckel, Lieberkühn, Du Bois Reymond, Henle, Ludwig, Brücke, Helmholtz, Pflüger.

Pflüger lived a retired life, devoted to his work in the laboratory and in the library, which he hardly ever left, and in which he did not welcome the interruption of the visitor; no one admitted except on business might well have been the inscription upon his door, and he was never seen at physiological congresses. I count among one of the pleasantest recollections of my life a day spent in Pflüger's laboratory with Pflüger himself and Heinrich Herz, whose simple demonstration of Maxwell's forecast had been made in the previous year, and whom death so soon cut short. We spent the day watching the movements of Lippmann's capillary electrometer, and the time passed unnoticed; there was no inhumanity in connection with the author of Pflüger's law when the accuracy of a physiological assertion of fact was to be scrutinised.

To the scientific world Pflüger's permanent monument consists in the 131 volumes of Pflüger's *Archiv*. Many workmen have contributed to that monument, and, among the mass of contributions, the work of Pflüger himself stands good as well and truly laid. The mechanism of spinal action in the frog, and his law of reflex action as studied upon the decapitated animal, were his earliest subjects of study, and are to-day still classical. We cannot discuss the mechanism of nervous coordination without at once appealing to the experiments of Pflüger and the decapitated frog more than fifty years ago, in preface to our discussion of the experiments of Sherrington on the spinal mammal which belongs to the last decade.

The tenth volume of Pflüger's *Archiv* (1875), containing his paper, "*Ueber die Physiologische Verbrennung in den lebendigen Organismen*," has played an important part in our knowledge and notions as to the chemical respiration of the tissues.

Pflüger's bloodless and salted frog continuing to discharge CO_2 in an atmosphere of nitrogen or in *vacuo* is clear evidence that CO_2 is not due to the immediate action of oxygen, but that it is formed from the dissociation of some storage compound, or, as Pflüger expressed it, previously absorbed oxygen has helped to wind up the physiological clock, the CO_2 discharged at the moment is a sign that the clock is running down. In discussing the latest contribution to our knowledge of this subject, those, for instance, brought out by Leonard Hill as regards the

beneficial effect of oxygen upon muscular work, we are obliged to refer to Pflüger's teaching.

Nutrition, its debtor and creditor account in the body in terms of nitrogen and of carbon; glycogen, its relation to carbohydrate antecedent and its questionable relation to protein antecedents; fat, its absorption, relation to carbohydrate, the problem of diabetes and the origin of diabetic sugar, formed the principal field of Pflüger's unceasing labours during the last twenty-five years of his life.

Pflüger died on March 17, aged eighty-one, at the end of over sixty years of single-minded and unswerving devotion as a student of physiology, fifty years of which were spent as ordinary professor of physiology in the University of Bonn.

A. D. WALLER.

NOTES.

IN consequence of the lamented death of the King, and out of respect to his memory, many scientific meetings and other functions have been postponed or cancelled. The *soirée* of the Royal Society, announced for May 25, will not take place. The meetings of the society will not be resumed until May 26. The president of the Royal Institution has decided that the lectures and evening meetings be discontinued until further notice. The anniversary dinner of the Royal Geographical Society, which was arranged for May 23, will not be held; the anniversary meeting will be held as arranged, at 3 p.m. The meeting of the Royal Meteorological Society which had been fixed for Wednesday, May 18, has been postponed to Wednesday, May 25.

WE notice with regret the announcement of the death of Prof. S. Cannizzaro, Foreign Member of the Royal Society and professor of chemistry in the University of Rome, at eighty-three years of age.

At the meeting of the Royal Society on May 5 the following candidates for fellowship were elected into the society:—Mr. J. Barcroft, Prof. G. C. Bourne, Prof. A. P. Coleman, Dr. F. A. Dixey, Dr. L. N. G. Filon, Mr. A. Fowler, Dr. A. E. Garrod, Mr. G. H. Hardy, Dr. J. A. Harker, Prof. J. T. Hewitt, Prof. B. Hopkinson, Dr. A. Lapworth, Lieut.-Colonel Sir W. B. Leishman, Mr. H. G. Plimmer, and Mr. F. Soddy.

Now that our returning summer migrants are being eagerly looked out for, and the arrival of many of them has been recorded during the last few weeks, the question arises in the minds of many people, "Do the same individual birds which nested last year come back to nest in the same place?" This is a question, of course, which might be equally well asked of our "resident" birds, but in the case of migrants, such as the swallow, which we know for certain does not winter anywhere north of Africa, actual proof that the same individual returns after its long journey to and fro, and its sojourn in its far off winter quarters, to the very same spot in which it nested the year before is sensational. Such proof in the case of one swallow, in any case, is just to hand. Dr. C. B. Ticehurst records the following in the last number of *British Birds*:—"On April 12, 1910, the first swallow (*Hirundo rustica*) was seen at 4 p.m. passing the house at Huntbourne, High Halden, Kent, which lies in the line of a small migration-route; at 6 p.m. a small flight of swallows passed over to the north, and from it four birds separated, and after flying round the house and settling on the chimney-pots, finally went to roost in a shed where two pairs bred last year. Two days afterwards I caught a

swallow at roost in this shed, almost certainly one of those that arrived on April 12, and found it was one which my sister had caught and ringed as an adult bird on May 8, 1909, the bird having come down one of the chimneys into one of the rooms. I may note that there was no mark or injury of any kind on the leg which bore the ring." The system of marking birds by aluminium rings will no doubt teach us much that we cannot learn by any other means. Last year more than 2000 birds were "ringed" by readers of Mr. H. F. Witherby's magazine *British Birds*, and this year at least double that number will be "ringed." Each ring bears a separate number as well as the inscription "Witherby, High Holborn, London," and careful details are kept of the date and place at which each bird was marked. Should any of these ringed birds fall into the hands of any readers of NATURE, Mr. Witherby would be glad to be informed of the date and place of the capture and the number on the ring.

PROF. WALTER NERNST, director of the Physical Chemistry Institute in the University of Berlin, has been elected an honorary member of the Manchester Literary and Philosophical Society.

AN International Conference will meet in Paris on May 18 to consider the questions raised by the development of aerial navigation, with the object of arriving at an international agreement with respect to them. Most of the European Powers will be represented. Delegates to represent the United Kingdom have been nominated by the Admiralty, the Army Council, the Board of Trade, and the Secretary of State for the Home Department.

THE prize of 20*l.* recently offered by the Scottish Meteorological Society for the best essay on a meteorological subject has been awarded by the council of the society to Mr. David MacOwan, of Edinburgh University, for an essay on "Atmospheric Electricity." The competition, it may be recalled, was open to students of the Scottish universities and to graduates of not more than five years' standing.

DR. AND MRS. SELIGMANN have returned from their first exploratory ethnological survey of the Anglo-Egyptian Sudan, to which they were appointed by the Anglo-Egyptian Government. They studied the hitherto uninvestigated Nubas of southern Kordofan, and the Shilluks, Dinkas, and Shir of the White Nile. A short time was spent between the White and Blue Niles, where a Neolithic site was discovered. Observations were made on the sociology and religion of various tribes, and some anthropometrical data were obtained, especially of the Nubas.

AT the meeting of the American Philosophical Society on April 23, the following foreign members were elected:—Prof. A. von Meyer, Madame Curie, Sir David Gill, K.C.B., Prof. E. Meyer, and Prof. C. E. Picard. We learn from *Science* that members of the U.S. National Academy of Sciences have been elected as follows:—Prof. F. R. Moulton, Prof. W. A. Noyes, Mr. T. B. Osborne, Prof. C. Schuchert, Prof. D. H. Campbell, Prof. J. Loeb, and Prof. J. Dewey. Dr. G. E. Hale has been elected foreign secretary of the academy, to succeed the late Prof. Alexander Agassiz. The Draper medal has been conferred on Dr. C. G. Abbot, director of the Astrophysical Observatory of the Smithsonian Institution.

THE Royal College of Physicians announces that the next award of the Weber-Parkes prize of 150 guineas and a silver medal will be made in 1912, and that the adjudicators have selected as the subject of the essay "The Influence of Mixed and Secondary Infections upon Pul-

monary Tuberculosis in Man, and the Measures, Preventive and Curative, for dealing with Them." The Croonian lectures of the college will be delivered in June next by Dr. F. W. Andrewes, the Harveian oration in October by Dr. H. B. Donkin, the Bradshaw lecture by Dr. G. N. Pitt, the FitzPatrick lectures by Sir T. Clifford Allbutt, and the Horace Dobell lecture by Dr. W. Bulloch.

THE annual autumn meeting of the Institute of Metals will be held in Glasgow on September 21–22, on which days papers of scientific and practical interest will be read and visits made to works of metallurgical interest. An influential local committee, of which Prof. A. Barr is chairman and Dr. Cecil H. Desch is honorary secretary, has already been formed to carry out the necessary arrangements, of which further notice will be given in due course. There has been established at the offices of the institute a pathological museum for specimens of metals and alloys, the first contributions to the museum having been received from the president, Sir Gerard A. Muntz, Bart. This museum, which is the only one of its kind, ought to be of great service to all interested in the metallurgy of the non-ferrous metals, as it is intended that it shall contain specimens showing the various ways in which such metals as copper, brass, aluminium, &c., can fail either as a result of faulty manufacture or of improper usage.

A REUTER message of May 5 from San Juan del Sur, Nicaragua, stated that Cartago, Costa Rica, was practically destroyed by an earthquake at 6.30 p.m. on May 4. Five Central American Republics reported earthquake shocks. The *Times* Washington correspondent says that though Costa Rica is supposed to be the southern limit of the earthquake zone, the discussion has again commenced as to whether a sea-level canal would not have been more stable than the lock type for the Panama Canal now under construction. According to Reuter, two hours after the shock a brilliant meteor passed over the Costa Rica-Nicaraguan frontier, leaving a luminous track behind it, and augmenting the fears of the populace. As in many other cases, this earthquake occurred as the moon was approaching perigee on May 8 and conjunction on May 9, so that the conditions were favourable to deformation of the earth's crust.

AN International Congress in Naval Architecture and Marine Engineering will be held in London on July 4–8. From a preliminary programme issued by the Institution of Naval Architects we learn that there will be a reception on the evening of July 4, and that the congress will be opened formally on Tuesday, July 5. The mornings of July 6–8 will be devoted to the reading and discussion of papers in the halls of the Institution of Civil Engineers and the Institution of Mechanical Engineers. The programme will include, among others, papers contributed by Admiral Sir Cyprian Bridge, G.C.B., Sir Andrew Noble, Bart., K.C.B., Sir W. H. White, K.C.B., Sir Philip Watts, K.C.B., the Hon. C. A. Parsons, C.B.; Italy, Colonel G. Russo; Japan, Admiral Kondo, I.J.N., Count Shiba, and Prof. Terano; Germany, Dr. O. Schlick and Prof. Flamin; and France, Prof. A. Rateau.

THE fifteenth annual congress of the South-eastern Union of Scientific Societies will be held at Guildford on June 8–11 under the presidency of Prof. E. A. Gardner, Yates professor of archaeology at University College, London. The presidential address will be delivered on the evening of June 9. There will be a reception by the Mayor on the evening of Wednesday, June 8, followed by the illumination of the Castle grounds, by the Mayor and Corporation, at whose invitation the union will meet at Guildford.

Papers will be read by Mr. Henry Bury, on the relation of the river Wey to the Blackwater and the Arun; Mr. E. A. Martin, on results of dewpond investigation; Mr. J. G. N. Clift, on the Pilgrims' Way between Farnham and Albury; Dr. W. Martin, the interpretation of maps of the sixteenth and seventeenth centuries; Dr. Vaughan Cornish, waves in sand and snow; Mr. J. W. Tutt, colour in insects; Mr. A. R. Horwood, the extinction of cryptogamous plants; and on Saturday evening, June 11 (after the congress), Mr. F. Enock will lecture on aquatic auto-crats and fairies. There will be several excursions and receptions, and a loan museum, which promises to be of exceptional interest. The local secretary is Mr. Frank Lasham, 61 High Street, Guildford, who will send further particulars on inquiry.

In the issue of the *Archæological and Ethnological Publications of the University of California* for March Mr. T. T. Waterman gives an elaborate account of the ritual of the Diegueño, or, as they call themselves, the Kawakipai, tribe occupying the extreme south of the peninsula. It is remarkable that they have a distinctive cultus of their own, bearing only a slight resemblance to that of their blood-kin the Mohave, or their immediate neighbours the Luiseno. These rites depend little upon their belief in spirit agency. They are based on one or other of two conceptions. The first is that in early infancy, and also at adolescence, persons of both sexes are in a condition of peculiar receptivity, children and young men and women being specially liable to external influences, both good and evil, the former being encouraged, the latter repelled by appropriate ceremonies. The second conception is the belief in the continued existence of the soul after death. Hence their mourning customs depend upon the fear of injury from the spirits of the dead, whom they endeavour to propitiate by various means, such, for instance, as by burning the goods of the dead man so that his property, in an etherealised form, may pass on for his use to the world of spirits.

DR. COMANDON gives details of the application of the kinematograph to the photography of micro-organisms in a paper published in the *Bulletin de la Société d'Encouragement pour l'Industrie nationale* (T. 113, No. 3, p. 318). Dark-ground illumination was adopted with sixteen views per second, the exposure being $1/32$ of a second. Such objects as trypanosomes and spirilla in blood seem to lend themselves well to the method. It is to be noted that Mr. Duncan in this country several months ago had taken kinematograph views of the circulation of the blood in the frog's web, &c.

THE *Bulletin of the Johns Hopkins Hospital* for March (xxi., No. 228) contains several papers of scientific interest, notably one by Major F. Russell (Medical Corps, U.S. Army) on anti-typhoid vaccination. No untoward results occurred in a series of 3640 vaccinations, and the author believes that the procedure undoubtedly protects to a very great extent against the disease, and is a useful adjunct to other prophylactic measures. In the April number of the *Bulletin* (No. 229) Drs. Marine and Zenhart make the interesting observation of the occurrence of gôitre (active thyroid hyperplasia) in fish. The fish were principally pike and bass of Lake Erie, and it is of interest that, in the same district, human gôitre is prevalent, suggesting that the disease is in some way associated with water, an hypothesis long held in connection with gôitre in man.

THE *Bulletins of the Sleeping Sickness Bureau* for March and April (vol. ii., Nos. 15 and 16) contain the usual useful summary of investigations on trypanosomes, sleeping-sick-

ness news, &c. The latter number contains a translation of an important memoir by Dr. Carlos Chagas on the new human trypanosome discovered in Brazil, and already referred to in *NATURE* (vol. lxxxi., 1909, p. 46). The parasite seems to be conveyed by a species of bug (probably *Conorhinus megistus*, Burm.), the developmental cycle occupying a period of at least eight days. Monkeys and small animals are easily infected. The record of human cases is at present meagre; in fact, laboratory work in this case seems to have outpaced the clinical. The Bureau has also issued a "subject-index" to the "Bibliography of Trypanosomes," with corrigenda, compiled by Mr. C. A. Thimm.

SOME experiments described by Mr. G. T. Atkinson in the last number of the *Journal of the Marine Biological Association* will be of interest to naturalists engaged in fishery research work. In a previous number of the same journal Mr. Atkinson showed that the plaice taken from the recently exploited fishing grounds in the Barentz Sea has a much slower growth-rate than similar fish in the North Sea, and also that the males and females did not become mature until much older than in home waters. In the course of a recent voyage to the Barentz Sea in a Hull steam trawler, Mr. Atkinson brought back a number of living plaice, and marked and liberated these fish in the North Sea in the vicinity of the Dogger Bank. The experiment was highly successful, and in the course of a year about half the plaice had been recaptured. The growth was very rapid when compared with that of normal North Sea plaice, and there was a great improvement in the "condition," this always having been characteristically poor in plaice caught in the Barentz Sea and in Icelandic waters. Such experiments as these point to the possibility of a future rational regulation of the sea-fisheries. Traditional methods of the control of the industry—restriction of fishing gear, fishing apparatus, inspection, and the like—have proved to be rather futile proceedings, and investigations such as that now under notice point to the practicability of the actual cultivation of the truly sea-fishes. It is pointed out by Mr. Atkinson that not only plaice, but even the valuable halibut, may possibly be transplanted into the North Sea, and that even such comparatively expensive operations as these are likely to be would be better economy than glutting the market with plaice of such poor quality that they sell for less than one-tenth the price of good North Sea fish, while many have actually had to be used for manure.

AN important contribution to the vexed question of the cytology of yeast is made in a beautifully illustrated paper published in the *Annals of Botany* (January), by Messrs. Wager and Peniston. In general confirmation of the earlier work of Mr. Wager, the authors regard the nuclear apparatus of the cell as consisting of the characteristic vacuole, which is so prominent a feature of this organism, together with a nucleolus, which is a homogeneous spherical or oval body lying outside, but in close contact with, the vacuole, and consisting of a plastin-like substance having very little affinity for nuclear stains. The vacuole contains a clear sap and a nuclear network, and both this and the nucleolus may become more or less impregnated with chromatin. This occurs to the greatest degree during the period of highest fermentative activity, and at the same time the chromatin, previously diffused throughout the cytoplasm, disappears. Other remarkable changes in the nuclear apparatus also accompany the process of fermentation, and it is clear that the nucleus is actively concerned in the phenomenon. In bud formation the nucleolus divides amitotically, and one portion passes into

the daughter-cell, together with a portion of the vacuole and chromatin. In spore formation the vacuole disappears, and the nucleolus then divides, forming two nearly equal portions, between which the granular chromatin is shared, and which again divide. Volutin granules occur in the cytoplasm and vacuole, and glycogen is deposited in vacuoles in the cytoplasm, and appears and disappears with astonishing rapidity under varying conditions of nutrition.

AN account by Mr. F. Pitcher of Victorian vegetation in the Melbourne Botanic Gardens, which appears in the *Victorian Naturalist* (vol. xxvii., No. 11), was prepared with the three-fold object of pointing out a few specimens of trees dating back to pre-settlement days, supplying a list of native plants under cultivation in the garden, and recommending a few of these as suitable for general cultivation. Of the last, the small flowering shrubs, for the greenhouse, are *Bauera rubioides*, *Bossiaea cinerea*, *Grevillea ericifolia*, *Hibbertia stricta*, *Leucopogon virgatus*, and *Tetratheca ciliata*.

AMONG the remarkable instances of plant dispersion cited by the Rev. G. Henslow in a lecture addressed to the fellows of the Royal Horticultural Society, the most striking is that of *Oxalis cernua*. This is a bulbous plant, indigenous to South Africa, that has spread to the Bermudas, Canaries, and Madeira, as well as along the north and south coasts of the Mediterranean. It appears to have been originally introduced to Malta, where it now carpets roadsides, covers old walls, and is generally ubiquitous. The plant in its native habitat is trimorphic, but in Malta and along the Mediterranean only one, the short-styled, form occurs, so that propagation is effected entirely by bulbs, borne on thread-like stems that proceed from the parent plant. In rich soil the stems may also grow above ground, forming runners. Further details will be found in the journal of the society (vol. xxxv., part iii.), where the lecture is published.

THE Bureau of Entomology of the United States Department of Agriculture adopts the very useful plan of issuing bulletins in which full accounts are given of the various insect pests troublesome to farmers, market gardeners, and fruit growers. Mr. Webster describes the lesser clover-leaf weevil (*Phytonomus nigrirostris*, Fab.), a fairly common European insect that appears to have got into the States some forty years ago, but is not yet very widely distributed there. It is, however, capable of doing so much damage if once it is thoroughly established that a careful watch is rightly being kept. A fungus (*Empusa* [*Entomophthora*] *sphaerosperma*) was found to destroy the pupæ. Mr. Phillips deals with the slender seed-corn ground-beetle (*Clivina impressifrons*, Lec.), which attacks recently planted maize seed in swampy, peaty soils. It is a native of the eastern States, and of the whole genus, is the only species that lives on plants, the others being carnivorous, according to our present knowledge. Dr. Chittenden describes the parsnip-leaf miner (*Acidia fratria*,

Loew.); the parsley-stalk weevil (*Listronotus latiusculus*, Boh.), an insect usually associated with aquatic or semi-aquatic vegetation, but found occasionally on terrestrial plants, and the celery caterpillar (*Papilio polyxenes*, Fab.), which attacks practically all umbelliferous plants—celery, carrot, parsley, parsnip, and so on. The larvæ are very conspicuous, and are readily picked off the plants; moreover, certain ichneumon flies destroy the insect in its pupal stage. Another bulletin, by Mr. Sanders, is devoted to the Euonymus scale (*Chionaspis euonymi*, Comstock), which can be kept in check by kerosene emulsion.

THE current number of the *Zeitschrift* of the Geographical Society of Berlin (1910, No. 3) includes statements as to the aims of the projected German Antarctic Expedition by the leader, Lieut. Filchner, and by Prof. Penck, and a message of goodwill from Prof. Otto Nordenskjöld. The plan of the expedition is based on the hypothesis that the

Sketch-map illustrating the possible connection of the Ross and Weddell Seas.

Ross Sea is directly connected with the south-western part of the Weddell Sea by a narrow belt of sea separating the main area of Antarctica from the land which is assumed to connect Graham Land and King Edward the Seventh Land. This possibility, and also the view that the Antarctic land to the south of the Pacific consists only of an archipelago, must have occurred to all who carefully considered the results collected by the expeditions of Captain Scott and Sir Ernest Shackleton. The meteorological evidence and the apparently well-marked westward trend of the land which drove Sir Ernest Shackleton on to the South Polar plateau seem, however, not very favourable to the idea of the direct connection of the Ross and Weddell Seas. Indications of any such connection might also have been expected from the tidal observations of the *Discovery*.

The evidence, however, is so uncertain that all geographers will hope that Lieut. Filchner will settle the problem by direct observation. Prof. Penck insists that to determine this question is much more important than reaching the Pole. His letter closes with the announcement of a contribution by an anonymous donor of 300,000 marks.

IN the monthly meteorological chart of the North Atlantic Ocean for May, issued by the Meteorological Committee, we note with pleasure two advances of considerable importance in maritime meteorology:—(1) Synoptic charts for barometer and wind have been drawn for the Atlantic and adjacent coasts, for 7h. a.m. daily, for current dates, based upon telegraphic reports for north-western Europe, reports by radio-telegraphy from the Atlantic, and information given in the *Paris Bulletin international*. These data cannot fail to be of great use in elucidating the conditions which affect the weather changes of our own region. (2) Charts showing the temperature of the sea surface, also for recent dates, are drawn for the North Atlantic for consecutive periods of seven days, with isotherms for each 10° F. As these means correspond to those given for the land in the *Weekly Weather Report*, they will be available for tracing any connection which may exist between sea temperature and the weather over the British Islands. We also note that the area of the monthly chart relating to the Indian Ocean has been extended from lat. 15° S. to 35° S., thus embracing the region traversed by vessels trading to India, China, &c.

Cosmos of April 23 states that Chile has fallen in line with Japan, Italy, Austria, Germany, France, Russia, the U.S.A. and other countries by establishing a Seismological Service. The director is the distinguished seismologist Comte de Montessus de Ballore. Earthquake-observing stations now exist between Tacna and the South Shetlands, that is, along a meridian nearly 3000 miles in length. At five of these heavy Weichert's pendulums have been established, while seismoscopes have been installed at thirty secondary stations. Altogether 550 observers note earthquakes at 430 different localities. During six months 740 different shakings have been recorded. This means that Chile, as an earthquake-producing country, runs neck and neck with Japan. At the central station in Santiago an arrangement of P. Maccioni has been set up. We are told that this instrument responds to electromagnetic waves, and gives warning of approaching earthquakes. This installation is said to be the first of its kind. Other instruments which have been installed, besides those mentioned, are the Bosch-Ömori and Staittesi pendulums. Instruments of the type adopted by the British Association, although they yield more records of undoubted seismic origin than any other type of instrument, do not appear to find a place in the Chilean programme.

A large proportion of the *Electrical Review* for April 29 is devoted to the problem of electrically driving the machinery of cotton and other textile mills. It appears that a considerable number of mills in Lancashire and Yorkshire have recently discarded mechanical in favour of electrical driving, the usual method being to instal a separate motor in each room. There appears to be no doubt that an increase of output has been obtained, but the figures given vary considerably. Two well-illustrated articles deal with the equipment of one of the mills mentioned, and with that of a mill in Germany. In the latter almost every machine is provided with its own motor, so that no shafting is to be seen in the rooms of which views are given.

THE April number of the *Journal de Physique* contains a communication made to the Société française de Physique

in December last by MM. Buisson and Fabry on the application of their interference method of measuring small differences of wave-length to the problems of solar physics. It will be remembered that in their method the light to be investigated is sent through an interferometer consisting of two plane surfaces lightly silvered, and produces a system of light and dark rings, which are focussed on the slit of a grating or prism spectroscope by means of a lens. Each ring produces in the field of view of the spectroscope two points of light the distance apart of which may be determined directly or by measurement of a photograph. When two wave-lengths are to be compared it is only necessary to measure with precision the difference of the distances of these points of light apart. On comparing the iron lines of the solar spectrum with those of the arc in air, the authors find that for some lines the solar is greater, for others less, than the arc wave-length. The solar wave-length is in every case greater, however, than that for the arc *in vacuo*. The authors conclude that if the latter differences are due to the pressure in the reversing layer of the solar atmosphere, that pressure is 5 to 6 atmospheres.

CONTINUING their physico-chemical studies on phosphorus, Messrs. Ernst Cohen and Katsuji Inouye give an account in the current number of the *Zeitschrift für physikalische Chemie* (April 26) of the solubility of ordinary phosphorus in carbon bisulphide, as the previous work on this subject by Giran indicated either the formation of a compound between phosphorus and the solvent or the formation of a new allotropic modification of white phosphorus. The purity of the materials and the method of determining the concentration of the phosphorus in the solutions were carefully controlled, and solubility determinations were carried out for nine temperatures between $+10^{\circ}$ C. and -10° C. The solubility curve found furnished no indication of the compound suggested by Giran, neither was any hitherto unknown allotropic modification of phosphorus obtained.

Science Progress for April contains the two first articles, by Dr. H. W. Wiley and Dr. R. Vincent, of a general series dealing with the ethics of food. The question is one of such great national importance, and so much has been talked and written on it of late years, that it is eminently desirable to have serious and unbiased criticism published under authoritative names. Dr. Wiley's legislative crusade in the United States in favour of pure food has made him the centre of a storm of indignation and attack from the threatened interests, but he has maintained his attitude that all considerations other than scientific truth and the public welfare are to be set aside in dealing with the purity of food. No doubt there is much need of a similar crusade in this country, but perhaps the initiative should come from the general public, backed by the manufacturers of repute, rather than from the analytical chemist, as appears at present to be the case. Dr. Vincent's article on milk should be studied by all who have to do with the feeding of children. He makes a very strong point of the fact that recent developments in the milk trade have been distinctly retrogressive, and unhesitatingly condemns the boiling and pasteurising of milk.

A NEW experimental steam engine has been installed at the Glasgow and West of Scotland Technical College, and was described by Prof. A. L. Mellanby at the meeting of the Institution of Engineers and Shipbuilders in Scotland on April 26. The engine was made by Messrs. Cole, Marchant and Morley, of Bradford, and is of the horizontal, compound, side-by-side type. The high-pressure cylinder is 12 inches, and the low-pressure cylinder

21 inches, in diameter, the stroke being 30 inches. Each cylinder is fitted at each end with separate steam and exhaust valves of the drop-piston type. A steam engine uses considerably more steam than is shown by the indicator to be present in the cylinder at any part of the stroke. This loss has been generally attributed to initial condensation, but more recently the belief has been held that valve leakage is responsible for much of the extra steam used. It is hoped that the trials upon this engine may be used to supplement the work done in other laboratories in elucidating this point. Thus the Armstrong College engine has slide valves; the Manchester Municipal School of Technology engines have permitted of work being done upon Corliss, double-beat drop, and slide valves; the drop-piston valves fitted to the new Glasgow engine should therefore afford opportunities of making useful comparisons.

OUR ASTRONOMICAL COLUMN.

COMETARY ORBITS.—Messrs. Crawford and Meyer give new elements for Halley's comet in Bulletin No. 179 of the Lick Observatory, based on observations made on September 17 and December 16, 1909, and February 28, 1910. The perturbations due to Mars in January were found to be ineffective, and the time for perihelion is finally given as April 19-67760 G.M.T.

When it became known that other computers found great difficulty in computing an orbit for comet 1910a, Miss Levy and Mr. Meyer, of the Berkeley Astronomical Department, decided to test a method devised by Prof. Leuschner. For this purpose photographic observations secured by Dr. Curtis, with the Crossley reflector, on February 1, 2, and 5, were selected, and a very satisfactory result obtained from the direct solution for an approximate orbit. Other observations were then considered, covering the period January 18 to March 13, and final parabolic elements calculated by the same method. These are given, with an ephemeris, in Bulletin No. 179, and the ephemeris indicates that the comet is still a little west of the Great Square, and is very faint. Observations by Dr. Aitken on April 13 gave corrections of $-0.9s.$ and $-4''$. Elliptic elements for Daniel's comet, 1909e, published by Sturla Einarsson and R. Young in the same Bulletin, give a period of 6.48 years.

Recently published elliptic elements for comet 1910a give periods of 202.6 and 41 years respectively.

MEASURES OF DOUBLE STARS.—No. 175 of the Lick Observatory Bulletins contains the measures of 136 double stars made by Mr. Olivier with the 12-inch and 36-inch refractors of the Lick Observatory. Generally, the stars measured are neglected pairs in the southern hemisphere, such as can be observed from lat. 38° N., or pairs which show signs of motion. Eleven new doubles are included, and of the 136 stars observed, 15 are separated by less than $1''$, 56 between $1''$ and $2''$, and 30 between $2''$ and $3''$. It is interesting to note that the 12-inch refractor was generally employed, and leaves nothing to be desired as regards definition; a power of either 500 or 625 was always used, and doubles down to $0.6''$ in distance could be readily measured.

MAXIMUM OF MIRA, 1909.—*Astronomische Nachrichten* No. 4403 contains two notes on the most recent maximum of Mira. The first is by Herr May, of the Kasan Observatory, who finds that the maximum took place on September 9, 1909, the magnitude being 3.14. The second is by Herr Landwehr, Münster, and gives September 4.7 and 3.15 respectively. According to Guthnick's ephemeris, the epoch of maximum was September 6.9, and the magnitude should have been 3.27.

PARALLAX OF THE PLANETARY NEBULA G.C. 4373.—From a photographic determination, Dr. Bohlin finds that the parallax of the planetary nebula G.C. 4373 (H. iv. 37) is $-0.170'' \pm 0.042''$, and the correction for the aberration constant is $-0.043'' \pm 0.042''$ (*Astronomische Nachrichten*, No. 4406, p. 232).

HALLEY'S COMET AND METEOROLOGY.

Proposed Meteorological Observations during Progress through the Tail of Halley's Comet.

THE International Commission for Scientific Aeronautics had arranged a series of ascents of kites and *ballons-sondes* for May 11-13, but seeing that it is possible that the earth may pass through the tail of Halley's comet on May 19, the members of the commission have agreed to postpone the ascents to May 18-20. A circular from Prof. Hergesell, the president of the commission, gives particulars of the proposed ascents, the times mentioned being as follows:—May 18, 7 a.m. and 10 p.m.; May 19, 2.30 a.m. and 7 a.m.; and May 20, 7 a.m. Observations should be made at the earth's surface, and *ballons-sondes* should be sent up about half an hour before these times, so that the balloon for the principal ascent should reach its greatest height about the time when the earth passes through the tail of the comet; one ascent should also precede, and one should follow, the principal ascent by precisely similar intervals of time.

Messrs. Assmann and Teisserenc de Bort suggest that it might be possible to carry out ascents of manned balloons as well as of *ballons-sondes*, and it is suggested that the *aéro clubs* of different countries should cooperate in the observations. A letter has also been sent out by M. Teisserenc de Bort describing the apparatus he has designed and used for several years for collecting samples of air from great heights. The use of Aitken's dust counter is recommended in connection with the ascents of manned balloons, and similar observations should be made at the earth's surface. Though it is unlikely that the passage of the earth through the tail of a comet will cause any measurable change of temperature in the upper air, yet it is felt by those engaged in the investigation of this subject that such a rare occurrence should not be allowed to pass without some notice.

Meteors from Halley's Comet.

Mr. Denning writes:—

"During the first week in May the weather was unsettled and stormy, and Halley's comet could not be well observed, nor could its supposed meteoric shower from Aquarius be suitably watched. Several meteors were seen, however, at places where the sky was clear or partially so, and they were directed from the radiant point of the comet, though no brilliant display of these phenomena seems to have been witnessed in England.

"There is a probability of an abundant display of meteors on the morning of May 19, when the earth may encounter the comet's tail, but this is doubtful. The sky should be carefully watched, however, on the morning named with the view of observing any meteors or peculiar auroral effects that may be visible.

"A rich display of meteors is reported to have been witnessed at Cape Town on the morning of May 7 between 2 and 5 a.m. There was no very active shower seen in England on the date mentioned, and further particulars will be awaited with interest.

"A fireball, presumably connected with Halley's comet, was noticed at Guernsey and other places on the morning of May 3 at about 2.50 a.m. As viewed from the Channel Islands, it had a long path ascending from just under β Pegasi to under β Cassiopeiae, with a duration of four seconds.

"The real path of the meteor was from sixty-seven to forty-six miles in height, and its position over the English Channel from near Dieppe to south-west of the Isle of Wight, and its course, of some 137 miles, was traversed at a velocity of about thirty-four miles per second. This is a slower rate of speed than calculation implies to the Aquarids, but atmospheric resistance evidently moderated the meteor's native velocity. From the south coast of England—especially Sussex and Hampshire—the object must have been a splendidly luminous one, presenting a very long and graceful flight along the southern sky, but I have not hitherto received any observations from this particular part of the country.

"That the meteor was really a fragment of Halley's comet cannot be absolutely proved, but it is suggestive and significant that it was directed at the correct date from the computed radiant of the famous comet now visible. It is hoped that further observations will be furnished of this and of any similar objects which made their apparitions at the important time when the earth passed near the cometary orbit."

Observations of Halley's Comet.

Mr. Gustave Gillman, writing from Aguilas on May 2, says:—

"I enclose a chart showing Halley's comet as seen at 4 a.m. this morning, and the extent to which the tail could be traced, i.e. to slightly beyond θ Piscium. I have seen it on two previous days, but there were too many clouds to be certain of the extent of the tail. I could see no bifurcation."

Dr. A. C. Jordan writes:—

"At Broadstairs yesterday morning, Sunday, May 8, I had a good view of Halley's comet. There was a slight mist over the horizon, but I was able to keep the comet in view from 2.50 until 3.25. It was easily visible to the unaided eye, and was brighter than Algenib (γ Pegasus), the nearest bright star. Through an ordinary binocular the contrast between this clearly defined star and the nebulous-looking comet was very well marked. Toward 3.30 the approach of day rendered this part of the sky so bright that it was no longer possible to keep the comet under observation."

Further details as to the appearance of Halley's comet, as seen at Malta with naked eye and field-glasses, are sent to us by Mr. C. Leach. The comet was seen by several people, and Mr. Leach found that both nucleus and tail were easily picked up without optical aid on April 24, 25, 26, 27, and 30. He states that it was seen best between 3.45 and 4 a.m., and faded in the dawn at 4.10 a.m. The tail is described as lengthening and getting more elegant, its length being a little greater than the distance separating the comet and Venus; this would mean an apparent length of about 7° or 8° , and an actual length of about ten million miles. The nucleus, on April 30, is described as being sharply defined and at the very beginning of the comet, its brightness being about equal to that of α Andromedæ (mag. 2.1). A rough sketch sent by Mr. Leach represents the comet as having a straight, narrow, bifurcated tail, reminding one of the Paris drawing of the great comet of 1843.

Mr. Gruning, of Ealing, reports having seen the comet on several occasions with field-glasses, and twice, on May 7 and 8, with the naked eye. To know where to look for it the first time, he observed Altair emerge from behind a chimney the previous evening, and then, by a simple calculation, found the time, and the position with regard to the same chimney, for the comet's appearance next morning.

Mr. Bellamy reports to the *Daily Mail* that the comet was observed at Oxford University Observatory from 2.40

to 4 a.m. on May 9. It was visible without a telescope, and was estimated to be about as bright as a second-magnitude star. Observations were also made at Greenwich with the altazimuth.

According to a correspondent of the *Daily Chronicle*, observations at the Milan Observatory, on May 8 or 9, showed a straight tail some twenty degrees in length, or, actually, about $14\frac{1}{2}$ million miles long. A tail of this length would probably reach to the earth at the time of transit.

Observations of the comet during its near approach to Venus on May 2 were prevented, at English observatories, by bad weather, so that the possible magnetic-attraction phenomena mentioned by Prof. Birkeland could not be looked for.

In an address delivered on Monday evening at the annual

Halley's Comet as seen at Aguilas on May 2, 1910, at 4 a.m.

meeting of the Victoria Institute, Mr. Crommelin directed attention to one or two possible references to the comet in historical writings, citing the "almond rod" mentioned in Jeremiah i., 11-14, as a possible allusion to the comet's tail seen rising before the head. He also directed attention to the improbability of our being able to detect the presence of the tail should the earth pass through it. In suggesting that the comet would afford a good display during the evenings of the last ten days in May, he warned his hearers not to expect such a spectacle as was afforded by the great comet of 1882.

In the *Atti della Pontificia Accad. Romana dei Nuovi Lincei* (February 20) Dr. Pio Emanuelli points out that the velocities of Halley's comet at perihelion and aphelion are often exaggerated, and, using Mr. Crommelin's elements, he determines the true values. These he finds to be 55 km. and 0.9 km. (35.6 and 0.56 miles) per second

respectively. Dr. Smart, using Pontecoulant's elements, obtained 31.3 and 0.62 miles per second.

Messrs. Cowell and Crommelin have been awarded, jointly, the Janssen medal of the Société astronomique de France, for their precise determination of the orbit of the comet for this present apparition.

A number of interesting representations of comets, some certainly of Halley's, are reproduced in the May number of the *Bulletin de la Société astronomique de France* from the "Theatrum Cometicum" of Lubienietz. Each drawing is accompanied by a note explaining it, and directing attention to contemporary occurrences; in concluding the article, M. Flammarion suggests that great comets were of more frequent occurrence in early times than they are now.

A NEW TELEPHONE RELAY AND ITS APPLICATIONS.¹

EVER since the introduction of the telephone a real need was felt for a telephone relay, for the distance over which telephones could be used was found to be comparatively limited. Edison, soon after his invention of the carbon button transmitter, caused an electromagnet to act upon the iron diaphragm, and thus turned it into a relay, but it was not a success. Hughes (Proceedings of the Royal Society, vol. xxvii., p. 362, 1878), in his paper before the Royal Society in 1878, describing his extremely delicate microphones, stated that a telephone receiver, if included in the microphone circuit and placed upon the resonant board, caused a continuous sound to be produced. It follows, he said, that the question of providing a relay for the human voice in telephony is thus solved. Unfortunately, it was not solved; he had shown how to make a relay that would magnify a noise or musical note, but not one that would intensify articulate speech.

Sir Oliver Lodge (Journal of the Institution of Electrical Engineers, vol. xxvii., p. 799, 1898), in a paper read in December, 1898, before this society, described a relay consisting of three or four reeds or tuning-forks, each carrying carbon contacts and working in series with one another. Each reed was arranged to resonate to one particular musical note, and when this note was passed through the string of relays it was multiplied in power to a considerable extent. An instrument of this character, however, is not effective in intensifying speech. An articulate relay must have its vibrating parts damped, or, in other words, possess no resonating properties; it is therefore far more insensitive to sound than one that is arranged to resonate to one particular note.

The invention of the powerful granular transmitters of the Hunning type stimulated further efforts to obtain the speaking relay, and some progress was made with this type of microphone, particularly in America. I will not describe these relays further than to say that they consist in combining the telephone receiver and the granular carbon transmitter; both of these are designed as efficiently as possible, and in some cases automatic means are provided to shake up the granules should they become packed. These relays are only partially successful. Their advantages are not decisive. They require relatively powerful currents to work them; that is to say, when the telephone currents become sufficiently feeble to require their services, it is at this point that the carbon instrument fails to work. The telephone relay to be successful has to magnify in a continuous manner varying currents that are too feeble to affect properly a Bell telephone receiver. Such currents would be of excessive weakness, say of the order of the one one-hundred millionth of an ampere (10^{-8} ampere), and the mechanical movements produced by such currents, which have in their turn to bring about the increased electrical changes, are therefore microscopic in dimensions.

The author's telephone relay has had to be developed along quite new lines. It takes as its basis the researches of J. J. Thomson, Earhart, Kinsley, and others, with regard to the flow of electrons across a microscopic air-gap between two conducting surfaces at different potentials (see "Conduction of Electricity through Gases," J. J.

Thomson, chap. xv.) Earhart made a series of experiments on the difference of potential required to produce sparks the length of which is comparable with the wavelength of sodium light, and he found that when the distance between the metal electrodes falls to less than about 3×10^{-4} cm., the spark potential falls off rapidly with the distance, and seems to become proportional to the distance; that is to say, when the electrodes are placed very close together, within a distance such that the average intensity of force F between the electrodes reaches a value of about a million volts per centimetre, the discharge or

FIG. 1.

current passing is determined by the condition that F , which is V/d , reaches this value (where V is the potential difference and d the distance between the electrodes). If the metallic circuit of a dry cell be interrupted by a minute opening or space of the order of 5×10^{-7} cm., the metal at the point of interruption being platinum, the current will continue to flow round the circuit and across the opening, and any slight alteration in the length of the space, which I shall call the conduction space, will vary its resistance and greatly affect the value of the current that flows round the circuit. This conduction space is therefore exactly what is wanted for the current-varying device of a telephone relay, where microscopic mechanical movements are to be transformed into large current changes. The dimensions of the conduction space are so small that it is difficult to ensure and maintain it by direct mechanical means. The current that flows across the space was therefore made to do its own adjustment, very much in the same way as the current that passes through the arc of an arc lamp is made to strike and maintain the length of the arc.

FIG. 2.

Fig. 1 is a side view of the instrument with the brass cover removed. N is a permanent magnet, continued by soft iron poles right up to, but not touching, the "invar" steel reed P. Round the soft iron pole extensions are wound the two sets of coil windings H and K. The telephone currents to be magnified circulate round the winding H, and thus, by varying the magnetism, set the reed P in vibration. M, O are the top and bottom metal contact-pieces, which are opened to an infinitesimal degree to form a microphone by the fine adjusting screw W and

¹ From a paper read before the Institution of Electrical Engineers on May 5 by Mr. S. G. Brown.

by the action of the local current passing through the contact and round the winding K. It is by the action of the local current operating through this winding that the induction space is formed and afterwards maintained. So good is the automatic adjustment that the instrument may be turned upside down, producing hardly any noticeable alteration in the value of the local current and without any effect on the working of the relay. The regulating winding K must not act when traversed by the rapidly varying telephonic currents; this is brought about by surrounding the iron under the coil by a closed circuited

currents. Speech or signals that are too faint to be heard in the ordinary Bell receiver may be heard clearly through the relay. If a watch be held against the ear-piece of a Bell telephone the induced currents produced when passed through the instrument will reproduce the ticking in the receiver attached; this is a severe test.

This property of magnifying feeble telephone currents has made it particularly useful in wireless telegraphy. On replacing the telephone by the relay the increased sensitive.

FIG. 3.

copper sheathing. Eddy currents set up in this sheathing by mutual induction destroy the self-induction of the coil.

Fig. 2 is an enlarged view of the reed P and the contact-pieces M, O. In the present instrument the contact is made between metal pieces of hard osmium iridium alloy. The top contact is pointed; the lower one is flat, and is soldered to the reed; both are polished, and work under a small drop of thin oil.

In earlier instruments the lower contact O was carried by a thin iron disc; the relay was then very susceptible to outside noises. For this reason a reed is now used; it exposes such a small surface to the air that it is practically unaffected by extraneous sound.

Fig. 3 shows the connections of the relay. C is a dry cell (this is the normal voltage, which is as high as it is

FIG. 4.

desirable to employ). K. the low resistance regulating winding, T the receiving telephone or telephone head-piece of approximately 40 ohms resistance, D is an amperemeter or current indicator; when the microphone contact is opened so as to cut down the local current to half its maximum value, the relay is usually at its best adjustment. The telephone currents to be magnified enter by the terminals marked A, and circulate through the winding H.

The relay will magnify the very feeblest telephone

ness thus obtained doubles the distance over which it is possible to receive signals. Its utility in this direction has been tested, among others, by the Admiralty and the Post Office. In a wireless receiving station, messages, the very existence of which was not even suspected, owing to their extreme feebleness, when listened for under former conditions with the relay in circuit, were easily read. At the invitation of Mr. Marconi I took two instruments to the Haven Hotel, Poole. In one of the tests (Clifden, in Ireland, sending with the Marconi musical spark) the signals were heard in the telephone, directly connected, as a faint but clear and pleasing series of musical notes; but with two relays joined to the system and working in series the notes were rendered so loudly as to be heard clearly by everyone in the room, and an operator listening at a distance of several yards from the instrument could have deciphered the message. The relay is not easily affected by extraneous noises and vibration. It can thus be carried on board ship and worked in all weathers.

As regards its utility on ordinary telephone lines, speech may be magnified many times in loudness without perceptible loss in the articulation, and it will work with large currents to a point at which the Bell receiver in its local circuit is responding with uncomfortable loudness. In experimenting over a 20-lb. standard cable and speaking only one way, it has been proved that, when the relay is applied, thirty miles may be added to any length through which it is possible now to speak direct. For instance, supposing the length of the core for direct speaking be twenty miles, this may be increased to fifty miles for the same loudness and approximate clearness when the relay is in circuit, either as a single repeater at the end of the first twenty miles or as a receiver at the end of the fifty miles.

These tests prove that the telephone currents must be

FIG. 5.—The Telephone Relay.

increased in strength to the extent of something like twenty times. If still greater magnifications are required than can be obtained with one relay, the simplest method would

FIG. 6.—Telephone Relay in brass case with upper arm raised for cleaning the contents.

seem to be to employ two relays working in tandem. Their combined power would then be 400 times. In the majority of cases it is not necessary to add to the natural electrical damping of the reed, but if a piece of soft rubber be made to touch it, the voice can be transmitted with greater clearness even than if the conversation were taking place ordinarily in a room. This may be due to the complete absence of echoes.

By means of the local regulating winding (see Fig. 2) the metal contact M, O is transformed into the most exquisitely delicate microphone, more sensitive, there is every reason to believe, than could be formed by light pressure between carbons. Such a microphone has rendered possible the construction of an electric stethoscope, an instrument by the use of which the sound of the heart or other internal organs may be greatly magnified. This, I have been informed, may render it possible to detect in the earlier stages heart disease, aneurism, and gall-stones.

Fig. 4 is a diagrammatic illustration of the stethoscope. A is the front part, and consists of a shallow brass cell faced by a thin ebonite diaphragm. A is placed upon the part of the body to be examined, say the heart; the beating of the heart is communicated to the ebonite diaphragm, then to the air inside the tube B, and thus the metal diaphragm D is set in vibration. M, O, as before, are the osmium-iridium contact-pieces. M is mounted on the diaphragm, and O on the steel reed. The magnet N, S and the reed are carried by a brass frame E, which is pivoted or hinged at the lower support Y. The conduction space is formed between the contacts M, O by turning the fine adjusting screw W, and by the automatic action of the local current from the cell C flowing through the winding K and round the magnet. T is a special telephone transformer of equal windings of, say, 20 ohms resistance in the primary and in the secondary.

The electric stethoscope in its present form causes the sound of the heart to be three times as loud as in the ordinary stethoscope. This is scarcely sufficient for practical purposes; but if a telephone relay, such as I have previously described, be attached to the wires of the transformer, the two instruments combined raise the intensity of the sound some twenty times and more, and this is ample for all ordinary purposes. The sound to be examined is picked up by the end of the tube A, and is heard in the telephones of a head-piece attached to the relay.

At the invitation of two physicians I took the complete instrument, stethoscope and relay, to the London Hospital, where it was tested upon a number of diseased heart cases. Not being a doctor myself, I cannot discuss the merits of the instrument with regard to its medical value, except to say that it seemed to render diagnosis particularly easy and revealed some phenomena only previously suspected. From a sound-magnifying point of view the general results were as follows. When the instrument was applied directly to the heart the sound of the beats given out in the telephone was uncomfortably loud, and easily heard by the patient and all those that stood round, and this even i

FIG. 7.—Electrical Stethoscope.

the telephones were in position on the head of the operator. The stethoscope as used increased the heart-beats to 10, almost complete exclusion of the shriller or breathing

sounds. This has been brought about by mechanically tuning the disc D and the reed P of the telephone relay to the corresponding low note, and by a proper proportioning of the volume of air enclosed by the tube B. On other occasions, during private experiments, the instrument has been tuned so that nothing but the breathing sounds were audible; the passage of air through the lungs was heard as the roar of the wind through a forest of trees. This power of discrimination should be of service in allowing the independent examination of various organs of the body.

Replacing the telephone head-piece by a transformer, the stethoscope has been joined to the telephone service in my house, and, for the sake of experiment, the sound of the heart has been transmitted over several miles of telephone line to doctors in various parts of London and to other friends who were interested. All of them reported that the sounds received in the telephone were as loud and clear as when heard locally. The line, therefore, does not appear to produce much loss or distortion. This trial proved that it is now possible for a specialist, say, in London, to examine a patient, say, in the country, stethoscopically, and to arrive at a correct diagnosis.

The instrument must of necessity, to replace the ordinary stethoscope, be more sensitive to sound than the human ear. This is proved by slight noises made in the room being heard in the telephones as loud noises. In consequence of this, the apparatus is padded and guarded, so far as is possible, from all outside disturbances, and the patient should be examined in a quiet room. If the instrument is provided with a small funnel in place of the tube B, it will pick up and magnify the slightest sound, and ordinary speaking may be increased to a deafening shout in the telephone. Such an instrument, when properly constructed for the purpose, may be of use to those who are afflicted with deafness.

FIG. 8.—Electrical Stethoscope and Telephone Relay ready for use.

The relay has been used on the electrophone system, and by its aid, damping the reed with a piece of rubber, the speaking and music from the theatres are rendered with loudness and greater clearness than it is possible to have on the telephones supplied by the company, and by adding a loud speaker with trumpet the sounds can be heard in the room.

THE IRON AND STEEL INSTITUTE.

THE annual general meeting of the Iron and Steel Institute was held on Wednesday and Thursday, May 4 and 5, at the Institution of Civil Engineers. The retiring president—Sir Hugh Bell—inducted the president-elect, His Grace the Duke of Devonshire. After presentation of the Bessemer medal to Mr. E. H. Saniter, of Rotherham, for scientific services rendered to the iron and steel industry, the Duke of Devonshire gave his presidential address. In the course of a long and detailed account of the rise and progress of the coal, iron, and steel industries in this and foreign countries, the president also reviewed the social and economic conditions over the period from 1869, when the institute was founded under the presidency of the seventh Duke of Devonshire, to the present time. Conditions of work are now safer and more sanitary; wages are better, and working hours lighter. Housing is better, and a host of improvements in traffic,

lighting, education, and public assistance have made for the comfort, health, and enlightenment of the people. Taking increase in wages paid to the worker, and also the increased spending power of these wages, into account, His Grace quoted statistics showing a net increase, for the period mentioned, of 90 per cent.

The meeting then proceeded with the reading and discussion of papers, thirteen of which were presented. Owing to lack of time, several of these had to be taken as read. In the case of those actually presented at the meeting, the time allowed to the author for explaining the contents of his paper was in each case ten minutes. The institute is to be congratulated on the high standard and importance of the papers presented, but we think that it will be difficult to maintain this standard unless in future more time is placed at the disposal of the authors at the meetings.

Mr. D. Selby Bigge, in a paper on the development in the production of electric power, pointed out that considerable progress had been made in the cost at which electricity can now be produced in iron and steel works having at their disposal waste gas, waste heat, and waste steam. One of the means by which low cost of production has been attained is the mixed pressure steam turbine. Such turbines differ from exhaust steam turbines in that the latter are intended to derive their supply of steam from engines which run continuously, such as blowing engines and pumping engines. Mixed flow turbines may work with reciprocating engines which are only in action intermittently. A continuous supply of steam is obtained for the turbine by adopting a form of regenerative accumulator, the action of which is as follows. The exhaust steam is taken from the engines and mixed with water, both coming to the same temperature. Supposing, now, a drop in pressure of $1\frac{1}{2}$ to 2 lb. per square inch to take place in

the accumulator, owing to the exhaust steam supply being cut off, the water in the accumulator at once gives off vapour, thus keeping up the supply to the turbine. Any sudden rushes of exhaust steam from the engine are utilised in storing heat in the accumulator, and will be drawn on for supplying the turbine during the next pause in the supply of exhaust steam.

The turbine is built in stages, one set being designed for the working pressure of the existing boilers, and so constructed as to give off the full output of the turbine upon live steam when required; the other set is designed for the utilisation of exhaust or low-pressure steam received from the accumulator in the case of engines working intermittently, or direct from the exhaust of engines running continuously. The low-pressure end of the turbine is also designed to give out the full rating or output upon low-pressure steam alone. Should the full supply of exhaust steam fail from any cause, live steam is automatically admitted to make up the temporary deficiency in the exhaust steam available. Further, high-pressure steam is admitted when required to the high-pressure stage without the intervention of a reducing valve. To secure efficiency, a high vacuum must be secured, and the selection of a suitable condenser must be carefully considered. Various types of turbines, gas engines, and electrical installations for steel works are described by the author in the paper. The adoption of any particular system must obviously depend on the circumstances; each case must be considered on its merits. It is of interest to note that the Duke of Devonshire in his address cited the economy effected last year at the Barrow Works, where the installation of eight gas engines to replace the steam-driven engines produced an immediate saving of 1500 tons of coal weekly.

An interesting paper on the cutting properties of tool steel was contributed by Mr. Edward G. Herbert, of Manchester. It is well known that a high-speed steel tool with

a light cut and a high speed will keep its sharp edge better than a carbon-steel tool. The durability of all steels, without exception, is very low at low speeds under light cuts, and increases as the speed is raised, the durability being measured by the amount of metal cut away before the tool becomes blunt. The engineer usually requires the steel that will remove the greatest amount of metal per hour without requiring too frequent sharpening, and it is useful to express the "duty" of a tool steel by the product of metal removed and corresponding cutting speed, thus obtaining a quantity which is proportional to the time rate of removing metal and to the durability of the tool.

To account for the fact that an increase in the cutting speed is accompanied by an increase in the durability of the tool, it has been suggested that the evolution of heat, and consequent rise in temperature of the cutting edge, may be the influencing factor, and experiments are described in the paper giving confirmation of this view. In these experiments heat was applied artificially to the tool while cutting by means of hot water, and tests were made at different temperatures. A law has been deduced from the results which may be stated thus: for constant durability of the cutting tool the speed varies as the cube root of the product of area of cut by thickness of shaving. Experiments were also made on the effects of temper and of the percentage of carbon on the durability of carbon steel, and on the effect of the cooling process in the case of high-speed steels.

Prof. J. O. Arnold, in his paper on uniform nomenclature of iron and steel, earnestly pleads with metallographers strongly to support Prof. le Chatelier in his effort to abolish personal names for the constituents of steel. Mr. Sydney A. Grayson, of Birmingham, gives the results of some recent investigations on case-hardening, from which it appears that it is necessary to classify case-hardening compositions both by the carbon per cent. obtained in the "case," and also by the graduation of the carbon diffusion, which is best shown graphically. This classification is necessary on account of one composition being more suitable for certain kinds of work than another. A high carbon "case," such as 1.10 per cent. carbon, would be very efficient for the kind of work where the pressure was fairly constant, such as a plain bearing, but it would be very unsuitable and inefficient for parts which had to resist repeated shocks, because of the strong tendency of the high carbon "case" to chip, or even to peel off. It is advisable, where all kinds of case-hardening have to be done, that two compositions be used, one of them to produce a high carbon wearing surface, and the other to produce a medium carbon wearing surface.

Mr. C. A. M. Smith, of East London College, adds to his previous work on the elastic breakdown of certain steels an investigation of the possibility of non-axial loading occurring in test-pieces held in the testing machine on spherical seats, and shows that, in the case of a 50-ton machine in which the radius of the seats is $1\frac{1}{2}$ inches, the eccentricity may amount to 0.15 inch, with a coefficient of friction of 0.1. The ratio of maximum to mean stress would then be at least 2.2, and in one test where eccentricity was known to exist, a ratio of 2.96 was found.

A GEOLOGICAL SURVEY OF COLORADO.

THE State of Colorado is one of the most famous in the history of American mining, but though its Geological Survey was created in 1872, and has included on its staff some distinguished men, it has done comparatively little, for it remained practically without funds until 1908. The Survey has now been provided with an annual subsidy and a staff, Mr. R. D. George being State geologist with sixteen assistants. Its first annual report has been issued, and shows that the Survey has been organised on sound lines, for it contemplates cooperation with the Federal Survey and private local geologists, and the advancement of local education by presenting a collection to illustrate the mineral wealth of Colorado to every high school in the State.

The first volume consists of five valuable memoirs upon the geology of Colorado, illustrated by geological and topographical maps. The stratigraphical geology of the foothills is described in a memoir by Mr. J. Henderson. They consist of a foundation of Archean and Algonkian rocks, which are covered by a long succession of sediments, representing continuous deposition from the Carboniferous to the Laramie, at the end of the Cretaceous. This succession consists of 10,000 feet of strata, partly marine and partly terrestrial, and apparently all conformable. The beds were laid down in the course of a slow subsidence of the country, so that the higher members of the series overlap one another on to the older rocks to the west. After the Laramie there was a break, and the chief Cainozoic deposits are of Miocene age.

The other memoirs deal with economic geology. Each is well arranged, and accompanied by a useful bibliography. Mr. R. D. George and Mr. R. D. Crawford contribute an outline survey of the Hahns Peak mining field, thirty miles from the railway terminus at Steamboat Springs. Hahns Peak itself is a porphyry laccolite, once covered by Cretaceous rocks. The goldfield is one of those interesting cases in which no certain source has been discovered of the gold in rich placer deposits. The lode mines hitherto found yield silver-lead ores, and their working has not been remunerative. The popular local belief as to the source of the gold is that it has come from the porphyrites, of which the junction with the sediments is generally mineralised; but it has also been attributed to conglomerates at the base of the Dakota formation and to pre-Cambrian metamorphic rocks.

Mr. George contributes a valuable memoir on the tungsten area of Boulder County, accompanied by notes on the intrusive rocks by Mr. R. D. Crawford. It includes a brief account of the tungsten deposits throughout the world, and of the technical uses of the metal. The Boulder tungsten field consists of gneiss of sedimentary origin, which is seamed by dykes of pegmatite, which the author claims, in this instance, to be an intrusive rock and not a pneumatolytic product. There are also dykes of latite, a rock intermediate between trachyte and andesite. The tungsten ores are mostly found in the granite; the veins in gneiss are narrower and less profitable, as that rock forms less open channels when disrupted. The veins are very irregular in arrangement, but are generally steeply inclined. The tungsten was introduced by four successive depositions. There has apparently been considerable difficulty in the concentration of the ore, owing to its extreme friability, and the author suggests the use of magnetic methods, which have proved successful in Cornwall. This report is illustrated by a series of plates, of which six are especially useful, as they show the various types of ores.

The last report is by Mr. H. B. Patton, on the Montezuma district of Summit County. The rocks of this mining field are the Archean schists and gneiss of the Front Range, injected by acid and diabase dykes. The ores are replacement veins composed of quartz containing lead, zinc and a little copper and some silver and gold. Unlike some Colorado mining fields, descending water appears to have had very slight effect upon the ores, and there has been little secondary sulphide concentration. The porphyritic dykes are of Cretaceous date, and the ores were introduced later than the formation of any rock in the district. The distribution of the ores appears to be quite independent alike of the dykes, pegmatite veins, and cleavage. The ore bodies lie along joint planes, on which there may have been some movement by strike faults. There is, however, no direct evidence that the ores were connected with faulting, for the cross-faults are barren, and the joint planes may have been mineralised simply because they were planes of weakness, which offered the ore-bearing solutions the readiest channel to the surface.

J. W. G.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Mr. C. L. Boulenger, of King's College, Cambridge, has been appointed to the lectureship in zoology rendered vacant by the resignation of Mr. Leonard Doncaster.

Dr. Leonard Parsons has been appointed assistant lecturer in pathology and bacteriology to succeed Dr. Leonard Mackey.

CAMBRIDGE.—On account of the death of his Majesty the King all invitations issued for the laying of the foundation-stone of the New Museum of Archaeology and Ethnology are cancelled.

The increased entry in the University is shown by the fact that on May 3 seventeen undergraduates matriculated. This brings the total number of students for the academic year 1909-10 up to the present date up to 1217, as contrasted with 1163 at the same date last year.

The Special Board for Geographical Studies has reported on the financial position of the Department of Geography. The University makes an annual grant to the Board of 200*l.*, and the Royal Geographical Society makes a grant of a similar sum. This latter sum is primarily assigned to the stipends of a university lecturer in regional and physical geography and a university lecturer in surveying and cartography, who are called the Royal Geographical Society's lecturers in their respective subjects. The department has, however, grown, and the Special Board is of opinion that a further 200*l.* a year is the smallest additional sum with which it will be possible to make adequate provision for the study of the subject. The Board is of opinion that further accommodation for the department is urgently required. Application has already been made for the assignment of a lecture room, a laboratory, and some private rooms in the block of buildings now under construction. In order that geography may assume its due place in the studies of the University the Board looks forward to the appointment of a professor and of a reader with three lecturers under them.

Mr. Cyril Strickland, of Gonville and Caius College, has been appointed assistant to the Quick professor in place of Mr. H. B. Fantham, who has resigned the post.

Dr. T. G. Longstaff will deliver a lecture in Cambridge on Thursday, May 19, at 5 p.m., on "Glacier Exploration in the Eastern Karakoram Himalayas." The lecture, illustrated by lantern slides, will be given in the Sedgwick Museum.

Mr. E. Torday will give a lecture on his investigations among the Bushongo of the Kasai basin on Thursday, May 19, at 8.30 p.m., in the Museum of Archaeology and Ethnology.

OXFORD.—Dr. G. C. Bourne, Linacre professor of comparative anatomy, and Mr. E. S. Goodrich, fellow of Merton College, have been appointed representatives of the University at the eighth International Congress of Zoology, to be held at Graz in August next.

MR. W. FISCHER WILKINSON has been appointed principal of the newly constituted School of Metalliferous Mining (Cornwall). Mr. Wilkinson's duties will not commence until the next session in September, but he has already associated himself with the governors in drafting the prospectus of the new school, which will be issued shortly. Mr. J. J. Beringer, who for twenty-eight years has been principal of the Camborne Mining School, will join the staff of the School of Metalliferous Mining and will take charge of the metallurgical subjects.

Science announces that Johns Hopkins University has received an offer of 50,000*l.* from the General Education Board for the purpose of aiding the University in its efforts to put into operation certain extensions and improvements that have been under consideration for several years, including the erection of new buildings. This sum will be contributed conditionally on the raising of a supplementary sum of 125,000*l.* by the University by December 31, 1910. The University, however, is endeavouring to raise 400,000*l.*, half for new buildings, while the other 200,000*l.* will be used for endowment. Among the extensions contemplated are a school of engineering, a department of preventive medicine, and a building for pathology. From the same source we learn that a joint hearing on the Bills to appropriate 130,000*l.* for new buildings for the College of Agriculture and 26,000*l.* for new buildings for the Veterinary College at Cornell University was given last month by the finance committee of the Senate and the ways and means committee of the assembly.

The seventh annual meeting of the central council of the Association for the Advancement of the Scientific Education of Indians was held in Calcutta on April 14. We learn from the *Pioneer Mail* that the resolutions were

carried unanimously to the following effect:—That the Government be asked to fulfil its promise of starting graduate classes in mechanical and electrical engineering, mining and industrial chemistry, in connection with the Sibpur Engineering College at an early date; that Indian capitalists be appealed to to start industries and employ Indian experts in preference to foreign experts; that this council strongly urges upon the University and the Government to insist upon the training of the hand and eye of students attending schools; that Indian capitalists may, with every prospect of success, start the following industries, which have proved successful in Japan:—matches, pencils, porcelain, enamel, tobacco, sugar, hosiery, soap, perfumery, paper, glass, umbrellas, biscuits, leather, and printing-ink; industries for which experts trained by the association are available; that a syndicate be formed to raise 25 lakhs of rupees from the people of Bengal for starting industries to give employment to the large number of students who have been sent to foreign countries for industrial education.

IN view of the fact that the Union Government will have to take over higher education shortly in Cape Colony, Prof. A. S. Kidd, of Rhodes University College, has prepared a brochure of forty-eight pages on the subject, and it is published by Messrs. Grocott and Sherry, of Grahams-town, at the price of one shilling. Prof. Kidd first explains the Higher Education Act of 1874, deals with the recommendations of the commission of 1879, and then describes the various colleges of the west and east of Cape Colony. His concluding section is concerned with the future of higher education in South Africa, and urges that one of the first duties of the Union Parliament should be to appoint a commission to inquire into and to report upon the whole subject. The chief work of the commission, Prof. Kidd thinks, should be the consideration of the following points:—which of the existing colleges deserve to be recognised as State colleges receiving generous support; what should be the constitution and functions of the various college councils; the special lines on which each college should be encouraged to develop; the salaries, good service pensions, and status of professors; the advisability of having some system of triennial inspection of college progress and efficiency; and the existing debts on colleges in Cape Colony, endowed chairs, bursaries, and scholarships.

As has been announced already in these columns, the third International Congress for School Hygiene is to be held in Paris from August 2 to August 7. The president of the congress is Dr. A. Mathieu, the honorary president being the French Minister of Public Instruction. The business of the congress will be transacted in ten sections, as follows:—educational buildings and furnishings, president, Prof. Courmont, of Lyons; hygiene of residential schools, president, M. Jules Gauthier, director of secondary education to the Minister of Public Instruction; medical inspection of schools and individual health records, president, M. Le Gendre; education and physical training, president, M. Cazalet; the prevention of contagious diseases in schools, president, Prof. Hutinel; out-of-school hygiene, president, M. E. Petit; the hygiene of the teaching staff, president, M. G. Lyon, rector of the University of Lille; teaching of hygiene, president, Prof. Pinard; teaching methods and syllabuses in relation to school hygiene, president, Prof. G. Lanson; and special schools for abnormal children, president, M. Gasquet, director of primary instruction to the Minister of Public Instruction. The general secretary of the congress is Dr. Dufestel, 10 Boulevard Magenta, Paris. Sir Lauder Brunton, Bart., F.R.S., is the president of the English organisation committee, and Dr. James Kerr and Mr. E. White Wallis are the honorary secretaries, to whom inquiries should be addressed at the Royal Sanitary Institute, 90 Buckingham Palace Road, London, S.W.

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, April 19.—Dr. S. F. Harmer, F.R.S., vice-president, in the chair.—Stanley Kemp: Notes on the photophores of decapod Crustacea.—J. Lewis Bonhote: Variations of *Mus rattus*, founded on an

examination of the forms of that species found in Egypt. The author pointed out that on examination of the hind-foot measurements of a considerable number he found that the curve showed three distinct apices, and that two of these apices belonged, respectively, to the two forms found in Egypt, these forms being also more easily distinguished by their colour characteristics. The author in dealing with the rats of this species from the Oriental region had some years ago subdivided them into three subgroups, and it was now shown that the size of the feet typical of the three Oriental subgroups corresponded with the three apices in the curve of the Egyptian forms. He was inclined to think that these apices represented centres of variation, and were probably inherited as Mendelian characters, for were this not the case the smallest apex would have become swamped, and a regular curve would result. It was, however, evident that the small foot character was present and ready to become the dominant form in a very short time should conditions giving advantage to a small foot arise. On comparing the curve of the hind feet of *Mus norvegicus*, three apices were also observed, showing that in this species the "hind-foot character" was also present, but as there were no corresponding colour differences it was impossible to tell to which group any particular individual belonged. The author drew the following conclusion, viz. that there was considerable *prima facie* evidence that the size of the hind foot and the colour of the hairs on the underparts were Mendelian characters, and pointed out that the former character was also found in another species, *Mus musculus*, and the latter in a third species, *Mus musculus*.—**G. E. Bullen**: An example of posterior dichotomy in an Aylesbury duckling. A detailed account of a dissection performed on a duckling having supernumerary legs. In addition to a re-duplicated pelvis and the usual condition of the limbs presented in posterior dichotomy, it was found that the specimen showed evidence of a further re-duplication of the part dichotomised.

Royal Microscopical Society, Apr^l 20.—**Mr. E. J. Spitta** in the chair.—**E. M. Nelson**: What did our forefathers see in a microscope? The author dealt with the subject of what sort of image would be seen in a microscope of the highest type before 1825, about which date the achromatising of objectives was begun. After describing various old forms of microscope, particularly Dr. Robt. Smith's catadioptric microscope, the author gave examples with modern instruments.—**E. M. Nelson**: Critical microscopy. The author described the image of an object as being critical when it had been obtained by means of an objective of fine quality which had been placed in correct adjustment for that object, and when the illumination was critical. An object was said to be illuminated critically when it was placed at the apex of a solid axial cone, the aperture of which was not less than three-quarters of the N.A. of the objective.

Institution of Mining and Metallurgy, April 21.—**Mr. Edgar Taylor**, president, in the chair.—**W. McDermott**: The elements of slime concentration. In this paper the author gave a brief review of certain factors in the problem of slime concentration which seem to be established by practice, and then proceeded to draw conclusions from that review which would show the lines on which inventive and constructive development should proceed. He made a broad classification of the types of machine in use into five groups having different functions, and from that went on to analyse the conditions essential to efficiency, these being, respectively, time required for settling, smoothness of surface in final separation, speed of the washing water, and the special shaking motion necessary for settling and separation. Following these points was a consideration of the direction likely to be taken in future improvements, which may or may not provide for the production of a middle product, while the desirability or otherwise of classification under commercial conditions also received notice.—**J. M. Campbell**: The origin of laterite. The author dealt more especially with occurrences of laterite in West Africa, which he had observed and studied, though he sought to establish a similarity of origin for the Indian laterites, also in con-

tradition to the generally accepted theories of the Geological Survey of India. His definition was, briefly, to the effect that laterite is a porous rock, formed above low water-level in the strata on low-lying gentle slopes, by the gradual removal of some or most of the mineral constituents of either alluvium or rock *in situ*, and of the deposition therein of ferric and aluminous hydrates from mineralised water coming from below, the deposition being determined by contact with atmospheric oxygen.—**J. M. Campbell**: Native iron smelting in Haute Guinée (West Africa). This is a brief note compiled from observations of some native furnaces which are probably survivals of an ancient system of iron smelting, no record of which appears to exist. Their chief interest consists in the method of operation by natural draught only, induced by the introduction of clay tuyers, which convey air to the combustible matter, so dispensing with artificial blast. The note is of historical interest only, as the method of smelting is now almost extinct.—**H. B. Williams**: Hammer drills in overhand stoping and raising. In this paper the author gives particulars of the construction, operation, and work performed by a hammer drill operated by compressed air, which has been in practical use for some time in some gold mines in British Columbia, and has shown some distinct advantage over hand labour and ordinary piston drills in certain classes of work.

Challenger Society, April 27.—**Dr. A. E. Shipley** in the chair.—**A. Earland**: The Foraminifera collected by the fishery cruiser *Goldseeker*, with special reference to the survival of boreal species in a southern locality. These Foraminifera had been dredged in the area of the Moray Firth and North Sea to the east of Scotland as far north as the extremity of Shetland, and eastwards to about 150 miles from the Scottish coast. Off Buchan Ness large and typical specimens of *Polystomella arctica*, P. and J., were obtained. In the deep "gully" off Burghhead, Moray Firth, *Botellina labyrinthica*, Brady, was found in abundance, and *Hippocrepina indivisa*, Parker, a truly Arctic type, was frequent. From these records, and from the gigantic size attained by many arenaceous types in the comparatively shallow water of the central North Sea, the author considered that the present rhizopod fauna of the North Sea was of Arctic origin, surviving from the comparatively recent geological times when the North Sea had no connection with the Atlantic in the south. The immigration of warm-water types by way of the north of Scotland was regarded as further proof of the correctness of the geological theory, and many instances of such rhizopod types occurring in the northern area of the Moray Firth, but nowhere south of it, were mentioned.

Geological Society, April 27.—**Prof. W. W. Watts**, F.R.S., president, in the chair.—**R. G. Carruthers**: The evolution of *Zaphrentis delanouei* in Lower Carboniferous times. The simple corals that belong to the gens of *Zaphrentis delanouei* are of common occurrence in the Lower Carboniferous rocks of Scotland. Their distribution is sporadic, but it is possible to collect over areas of which the stratigraphy is known. Many specimens have been got together from horizons scattered throughout the sequence. The ontogeny has been investigated by serial transverse sections. The evolutionary changes observed are confined to the disposition of the septa, which has influenced the shape of the cardinal fossula in a marked manner. *Zaphrentis delanouei* is typically a Tournaisian species, and it has a wide fossula, expanded inwardly. When the gens first appears in the Scottish rocks *Z. delanouei* is the predominant form, but is associated with a mutation in which the fossula is parallel-sided. In the higher limestones of Lawston Linn another mutation appears, which is regarded as a sport from the direct line. In the succeeding Lower Limestone group the gens undergoes further modification. Adults of the two Cementstone species are extremely rare, and the predominant form has a fossula which narrows rapidly to the inner end. In the still higher horizons of the Upper Limestone group the last-mentioned mutation becomes predominant, and persists up to the Millstone Grit, where the septa become more

amplexoid. All these mutations in neanic life have characters seen in adults of the preceding form. Mutational percentages are given for many localities in the Carboniferous Limestone series of the Central Valley, together with an analysis of the data so obtained.—**A. Wilmore**: The Carboniferous limestone south of the Craven Fault (Grassington-Hellfield district). Some of the beds are massive, coarsely stratified limestones, made up largely of crinoids, or corals, or shells; others are well bedded, almost flaggy, black limestones made up of comminuted matter, with abundant foraminifera. The strata are much disturbed everywhere. A series of folds strike roughly north-east and south-west, and are somewhat complex. The well-known knolls ("reef-knolls") are discussed. Their beds and those in the neighbourhood are much disturbed. Irregular coarse bedding, folding, and weathering will explain their structural peculiarities. A typical knoll is dissected, and it is seen to consist of folded, faulted, grey, coarsely bedded limestone, with great joints and much internal weathering. It is not easy to work out the exact zonal sequence, because of the disturbed character of the strata and the prevalence of glacial and fluvioglacial drifts. The strata are apparently all Viséan (and probably there is nothing lower than Middle or Upper S). In some beds, and in some circumstances, fossils are exceedingly plentiful. Some corals receive special notice.

MANCHESTER.

Literary and Philosophical Society. April 5.—**Mr. Francis Jones**, president, in the chair.—**R. L. Taylor**: A preliminary note on the action of carbon dioxide and of air on bleaching powder and similar substances. Contrary to what is generally supposed, carbon dioxide, in presence of moisture, liberates no hypochlorous acid from bleaching powder, either solid or in solution, but only chlorine. Similarly, carbon dioxide liberates nothing but bromine from a mixture of a bromide and a hypobromite. When air, freed from carbon dioxide, is passed through a solution of bleaching powder, it slowly sweeps out hypochlorous acid, which is present in the free state in the solution, being produced by the action of water on the calcium hypochlorite. If, however, moist air containing the usual small amount of carbon dioxide is passed through bleaching powder, either solid or in solution, a mixture of chlorine and hypochlorous acid is given off, the chlorine usually largely predominating. In the case of the solid substance, after the moist air has been passed through for a considerable time, and the bleaching powder has thus become quite wet, there is no hypochlorous acid produced, but only free chlorine. When bleaching powder is heated with water and boric acid, practically pure hypochlorous acid is given off, no matter what proportion of boric acid is used. This forms a convenient method of preparing a solution of hypochlorous acid. Under similar conditions, a mixture of a bromide and a hypobromite evolves nothing but bromine.

April 20.—**Mr. Francis Jones**, president, in the chair.—**G. P. Varley**: The state of magnetisation of the iron boundary fence on the ridge between Black Sail Pass and the top of the Pillar Fell in the Lake District. The heavier iron uprights, which were firmly fixed in the rock, showed a north polarity below and south polarity above, while the floating uprights used for spacing the wires had, with few exceptions, the south pole below and the north above. The magnetisation of the heavy fixed bars was what one would expect from the action of the earth, but that of the floating uprights was not readily explicable.—**Prof. S. J. Hickson**: A new octoradiate coral. Some corals observed by Mr. Standen, of the Manchester Museum, in a bottom deposit obtained by Mr. Townsend at a depth of 156 fathoms in the Gulf of Oman (Persian Gulf) were submitted to the author for examination, and were found to belong to a genus that had not previously been described. It was therefore proposed to name them *Pyrophyllia inflata*, from the resemblance of the undulating septa to flames issuing from a cauldron. The zoological position of this coral could only be considered fully when its structure had been more carefully studied. All that could be said at present was that there were only two recent corals that seemed to approach it at all in the

system of Zoantharia. These were *Guynia annulata*, Duncan, from the Adventure Bank in 92 fathoms of water, and *Haplophyllia paradoxa*, Pourtales, from off the coast of Florida in 324 fathoms of water.

EDINBURGH.

Royal Society, March 21.—**Dr. R. H. Traquair**, F.R.S., vice-president, in the chair.—**Dr. J. R. Milne**: A photometric "paddle-wheel." This apparatus has some resemblance to the well-known rotating sector, but possesses the advantage that the brightness of the light can be altered and the intensity recorded without the wheel being stopped. In its simplest form it consists of a disc fixed to the axle of a small electromagnet, and furnished with a number of vanes projecting beyond the edge of the disc, and set paddle-like with their planes parallel to the axis. When the axis of the disc is set parallel to the beam of light the vanes move in succession across the field edge on, and intercept very little light. If, while the wheel is rotating, the axis is inclined to the direction of the beam, the vanes will intercept a certain amount of light, depending upon the inclination of the axis to the beam. The paper contained graphical tables, from which the percentage of light transmitted can be found for various forms of vane and different angles of inclination of the axis. The position of the wheel can be recorded by a simple device, which in no way interferes with the rotation. The observer adjusts the rotating wheel until the intensity of the beam is brought to the right value, marks the position by means of a needle prick upon a strip of paper, and then proceeds to the next comparison without removing his eye from the eye-piece of the telescope.—**Dr. J. R. Milne**: A photometer on the flicker principle. The chief novelty of the instrument lies in a part consisting of a small telescope, in front of which two semi-circular glass wedges are rotated by an electric motor in such a way that there is made to fall alternately on the observer's eye first the light that has passed through the absorbing solution and then the light that has passed above it. The brightness of the latter beam is cut down by means of the photometric paddle-wheel described above until it is equal to the brightness of the former, this equality being shown by the absence of flicker.—**D. P. Macdonald**: A chemical investigation into the nature of the clay substance in the Glenboig fire-clay. The results obtained show that the clay substance contains 1.5 per cent. of water in excess of that required to satisfy the formula for kaolinite, and that the mineral is almost entirely decomposed by boiling in concentrated hydrochloric acid for thirteen hours.—**W. A. Caspari**: Contributions to the chemistry of submarine glauconite. Glauconite grains, when subjected to the action of acid, followed by that of alkali, disintegrate with formation of colloidal suspension of glauconite, whence pure amorphous glauconite may be coagulated. The pure glauconite prepared from grains found off Panama and the Cape of Good Hope answered to the formula $KFe_2Si_2O_7 \cdot H_2O$, where K_2O is largely replaced by MgO and FeO . Glauconite grains contain a small percentage of organic matter closely resembling alkali-soluble humus. This and other facts indicate that humus may well play a part in the formation of glauconite. Experiments on the absorption of water by glauconite show that it belongs in this respect to the same class as zeolites or colloidal silicates.

PARIS.

Academy of Sciences, May 2.—**M. Émile Picard** in the chair.—**J. Violle**: The fight against hail in the Beaujolais. The conclusion drawn by M. André in a recent note was to the effect that hail cannon serve no useful purpose. The author criticises the statistical methods of M. André, and states that during the six years 1901-6 the annual losses in the districts provided with hail cannon were only 0.24 of the average annual loss for the preceding twenty years. In the whole department the losses were 0.76 of the previous annual average.—**C. Guichard**: A mode of generation of triple orthogonal systems with spherical lines of curvature in a single system.—The perpetual secretary announced the death of Édouard van Beneden, correspondant for the section of anatomy and

zoology.—Ernest **Esclançon**: The changes in Halley's comet. On April 27 the most brilliant part of the nucleus was very close to a seventh-magnitude star in brightness, but the comet as a whole would appear to be of a higher magnitude to the naked eye. In the nebulous mass surrounding the nucleus there are two clearly marked surfaces of discontinuity, meeting at the nucleus at an acute angle.—J. **Haag**: Certain triple orthogonal systems.—P. E. **Gau**: The integration by the method of M. Darboux of the partial differential equations of the second order of the form $s = a(x, y, z)p + b(x, y, z)q + c(x, y, z)$.—A. **Chatelet**: The summation of continued arithmetical fractions.—Jean **Chazy**: The differential equations deduced from certain invariants of linear forms.—S. **Lattès**: The convergence of the relations of recurrence.—Léon **Lichtenstein**: The general definition of analytical functions.—André **Léauté**: Superintensities and supertensions due to the working of switches on the switchboard.—Eugène **Bloch**: The curves of saturation in the Hertz photo-electric effect.—M. de **Broglie**: The ionisation of gases by the actions of mechanical division of liquids: active and inactive bodies.—A. **Besson** and L. **Fournier**: The action of the silent discharge on chloroform and carbon tetrachloride in presence of hydrogen, and also upon methyl chloride. The products isolated from the first of these reactions include tetrachlorethylene, trichlorethylene, hexachlorethane, hexachloropropylene, and higher boiling products. Methyl chloride (without hydrogen) gave a complex mixture which proved to be very difficult to separate by repeated fractional distillation.—G. **Dupont**: The isomerides of some acetylene γ -glycols. The glycols examined included

and

$$(\text{C}_6\text{H}_5)_2(\text{CH}_3).\text{C}(\text{OH}).\text{C}\equiv\text{C}.\text{C}(\text{OH})(\text{C}_6\text{H}_5)(\text{CH}_3),$$

two isomers of each glycol being described.—H. **Gault** and G. **Thirole**: The condensation of the secondary amines with γ -bromodimethylacetic ester.—J. F. **Thorpe** and G. **Blanc**: The product of the methylation of diacetoapocamphoric ester of M. G. Komppa. It is shown that the diketocamphoric ester of M. Komppa, one link in the synthesis of camphoric acid, has not the constitution assigned to it.—G. **Vavon**: The addition of hydrogen to essence of turpentine. The fractions from French, German, and American turpentine boiling under 165° , on treating with hydrogen in presence of platinum black, all gave a hydrocarbon with the same density, boiling, and melting points. Hence both α and β pinenes give the same hydride.—A. **Arnau**d and S. **Posternak**: The partial hydrogenation of the acids of the stearic series and the isomerism of their addition compounds with hydriodic acid.—M. **Biéler-Chatelan**: The function of micas in arable soil.—H. **Sérégé**: An experimental study of the specific action of the Vichy springs employed in thermal therapeutics.—A. **Moutier**: The rôle of the arterial wall in the measurement for clinical purposes of the arterial pressure.—H. **Vallée** and L. **Guinard**: The physiological properties of extracts of the Koch bacillus, condensed and rendered sensitive. A study of the physiological properties of the precipitate obtained by adding serum from a horse which had been subjected to a special immunising treatment to culture solutions of the Koch bacillus.—Gabriel **Bertrand** and M. **Rosenblatt**: The temperature at which the plant tyrosinases lose their diastatic activity. The temperatures found varied between 60° and 95° , and these differences cannot be attributed to the nature of the solvent, but rather appear to be a specific property of the diastatic substances.—L. **Launoy**: Certain protoplasmic enclosures of the normal hepatic cell of the rabbit. The author describes under the name of pigmented lipid bodies certain hitherto unnoticed corpuscles of complex structure in the hepatic cell of the adult rabbit.—Jean **Boussac**: The tectonic interpretation of the flysch of central and eastern Switzerland.—F. **Grandjean**: Remarks on the siphon of the ammonites and belemnites. The envelope of the siphon consists chiefly of calcium phosphate, and not calcium carbonate, as hitherto supposed.

CALCUTTA.

Asiatic Society of Bengal, April 6.—E. **Brunetti**: Review of our knowledge of the Oriental Diptera. The paper is a comparison between our present knowledge of the Oriental Diptera and that possessed by entomologists at the date of Van der Wulp's "Catalogue of South Asiatic Diptera" (1896).—Lieut.-Colonel D. C. **Phillott**: Vocabulary of technical and sporting terms in Urdu, Persian, and Arabic.—E. R. **Watson**, Monohar **Gupta**, and Satish Chandra **Ganguli**: A chemical examination of the butterfat of the Indian buffalo.—E. W. **Vredenburg**: *Chondrodonta bosei*, a new species of fossil lamellibranch from the hippurite-bearing beds of Seistan. The first bivalve mollusc described in the Records of the Geological Survey, vol. xxxviii., part iii., proves to be a Chondrodonta, here named *Chondrodonta bosei*.—Hem Chandra **Das-Gupta**: Palaeontological notes on the Gangamopteris beds of Khunmu (in Kashmir). On a visit to Khunmu, in Kashmir, remains of a palaeoniscid and an ichthyod orulite fish were found, which are briefly described.—H. E. **Stapleton**: Contributions to the history and ethnology of north-eastern India; ii. This paper deals with the coinage of Assam in its relation to the history of Assam as given in the *Buranjis*. The chief materials on which it is based are:—(a) the find of nearly 1000 coins made in 1906 at the Daflating Tea Garden, near Jorhat, in Assam; (b) the cabinet of Assamese coins in the possession of Mr. A. W. Botham, C.S.; (c) the recent catalogue of Assamese coins in the British Museum, published in the *Numismatic Chronicle* by Mr. J. Allan; and (d) the writer's own collection of Assamese coins.

THURSDAY, MAY 19, 1910.

THE COMPARATIVE PHYSIOLOGY OF
RESPONSE IN ANIMALS.*Umwelt und Innenwelt der Tiere.* By Dr. J. von Uexküll. Pp. 259. (Berlin: J. Springer, 1909.) Price 7 marks.

THIS is one of the most interesting summaries of biological work that has appeared recently. Written by one who has had a large share in physiological research, it deals in an intimate manner with the comparative physiology of reflexes among the lower animals and with the adaptation of structure and function to varying habits in the case of allied genera. The influence of Sherrington's work is very obvious, and is suitably acknowledged, but whereas "the integrative action of the nervous system" is a profound study of the higher animals, the present work attempts the same analysis of action in various lower types, and then synthesises conduct in the light of the reactions so displayed. The anatomical knowledge required for this purpose is not great, and the technical physiological difficulties of terminology, though more formidable, are not insuperable. When these are acquired, the analytic skill of the writer in delineating the inwardness of animal movement becomes a source of real pleasure.

The main theme of the book is to discriminate (1) the effective external stimuli that constitute the "Umwelt" of each selected group or typical example; (2) the nervous stimuli set up within these creatures and forming the "Innenwelt," and (3) the sense of perception or "Gegenwelt" that arises in the "brain" of the higher groups. What part of its environment really affects an amœba, a sea-anemone, or a jelly-fish can only be determined by a study of its reactions, by an analysis of its neuro-muscular activities. Hence the need for a renewed analysis of muscular action and of nervous control. Accordingly, in each chapter the author, with a few vigorous sentences, sketches out the habits and movements of the type selected, and the dominant features of its muscular and nervous topography. A more detailed account of its reactions in relation to its mode of life is then given. Finally, the muscular action in relation to nervous stimulation is dealt with in detail, and the effective outer and inner world of the creature is summed up in a few lines.

The nature of protoplasm and the origin of structural organisation form the problems of the first chapter. "Does protoplasm possess a structure or is it a fluid?" is a question that has been varyingly answered for the last eighty years. Even if we agree with Bütschli and Rhumbler in assuming a certain structure in fluid protoplasm when at rest, the behaviour of "streaming" protoplasm (as in Amœba and cyclosis) forbids the assumption that any structure persists when the mass flows and points to its essentially fluid unorganised nature. Thus the first paradoxical property of this living substance becomes

apparent, namely, its power of converting a fluid into an organ, into a series of organs, and then of withdrawing these and resuming its structureless condition. The Amœba or the digestive cell of a lowly worm "puts out" a highly organised process made from fluid unorganised protoplasm, and, having therewith enclosed some food, withdraws this appendage. The undifferentiated egg of animal or plant becomes organised, and the organisation may become resolved under adverse conditions into a structureless mass (as in the "brown-bodies" of Polyzoa), which is reorganised as more favourable conditions recur. This property of morphogenesis and regeneration separates living things from all machines, and when taken together with the phenomena of "regulation" (physiological changes in organisms consequent on stimulation), it shows, in the author's words, the supra-mechanical nature of the origin of structure, however mechanical the functions of organisation may be.

The physical basis of life is indeed a paradox. Its organisation hinders rather than helps additional complexity, for that which is to constitute the addition has to be made, not out of what is already organised, but out of what has been left over of the unorganised protoplasm, and in this process not a present, but a future, mechanism determines the process. We think of action as the relation of precedent to consequent, but in protoplasmic action, what is consequent determines the initial stages of change. Animals and plants arise like a musical composition in which the later parts condition the earlier ones, even though they are only reached through the opening bars or movements. They are not like machines, unities in space only. They are also unities in time. In this sense von Baer's metaphor is magnificently expressive. Organisms arise, he says, like a kind of melody.

From this preface the author passes to a systematic treatment of invertebrates. On the basis of Jennings's researches, he concludes that Amœba (or at least *Amœba terricola*) responds only to three kinds of stimuli—mechanical, chemical, and luminous. Paramecium, by a series of delicately poised adjustments, "rests more safely in its environment than a child in its cradle." It is so adjusted that all happenings bring it luck except the arrival of a carnivore of its own kind (Didimium). Far lower than these Protozoa in poverty of response is the ascidian *Ciona*. The effective environment of this creature during its active larval stage has not been analysed, but the adult sea-squirt is apparently dead to every impulse save one. Only mechanical shocks are recognised, and these in successional order. An interesting study of sea-anemones brings the writer to reflex-actions, of which these animals exhibit three—contraction of the circular muscles, secretion of slime, and contraction of the longitudinal muscles. The influence of tides and of light are certainly felt in littoral species, though in the case of the Mediterranean forms studied by the author their effect is apparently extremely slight. We feel, however, that the light-reactions will prove vastly more important than is here assumed, for the

simple reason, overlooked by von Uexküll, that these anemones are infected by symbiotic algæ.

The effect of wave-action is analysed in a most interesting section devoted to the higher medusæ. The simpler nature of the muscular reflex in Rhizostoma is first explained. It is shown how contraction of the circular muscles of the bell-margin, together with that of the stomach-wall, subserves at once locomotion, respiration, and nutrition. The food of Rhizostoma (Diatoms) is obtained by filtering the sea-water through the minute pores into which the oral aperture is converted. Especially attractive is the contrast in this section between the two allied genera, Rhizostoma and Gonionemus. The first leads a life of one stimulus. The rhythmical pulsation of its bell is its only act, its one stimulus. Gonionemus, on the other hand, though not structurally very diverse, leads a full life. It responds to light and to darkness, to gravity, to chemical and mechanical stimuli. The same world environs each animal: but an organism is, as it were, a wonder-world shut off from this environment, and only the right key opens it. When there is no lock there is no key, and such is the plight of Rhizostoma. Gonionemus has many doors, each with its special key.

From jelly-fish the author passes to the study of sea-urchins, and here he is thoroughly at home, leading the reader through a study of bionomics to an analysis of muscular contraction that is of the greatest importance to physiologists.

Of the author's analysis of the movements of the earthworms, leech, and Sipunculus we have no room to speak, but recommend it to the attention of all physiologically minded biologists; but a word must be said on Jordan's recent work on the locomotion of the mollusc, *Aplysia*. The body of this creature is enclosed in a muscular sac provided with a thick nerve-network. Each nerve is connected with this diffuse nervous system as well as with the ganglia. The extraordinary thing about the stimulation of this system is that, if the pedal ganglion be stimulated, the effect upon the network and muscular sac is entirely different from that proceeding from the cerebral ganglia. The "brain" inhibits motion; it acts as a brake. These animals, and possibly all Mollusca, resemble such machines as give rise to an excess of steam in all their parts, which excess is allowed to escape by numerous exits. The idea of a group of animals which acts in this way is an entirely novel one.

The further studies on crabs and dragon-flies are of great interest, and we wish it were possible to reproduce their conclusions. Enough, however, has been said to indicate the value of this work. If only the nature of the author's views on reflexes were expressed more clearly we should be inclined to place this book among the most attractive, as it certainly is one of the most illuminating, comparative studies that have appeared. It should appeal to the physiologist and psychologist as much as to the naturalist, and if translated (with a glossary appended) would be eagerly read by a much larger public than will appreciate it in its present form.

F. W. GAMBLE.

SCIENCE AND BELIEF.

Science and Religion in Contemporary Philosophy.

By Prof. Émile Boutroux. Translated by Jonathan Nield. Pp. xi+400. (London: Duckworth and Co., 1909.) Price 8s. net.

THIS book is an able study of the various attempts which have been made since the beginning of the great scientific movement of the nineteenth century to comprehend science and religion in one system. The writers considered fall into two groups, according as they approach the problem from a naturalistic or spiritualistic standpoint. As representatives of the former M. Boutroux takes Comte, Spencer, Haeckel, the psychologists and the sociologists. The inclusion of Haeckel was perhaps due to his popularity; his dogmatism and inconsistencies are too crude to be worth the attention of an analyst so subtle as M. Boutroux. The discussion of the others might be said to be a discussion of three suggested unifying notions—the notion of humanity, that of the unknowable, and that of fact. The first M. Boutroux finds too narrow, for science refuses to accept an ideal from practical human need, and the essential object of religion is something that is more than man. The concept of Spencer gives liberty at the cost of significance; M. Boutroux shows very clearly that Spencer was led to it by a false standard of knowledge, the standard of pure objectivity, according to which to know the absolute would be to know it as one thing among others. As for the psychologists, who show that the scientific and the religious activities are amenable to common psychic laws, their reconciliation ignores the difficulty, which is the disparateness of the specific ideals inspiring these activities. The sociologists are in no better case; for the given social ends to which they propose to make religion and science both subservient are being by these continually recreated.

M. Boutroux's analysis of the spiritualistic efforts to solve the problem is equally searching. He deals first with the apologists. Some, like the Ritschilians, appeal to immediate internal conviction as the sufficient defence for religion; there are others who, by a criticism of science, show that it is ultimately founded on certain practical beliefs, and contend that science cannot object to religion merely as belief. But the first, since they have discarded all theory, can do nothing but indicate a mere subjectivity, and the second can offer only what appear to be arbitrary beliefs as against the verified hypotheses of science. Next is considered that philosophy which professes to find in activity a principle of unity deeper than the level of our intellectual contradictions, and regards science and religion as complementary but independent expressions of that unity. M. Boutroux points out here a dilemma; if the activity is indeterminate it is without meaning; if it is concrete it returns to us the problem with which we started. Finally, the hypothesis of James that religious experience belongs to the subconscious realm is discussed; the objection is made that the subconscious must be mediated by the conscious, and that hence its import will again be

conceived under the limitations of ordinary cognition.

The concluding chapter dwells on the relative and symbolic nature of science and its subordination to life; on the insufficiency of human life in itself as an end; on the ideal of duty which summons us beyond the specifically human to a noble struggle and a great hope, an ideal which implies faith and love, which demands a God, and a God with whom we can be in communion. It is in the "living reason" interpreted in the light of duty that science, without which we cannot live, and religion, without which we do not wish to live, find their reconciliation. It must be admitted that this chapter, fine as it is, could not endure the rigorous logic which M. Boutroux has applied to others. His duty is formal, and though a formal notion may, as he says, be efficacious, that concrete efficacy is psychological; we are no nearer a logical synthesis than we were, say, with the notion of concrete activity. But the failure of this effort at construction does not diminish the success of the book in its main intention of critical estimation. M. Boutroux is, like most French writers, a master in exposition; he excels especially in revealing that natural logic by which a biased view tends to correct itself, an excellence which indicates both the generous critic and the trained philosopher. Probably no book has been written on the subject which will so well repay the student's attention.

THE CHEMISTRY OF THE SUGARS.

The Simple Carbohydrates and the Glucosides. By Dr. E. Frankland Armstrong. Pp. ix+112. (London: Longmans, Green and Co., 1910.) Price 3s. 6s. net.

CHEMISTS as well as physiologists will welcome the latest addition to the monographs on biochemistry, for there is no other branch of the subject which has afforded so many brilliant examples of successful synthesis or shed so much light on the intricate problems of enzyme action.

The editors have been fortunate in securing the collaboration of Dr. E. F. Armstrong, who has made a special study of the chemistry of the carbohydrates, and writes with an intimate practical knowledge of his theme. At the first glance through the pages of this volume one receives the impression that the author starts on too high a plane, and assumes an acquaintance with the methods and problems of stereochemistry which the biochemical reader may not possess; but one realises on reflection that if he has to compress into ninety-two pages the substance of a subject upon which volumes have been written, he has determined wisely in concentrating into this restricted space those modern developments of sugar chemistry which are of special interest to the biologist, and in leaving other things to take care of themselves.

It is, no doubt, for this reason that the main attention is directed to the natural sugars and glucosides, and that the artificial products are only touched upon where questions of a more general nature are concerned.

The first two chapters are devoted to the structure

and properties of glucose, and are followed by one describing the natural hexoses and pentoses, whilst the fourth contains a description of the disaccharides. The succeeding two chapters contain an account of problems with which the author is more closely identified, and furnish much the most interesting reading. In the first of these the subject of configuration in its relation to enzyme action is discussed, and includes the selective action of maltase and emulsin on the glucosides to which Fischer first directed attention, and the selective oxidation of alcohols and sugars by the *sorbose bacterium* described by Bertrand.

Under "Hydrolysis and Synthesis," in which reference is made to the rate of hydrolysis of the disaccharides by acids and enzymes, the author discusses his stereochemical hypothesis, based on a series of interesting numerical data. Such a hypothesis, which may be tested experimentally, can only enlarge our outlook, and the same may be said of the mechanical similes of templates (p. 71) and glove fingers (p. 58), provided we regard the latter, as Fischer did his lock and key, as similes only and nothing more. The writer would, however, like to raise a mild protest against a fusion of the two ideas which the author makes use of in the formula on p. 58, where the atoms of enzyme and substrate are represented as interlocked, a theory which, on the one hand, can never be tested experimentally, and, on the other, can offer no advantage over the lock and key or other mechanical simile.

On the whole, the subject is well and clearly written, and there is very little with which the critical reader can find fault. Here and there certain passages occur which might be improved by expansion or modification, and in this connection reference may be made to the following paragraphs:—

On p. 66 we are told that the difference in the hydrolytic behaviour of enzymes and acids is "due mainly if not wholly (1) to the superior affinity of the enzymes for the carbohydrates; (2) to the very different behaviour of the two classes of hydrolysts toward water—which is a consequence of the colloid nature of the one and the crystalloid nature of the other." One would like to know more precisely how the "superior affinity" and "colloid nature" act in favour of the enzyme.

On p. 70 the author refers to Fenton's reduction of carbon dioxide to formaldehyde by magnesium as a deeply significant observation when considered in relation to Willstätter's discovery that chlorophyll contains magnesium. Are we to suppose that the magnesium in chlorophyll plays the part of the free metal? If not, what is the deep significance of the observation?

There is a slip on p. 59, where α -carbon atom should be "first carbon atom," and on p. 68, where it is stated that sorbose is derived from mannitol. Xylose is not limited to straw, but is found in most kinds of wood (p. 37). In the separate description of the disaccharides, for some reason not given, three members in table viii. are omitted. On the first page of the introduction the author says, "The members of the sugar group are usually distinguished by names hav-

ing the suffix *ose*." This being the case, it seems a little unfortunate that the termination "ide" for the generic names of the groups should have crept into our system of nomenclature. It is equally unfortunate that our present system recognises no means of distinguishing rotatory sense and configuration, and an official revision of both is urgently needed.

In conclusion, a word must be added in praise of the excellent bibliography at the end of the volume, the usefulness of which would be greatly enhanced if the references were numbered to correspond to those in the text. Under the present arrangement, reference to the source of information necessitates a reference to the chapter, then to a long list of names, and, finally, to the contents of a whole volume or series of volumes and original papers. J. B. C.

A PROSPECTOR'S HANDBOOK OF MINERALS.

The Recognition of Minerals. Being a Collection of Notes and Simple Tests for the Use of Travellers and Prospectors. By C. G. Moor. With Monographs on Geology, Ore Deposits, &c., by Donald A. MacAlister. Pp. vii+231. (London: The Mining Journal, n.d.) Price 7s. 6d. net.

THE old days of prospecting, when scanty equipment and slender knowledge, if backed by sufficient perseverance, were all that was requisite, have gone never to return. The insatiable demands of present-day life for purposes both of peace and war—may be for a filament for an electric lamp of improved efficiency, or a new alloy to impart exceptional hardness to steel—have enormously increased the range of mineral substances which a successful prospector must bring within his purview. In fact, it is necessary for him to have at hand more knowledge than can be conveniently or accurately assimilated by the memory, and he is compelled either to prepare for himself a series of notes or to put in his pocket a book such as that which Mr. Moor has prepared. Himself a traveller, Mr. Moor writes with the understanding of one who knows what exactly is the information required, and many of the sections, for instance, those dealing with the subjects of "panning" and "vanning," contain much detail of great practical value which may save the novice much time, trouble, and annoyance. To give that basis of theoretical knowledge which makes the radical difference between an intelligent understanding of the principles of the methods and merely blind rule-of-thumb working, several important monographs by Mr. MacAlister have been incorporated in the book. He has followed the customary treatment of the subjects, and discusses them in sufficient fulness for the purpose in view.

In the recognition of minerals, which, as the title tells us, forms the main subject of the book, reliance is placed upon the colour as an initial criterion. It is, as Mr. Moor points out, far from a constant character of most species, and, moreover, suffers from the disadvantage that the terms in which it is expressed are wanting in precision, and that the appreciation of delicate differences varies considerably with

the individual. On the other hand, it is the most obvious of the physical characters, and suffices for a preliminary separation. The range is subsequently narrowed by the crystalline form, if any, and by determinations of the hardness and the specific gravity, until the identity of the mineral is established; the conclusion may be confirmed by the application of a few simple blowpipe and other chemical tests which are possible with a prospector's outfit. A full description of each mineral is given under the colour which most commonly characterises it, but cross-references are added under the less usual colours. The data that are given for each species include the hardness and the specific gravity, the ordinary chemical reactions, the localities where it has been found in workable quantity, and its commercial value. At the end of this section useful lists are added of minerals soluble in water, hydrochloric acid, and aqua regia, and of minerals which are unaffected by these liquids.

The section that follows on the metallic and non-metallic elements is particularly useful, because this information is not contained in a text-book on mineralogy. Under each element is given a list of the principal minerals in which it occurs, their physical and chemical characters, and particulars of its commercial use and value. Other sections deal with the important subjects of the working of the lodes and the extraction of the metal desired; a special section in the appendix is devoted to the extraction of gold. Mr. Moor mentions the precious stones, but gives few details, and refers the reader to two works the scope and nature of which he describes in the appendix. Of these one is quite satisfactory, though costly and too large for a traveller to carry about; but the other is full of mistakes in facts and principles, and is likely to prove a broken reed; it is strange that Mr. Moor should so strongly recommend it.

The book originally appeared in parts in the columns of the *Mining Journal*, and this fact may, perhaps, account for the eccentric pagination, the first page coming in the middle of the introduction, and for the division into sections and not into well separated chapters. The text is printed on the right-hand page only, the other being left blank, presumably for the addition of notes; interleaving would have been a neater and equally effective method. The index is fairly complete, but why should an irrelevant advertisement have been sandwiched between it and the text?

ELECTRIC DISCHARGES THROUGH GASES.

Conduction of Electricity through Gases and Radio-activity—a Text-book with Experiments. By Dr. R. K. McClung. Pp. xvi+245. (Philadelphia: P. Blakiston's Son and Co., 1909.) Price 1.50 dollars net.

THOSE teachers of physics who are considering the desirability and practicability of introducing into their more advanced courses of laboratory work some experiments on the discharge of electricity through gases and on the phenomena of radio-activity will find this book a useful guide. Believing that our

knowledge of the fundamental facts has now become sufficiently definite to justify the step. Dr. McClung has arranged a series of experiments designed to give a practical knowledge of the methods employed and the results obtained in these newer developments of electrical science. The description of the book as a text-book with experiments indicates the plan on which it is written. A connected account of the subjects considered is given from an experimental point of view, with descriptions and diagrams of suitable apparatus by means of which students may perform the experiments and test the results stated, without unnecessary complications. Thus the book provides a convenient summary of the results of recent researches, and is not a volume for the laboratory only.

The book is divided into two parts; chapters i.-vii. deal with electric discharges through gases, and chapters viii.-xvi. with radio-activity. In part i. accounts of kathode and Röntgen rays and a sketch of the ionisation theory are given, while descriptions of a few experiments on ionisation by ultra-violet light and by incandescent solids are added. We commend to the notice of those beginning research in this department the valuable chapter on the apparatus and instruments used in the investigations. The practical hints on the manipulation of electrometers and electroscopes, given by an experienced worker, cannot fail to be helpful. In part ii. experiments on the radiations and emanations from radio-active substances, on induced activity, and on the radio-activity of the atmosphere are described, and a sketch of the disintegration theory is added. A list of 125 experiments is given at the beginning of the book; the author suggests that the more difficult experiments, of which twenty are indicated, may be reserved by the student for a later stage.

We think that students contemplating research in these branches of physics would find the course a valuable preparation for their work. From the nature of the experiments, however, it will be evident that most of them could be undertaken profitably only by those who, as a result of their previous experience of practical work in electricity, have acquired considerable skill in manipulation; for it would be useless to set a student who was unable to manage a galvanometer to struggle with the difficulties of an electrometer. To set up the apparatus and perform the whole of the experiments would require a considerable time; but a student who worked through even a small number of experiments selected from the list would gain a valuable insight into the methods of investigation in use in this part of the subject. The provision, for purposes of instruction, of the apparatus which is necessary would, we fear, form a difficulty in some physical laboratories, and, paradoxical as it may seem, not least in those in which researches dealing with the subjects of the book are in full progress.

A few of the definitions in the theoretical sections require more careful statement, and the remarks on the law of decay at the end of chapter xii. need revision. The book is also capable of considerable improvement in literary style.

TWO BIOLOGICAL TREATISES.

- (1) *Die Selektionstheorie*. Eine Untersuchung von August Weismann. Pp. vi+69. (Jena: Gustav Fischer, 1909.) Price 2 marks.
- (2) *Experimentelle Studien zur Soma- und Geschlechts-Differenzierung*. Erster Beitrag. Von Prof. Johannes Meisenheimer. Pp. vii+149. (Jena: Gustav Fischer, 1909.) Price 6.50 marks.

(1) **A**MONG the most welcome effects of the Darwin commemoration held last year at Cambridge has been the reappearance of Prof. Weismann in the lists as a champion of the doctrine of natural selection, a cause which for the last fifty years he has never ceased to defend with the whole weight of his authority and learning. But for the invitation from Cambridge to contribute to the memorial volume published on that occasion, the veteran professor, as he informs us in the preface to his "Selektionstheorie," would scarcely have undertaken to add anything to his former writings on the subject. Now, however, he has not only enriched the Cambridge "Festschrift" with the English essay in which his views are so admirably stated, but he has published the same treatise in German, substantially unaltered, but with the addition of certain passages in which his conclusions on the subject of the reality of the selection-process are driven home with fresh force and cogency.

In this production Weismann's dialectical ability and literary skill shine out as conspicuously as ever; and it would be difficult to find, within the same compass, an equally convincing presentment of the case for Darwin's conception of the action of natural selection in the formation of species, or one more aptly illustrated by examples drawn from many departments of organic nature. While so much continues to be written which tends to overcloud and confuse the simplicity of the Darwinian position, it is refreshing to see how Weismann goes straight to the point, brushing aside those objections that proceed from imperfect appreciation of the facts to be explained, and quietly putting in their proper place, as subordinate to the selection-theory, certain well-attested phenomena which have in some quarters been supposed to be hostile to Darwinian interpretations. All this is done with the utmost candour and courtesy, and without the least trace of arrogance or contempt for adverse opinion. In full agreement with both Darwin and Wallace, Weismann here holds, as he has always done, that adaptation is a universal principle in the world of life, and that of this principle selection affords the one and only possible explanation. After reading the masterly defence of the position to be found on pp. 48-69 of the present treatise, those younger biologists who may have allowed themselves to be troubled with doubts as to whether, after all, the theory of adaptation by selection has not been overdone may well take fresh courage and renew their confidence in Darwin's solution of the teleological problem.

Sexual selection, to which Darwin attached much importance, has been vigorously attacked from many

quarters. Some of the staunchest upholders of natural selection, including Wallace himself, look askance at the theory which seeks to explain certain features of colouring and other ornamentation in male animals as the result of female preference. Here also Weismann ranges himself unhesitatingly on the side of Darwin. Sexual selection is to him a real and active transforming force, as demonstrable as natural selection itself, and passing into the latter by an easy transition. A specially interesting section of the present essay deals with the scent-producing organs of male Lepidoptera, the perfume distributed from which is now known in very many cases to be as agreeable to the human perception as it presumably is to that of its possessors or their mates. Weismann's own ancillary theory of germinal selection, suggested to some extent by Roux's conception of the "struggle of parts," is here lucidly expounded. Whether the theory be accepted or not—and many, it must be admitted, have found it unconvincing—there is no doubt that it would account for many facts at present not easy of explanation.

(2) The second treatise is of a different character. It contains a detailed account of elaborate experiments on the removal and transplantation of the primary sexual organs in the larva of *Lymantria dispar*, commonly known as the "gipsy-moth." Meisenheimer has succeeded, by the help of the galvanic cautery, in destroying the reproductive glands in larvæ of both sexes at various periods of growth, beginning with the earliest stage after emergence from the egg. In partly-grown larvæ he has been able to transplant the male primary reproductive organs into the body of a female, and *vice versa*. As principal results of his experiments he considers himself to have proved the inability of the reproductive organs, as distinct from mere sex-characters, for regeneration; and also the absence of any formative stimulus for secondary sex-characters, emanating from the primary sex-organs themselves. A transplanted ovary is shown to have no impeding effect on the development of the male reproductive apparatus, while the ovary itself can reach its fully mature condition when artificially inserted into the body of the male. The regeneration of sex-characters, where this takes place, is entirely unaffected by the absence of the primary sex-organs of the individual concerned, or by the presence of those of the opposite sex. The conditions obtaining in hermaphrodites naturally occurring among the Articulata are similarly adverse to the theory of a special formative stimulus for the secondary sexual characters. Meisenheimer is, of course, well aware that the experimental evidence derived from vertebrates seems, *prima facie*, completely at variance with his own results; but he adduces much ingenious argument with the purpose of showing that the "internal secretion" of the testis and ovary, which is certainly a reality, has nevertheless no such specific influence on sex-characters, whether somatic or psychic, as has been supposed. It is, according to him, entirely a matter of enhanced or impeded exchange of material (Stoffwechsel). Metabolism is partially checked by castration, and can be restored by the artificial re-

introduction of generative products, not necessarily of the same species. But this metabolism is not specially concerned with the sex-apparatus or secondary characters, and any effect it may have thereon is incidental and not essential. The author's facts are undoubtedly striking, and his criticisms of adverse views are weighty. But his argument as regards vertebrates is not entirely convincing.

F. A. D.

OUR BOOK SHELF.

Metallography (Printing from Metals). Being a full consideration of the Nature and Properties of Zinc and Aluminium, and their Treatment as Planographic Printing Surfaces. By Charles Harrap. Pp. xvi + 170. (Leicester: Raithby, Lawrence and Co., Ltd. 1909.) Price 3s. net.

THIS treatise professes to be a text-book on the subject of printing from metal plates instead of stone, and is addressed to the lithographic trade. The term "metallography" is a word invented to specify this particular form of printing as distinct from "metallography" as used by metallurgists in a general sense.

Although metal has been in use with more or less success during the past century, it is evident that it is fast coming into more general demand. Zinc was first used, and is still used very largely, but aluminium has more recently been employed as the basis for taking or holding the design to be printed from. The readiness to which either metal lends itself in bending or curving has in turn suggested the manufacture of printing machines of a rotary character, and the result is that there has been a remarkable development in the presses used in producing printed work by the lithographic method.

For some classes of work the stone is still preferred, and probably better results can be obtained from this material in some instances; but if the question of first cost of stone as compared with metal plates is to be studied, the latter are the more economical. Again, the question of space occupied and the great weight of stones for both storage and carriage must be considered. As already indicated, the introduction of metal plates has allowed more scope for the machine-builder, which has quickened and cheapened the output. With the ordinary lithographic stones, which must be printed from the "flat," it was hardly possible that the old forms of presses could be much improved upon.

One other important development has been the introduction of the rotary off-set presses by several manufacturers, which may be used in connection with one or more colours in printing. Either zinc or aluminium plates may be used, and these are fastened round a cylinder, which gives its impression or off-set to another cylinder fitted with a rubber sheet or blanket. The paper to be printed is then conveyed by grippers to a third cylinder, which in motion receives its impression from that which is covered by the rubber.

Very good results are given on cards, or even rough paper, without previous dampening of either material; this obviates the employment of glazed or calendered surfaces, which is a decided advantage. The finished sheets are delivered automatically and the printed face upwards, so that the work can be easily watched in course of production. Such machines as these will produce 1500 or more copies per hour, fed in singly by hand, but the output may be considerably increased by adopting an automatic feeder.

The author has treated the whole subject in a very practical manner, and his long experience as a

technical teacher enables him to put the book into a succinct form, suitable alike for the worker and for the student. The volume is also to be recommended to the general seeker after knowledge of the printing arts.

Modern Telephotography; a Practical Manual of Working Methods and Application. By Captain Owen Wheeler. Pp. 80. (London: Ross, Ltd., 1910.) Price, paper, 1s. 6d.; bevelled boards, 2s. 6d.

CAPTAIN OWEN WHEELER is an enthusiastic and successful user of telephotographic lenses, and in this small volume he sets down his experiences in plain language, and gives the rules that he has found serviceable. He refers only to the lenses issued by the publishers, but this is the only drawback to an eminently practical and useful treatise. Seeing that the one advantage of a telephotographic lens is that it gives the image on a larger scale, without the need for an equivalent length of camera, and that it is as applicable to near, as to distant objects, the photography of near objects is very meagrely dealt with. But this is rather an advantage than otherwise, as it indicates that the author treats only with those matters of which he has had considerable experience.

The two details that the author's name is chiefly associated with are the use of a hood in front of the lens to cut off extraneous light, and the use of negative lenses of different powers for different magnifications, instead of trusting to variations in the length of the camera. It is hardly too much to say that, trivial as these details appear, Captain Owen Wheeler has by means of them revolutionised the practice of outdoor telephotography. He truly claims that his photographs bear no sign of their special method of production, the flatness and fog so often present being completely obviated. The long hood that he first caused to be available had a rectangular opening in front, and was of liberal dimensions—here he seems to refer only to telescoping tubes little, if any, larger than the outside of the lens mount. If this is so, it is distinctly a step backwards in efficiency, though the aluminium tubes may be more appreciated by the manufacturing optician. Concerning the choice of lenses, with an ordinary half-plate camera and a lens of about seven inches focal length, and a camera extension of fourteen inches, the author advises negative lenses from about $2\frac{1}{2}$ -inches to 1-inch focal length, the last giving an equivalent focal length of about 8 feet, or a magnification of about fourteen diameters. The aperture of such a combination obviously must be small, but he does not find diffraction to interfere vitally with definition, even at an aperture of $f/480$. There are many excellent illustrations in the book, and a final chapter on telephotography as applied to the special requirements of the army and navy.

C. J.

A Text-Book of Nervous Diseases. By Dr. W. Aldren Turner and T. Grainger Stewart. Pp. xvii+607. (London: J. and A. Churchill, 1910.) Price 18s. net.

THIS book has been written for the purpose of providing the practitioner and senior student with a short and practical account of the diseases of the nervous system, and is not expected to take the place of the larger works on the same branch of medicine. Owing to the limitation placed upon the size of the book, the description of certain disorders, such as myxœdema and acromegaly, usually contained in works of this description, has been omitted. This we cannot but regard as an advantage, for there seems no scientific reason why diseases of ductless glands should be catalogued with diseases of the nervous system.

It is of the utmost importance, in dealing with

organic nervous affections, that the student should possess an efficient knowledge of anatomy, and be acquainted with some methodical plan for the clinical examination of the nervous system. We are happy to find in this work a short but clear and satisfactory description of the various tests which are available to inform us as to whether a given system is normal or not. There is no obfuscating mass of detail from which the student has by long experience to abstract the useful and eliminate the comparatively unimportant, but a clear, succinct presentment of all that is really essential. The anatomical chapters are similarly well rendered. The book, so far as organic nervous disorder is concerned, is singularly replete, and we can think of no recognised affection which has escaped adequate attention. Considering the relative proportion of the incidence of organic and of the so-called functional disorders, we cannot but regard it as rather a pity that more space has not been devoted to the symptoms, diagnosis, and treatment of the latter class. Herein, however, the authors are only following the trend of British neurology, which has always been rather in the direction of the study of organic disease. In these days, when such an enormous amount of work is being done by non-scientific bodies in the treatment of functional maladies, it becomes very necessary for the trained physician, with his infinitely superior opportunities, to make himself familiar with therapeutic measures suitable for such ailments. Only in this way can unfortunate sufferers be saved from those errors of diagnosis which untrained and self-constituted professors of certain modes of therapeutics are frequently making, and which are so often of fatal consequence. The illustrations and diagrams with which the book is garnished are admirable, and are most helpful in illuminating the text. The work cannot, we think, fail to be of assistance to those for whom it is intended, that is, to the student and practitioner.

Australasian Medical Congress. Transactions of the Eighth Session held in Melbourne, Victoria, October, 1908. Vols. i., ii., iii. (Victoria: J. Kemp, Melbourne, 1909.)

THESE three volumes of transactions are sure evidence, if that were needed, of the activity of our kinsfolk over the sea in matters medical. It is quite impossible in a short space to deal with their subject-matter, which embraces the whole range of medicine, surgery and gynaecology, anatomy and physiology, pathology, bacteriology and public health.

Dr. Julian Smith discusses the opsonic test and its applications to tuberculosis. He considers that in competent hands opsonic determinations are trustworthy and accurate, and in many cases invaluable as an aid in diagnosis and a guide to therapeutic measures. Various papers deal with tuberculin and sanatorium treatment in tuberculosis. Prof. Welsh, Dr. Chapman, and Mr. Storey discuss some applications of the precipitin reaction in the diagnosis of hydatid disease. It was found by Welsh and Chapman that the blood serum of a patient suffering from hydatid disease, which is relatively common in Australia, gives a precipitate with the fluid of the hydatid cyst. In the present paper the extension of the test by the use of old hydatid fluids is discussed. Hæmogregarine parasites in a marsupial flying squirrel and in the native cat are described by Drs. Welsh, Barling, Dalyell, and Burfitt, and Dr. Elkington describes a new cestode worm (*Dibothriocephalus parvus*) obtained from a Syrian patient. The volumes are well printed, and illustrated with many excellent plates.

Atlas of Japanese Vegetation. With explanatory text. Edited by Prof. M. Miyoshi. Set xiii., plates 86-92, pp. 6: *Coast Vegetation of Middle Japan*. Set xiv., plates 93-101, pp. 7: *Mountain Vegetation of Northern Japan*. (Tokyo: L. P. Maruya and Co., Ltd.; London: W. Wesley and Son. 1909.)

THE series of botanical plates illustrating Japanese vegetation, of which the two sets under notice are late numbers, are phototype reproductions illustrating plant-landscapes and a few cultivated plants, arranged for the most part topographically. The thirteenth set contains photographs of a temperate region, in which *Pinus Thunbergii* is a typical tree along the coast. It is shown with a foreground in one case of *Rosa rugosa*, and in another of *Calystegia soldanella*. Another photograph represents a broad expanse of the *Calystegia*, and two plates show a curious segregation of male and female plants of *Carex macrocephala*. The nine plates forming the fourteenth set are taken from three different mountains. Two photographs taken on Mount Azuma depict *Rhododendron Albrechtii* and a natural double-flowered variety of *Rhododendron brachycarpum*. The scenes from Mount Iide include a fine spread of *Phyllodoce aleutica* interspersed with *Geum dryadoides*, and an association of *Geranium davuricum* with *Adenophora polymorpha*. Mount Iwate is the station which provides an unexpected combination of *Rhododendron kamschaticum* and *Pinguicula vulgaris*. The illustrations, measuring about nine inches by six inches, are remarkably sharp and well defined, and are highly creditable to Prof. M. Miyoshi and Mr. G. Nakhara, who are responsible for the original negatives.

Actualités scientifiques. By Max de Nansouty. Pp. 38a. (Paris: Schleicher Frères, 1909.) Price 3.50 francs.

THIS interesting "annual" of M. Max de Nansouty, the sixth to appear, will be welcomed by the general reader anxious to acquaint himself, in as pleasant a manner as possible, with the more popular of the recent advances in science. It is natural in this issue to see great prominence given to the problems in connection with aviation and to electricity in its applications, but readers will find that most branches of science have been drawn upon to produce an interesting miscellany. The volume may be recommended specially to students of science anxious to keep up their French without neglecting their own special work unduly.

Mathematical Tables: with Full Tables of Mathematical and General Constants. By R. W. M. Gibbs and G. E. Richards. Pp. 17. (London: Christophers, n.d.) Price 8d. net.

THESE conveniently arranged tables provide all that pupils in ordinary secondary schools and technical classes require in their mathematical and science lessons. They include logarithms and antilogarithms, natural and logarithmic sines and cosines, tangents and cotangents, and tables of formulæ and data.

Weighing and Measuring. A Short Course of Practical Exercises in Elementary Mathematics and Physics. By W. J. Dobbs. Pp. ix+176. (London: Methuen and Co., 1910.) Price 2s.

THOUGH there is little that is new either in the method or contents of this book, teachers will find here a clear, well-arranged set of practical lessons on the measurement of length, area, volume, mass, and density. An abundant provision of questions—original and otherwise—has been made, especially for candidates in the Army Qualifying Examination.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

A Sponge with a Siliceous and Calcareous Skeleton.

IN Willey's "Zoological Results," part iv., 1900, J. J. Lister described certain small columnar coral-like organisms from 35-100 fathoms off Lifu and Funafuti as calcareous sponges. He named them *Astrosclera willeyana*, and, on account of their isolated position, placed them in a new family—*Astroscleridae*. The skeleton was formed of minute calcareous spherules, separate above, but welded below into solid walls and blocks, the spherules being formed each in a single cell.

Recently Dr. C. W. Andrews obtained from 46 fathoms off Christmas Island four more specimens of this sponge. A decalcified section showed that *Astrosclera* was probably a siliceous Ectyonine sponge, for its canal walls were bristling with spiny nail-shaped siliceous spicules (Fig. 2). I concluded that this siliceous sponge had formed a supplementary calcareous skeleton from foreign particles which had been picked up from outside, so extremely improbable did it seem that a sponge could secrete both lime and silice. Later preparations, however, have shown

FIG. 1.—A specimen of *Astrosclera willeyana*, Lister. Natural size.
FIG. 2.—Section showing laminae and masses of calcareous spherules, and nail-shaped siliceous spicules. $\times 50$.
FIG. 3.—Nucleated cells containing calcareous spherules. $\times 600$.

me that Lister was right, and that each spherule (apparently of conchite) is formed in a single cell (Fig. 3).

Fig. 1 is that of a living specimen and not of a dead stock, and yet I can find no trace of anything else than sponge tissue and spherule cells. Further, the superficial stellate grooves which are excavated in the calcareous mass are formed by the terminal exhalant canals of a sponge.

I continue to regard *Astrosclera* as a siliceous sponge, though I have just become aware that an eminent German zoologist has a very different opinion concerning its nature. Assuming that my theory is correct, *Astrosclera* may possibly owe its unique character to an ancestral habit of picking up foreign particles—in this case—of calcareous detritus, for the sponge has only been found on coral reefs. Some of the lime would dissolve and become re-crystallised in the connective tissue cells. When once this character had been acquired, the clumsy method of the sponge choking itself up with débris would be replaced by the more "scientific" process of elaborating lime direct from the sea water. I hope soon to set forth in detail the *pros* and *cons.* of this theory.

R. KIRKPATRICK.

British Museum (Natural History), South Kensington.

A Difference in the Photoelectric Effect caused by Incident and Divergent Light.

In a letter dated April 26 which appeared in *NATURE* of May 12, Mr. Stuhlmann, of Princeton University, U.S.A., describes some experiments which he has carried out on the photoelectric effect of incident and emergent light. I should like to mention that I have been carrying out some experiments on the same subject at the Cavendish Laboratory, Cambridge, and obtained the same effect as that described quite recently by Mr. Stuhlmann. The experiments were completed more than two months ago, and the results obtained described in a paper communicated by Sir J. J. Thomson to the Royal Society on March 25. In view of the appearance of the above letter they may be briefly described here.

A thin quartz plate was covered with a very thin film of platinum in a discharge tube by directing the discharge from a platinum cathode on to it. The kathode radiation per unit time from the film under the influence of ultra-violet light was measured (1) when a constant beam of ultra-violet light was incident at right angles to the film; (2) when the beam emerged from the film, passing in this case first through the quartz plate. The intensities of the kathode radiations were found to be as 1 to 1.16, while the intensities of the incident and emergent beams were as 1 to 0.5. The conclusion that can be drawn from the experiments is that an electron liberated by ultra-violet light has a component of motion in the direction of propagation of the exciting light.

Cambridge, May 14.

R. D. KLEEMAN.

Steam Tables.

IN *NATURE* of April 21 a review appeared of Profs. Marks and Davis's excellent new tables of steam properties, in which it is stated, without qualification, that the new calculations of the total heat of saturated steam are based upon a second-degree equation $H = a + bt + ct^2$. Both in the explanatory notes to the tables, and still more emphatically and repeatedly in a paper printed in the *Proc. Am. Acad. Arts and Sciences*, March, 1910, the authors state that this equation does not apply outside the limits 200° – 400° F. Simple numerical tests also prove that the tabular figures do not agree with this formula outside these limits, and the formula would give H its maximum value at 724° F. higher temperature, and four heat units more in quantity, than the tables make it. Mr. Davis says that no formula yet discovered will apply throughout the full range, and above about 450° F. the figures given are not credited with a high degree of accuracy or certainty.

Basing upon these new tables, I constructed a formula for total heat, which was published on December 24, 1909, in the *Engineer*, and gives the tabular results with practical exactitude from 70° to 500° F., that is, from 0.36 to 684 lb. per sq. inch absolute pressure. This formula is

$$H = 1826 + t - 10^{-7} \div 8(1620 - t).$$

The following are its "errors" as compared with Marks and Davis's tables:—

t F.	30	50	60	70	80	100	150	200
H Diff.	-3.7	-1.6	-1.2	-0.7	-0.3	0	+0.4	-0.1
t F.	250	300	350	400	450	500	600	
H Diff.	-0.2	-0.1	+0.3	+0.1	-0.4	+0.9	+24.9	

The order of accuracy aimed at in this formula is further illustrated by the factors 0.9938, 0.9977, 1.0066, and 1.055 having been tried for the term in t instead of 1, and having failed; while, in place of $10^{-7} \div 8 = 1,250,000$, one of the factors which was tried and failed was 1,251,150.

The maximum value of H given by this formula is 1210, which is identical with that of the tables, but it occurs at 502° instead of 480° . Exactitude in placing this temperature of maximum H by the purely graphic analysis of a very few experimental results in its neighbourhood which was used by Marks and Davis, is evidently impossible. The tables do not venture to give any values of H above 600° F. My formula may very likely give considerable errors near the "critical point," which is somewhere near 690° F. Here other physical influences probably become prominent, as also, very probably, at low temperatures near that of maximum water density.

ROBERT H. SMITH.

3 Thirlmere Road, Streatham, S.W., May 2.

I NOTICED at the time of its publication in the *Engineer* Prof. Smith's communication of the discovery of an empirical formula which would represent the values of the total heat even more accurately than that of Messrs. Marks and Davis. When speaking of their own formula the authors remarked (pp. 100–1):—"It has been used for the range above 212 in these tables"; but they evidently meant to limit the range to 400° F., although this is not clearly expressed in the paragraph from which the above extract is taken.

I agree with Prof. Smith that it is too much to expect any empirical formula to predict what will occur at the "critical point."

THE REVIEWER.

Fireball in Sunshine.

ON May 10, at 7h. 52m. a.m., a magnificent meteor was seen by many observers in the Midlands. I have read a considerable number of descriptions of the object, but they are not very definite. The meteor was witnessed by persons not well versed in astronomy and exact positions for the apparent flight. It was a brilliant object with a bluish nucleus and tail of red sparks; the observed velocity was moderate. Though the sun was shining the meteor shone with conspicuous effect, and more than one person supposed it to be Halley's comet, or, at any rate, a fragment of that body.

Seen from Birmingham, the meteor's path was from the north-east to north-west, and one good observation ascribes to it an altitude of 30 degrees in a perfectly horizontal course. It is difficult to assign the real path, but an approximate computation places the height at from about 83 to 32 miles along a luminous trajectory of nearly 100 miles at a velocity of 20 miles per second. The position of the radiant point is doubtful, but several of the observations indicate it in Auriga or Perseus. The meteor travelled over the region of Yorkshire or Lincolnshire towards the district of Liverpool, but in the absence of more exact materials it is quite impossible to derive the path with certainty.

No stars being visible in the bright blue of the May morning which presented this unusual celestial phenomenon, the observers could not locate the position with the required accuracy; but it is hoped that further observations will come in from the northern counties of England. The "daylight fireball" of May 10 last reminds us of a similarly brilliant object which flashed out amid the sunshine on October 6 last at 9.40 a.m. W. F. DENNING.

Observations of Halley's Comet and Venus.

It may interest readers of *NATURE* to know that the planet Venus was visible—plainly visible—in Natal all day to-day up to the time of its setting. The air was wonderfully clear and free from dust or moisture. At four o'clock in the morning Venus was unusually brilliant, the light therefrom shining into my bedroom. Halley's comet rose above the horizon at about 4.30, and, although distinctly visible to the naked eye, was pale and insignificant compared to the planet. By six o'clock the comet was no longer visible, having paled away before the sun had actually risen. At mid-day excited groups of natives and Europeans were gazing with wonder at what was mistakenly considered to be Halley's comet visible in broad daylight! Venus was then in the zenith, her glory defying the power of the mid-day sun. E. T. MULLENS.

Pietermaritzburg, Natal, April 22.

Earwigs of India.

IN *NATURE* of April 14 was published a review of my half-volume on the Dermaptera in the "Fauna of British India" series, in which the reviewer directed attention to a most regrettable oversight on my part in omitting to allude to the British Museum when acknowledging the various sources which supplied me with material.

Fortunately, the frequent references in the text betray my indebtedness, but I should be glad to take advantage of the hospitality of your pages to make amends, at the same time thanking your reviewer for pointing out this extraordinary omission, by expressing now my appreciation of the invariable and well-known courtesy of my good friends among the officials of the museum.

Eastry, Kent, May 5.

MALCOLM BURR.

THE TOTAL SOLAR ECLIPSE OF MAY 9, 1910.

IT was reported in last week's NATURE that, owing to very unfavourable weather conditions, the eclipse of the sun, visible from Tasmania, could not be observed at all. In spite of the fact that the weather conditions in that month were not considered to be very favourable, the parties that set out from England and Australia did not expect to have to contend with the very abnormal weather that they actually experienced. Indeed, the southern part of Australia has, according to recent mails, been suffering also from weather frolics, so that these exceptional conditions were not limited to the eclipse stations.

Those who have been out on eclipse expeditions can quite understand the amount of work involved in the erection and adjustment of several high-powered instruments. Under such conditions as "only two fine days in the last fortnight; terrific gales and thunder frequent," as Mr. Frank K. McClean reports from his station, an idea will be gathered of the difficulties under which he and his party had to labour.

Although the results of the eclipse are negative, it is nevertheless of interest to place on record the elaborate instrumental equipment which Mr. McClean took out with him to use. They consisted in the main of two spectrographs for obtaining photographs of the spectra of the chromosphere and corona, and three coronagraphs of different powers for securing

Brooks, Sydney; J. Worthington, England; H. Winkelmann, Auckland; Allan Young, England; S. G. Dowsett, Auckland; and Ernest Jeffs (steward), Auckland; Arthur Wilson (assistant steward and carpenter), Hobart.

April 4, 1910.

On arriving at Hobart on March 24 I found that Mr. Brooks and Mr. Worthington had already obtained much information about the possible localities for the Eclipse Camp. Mr. Worthington had also examined the east coast to the south of Hobart, and from him I learnt that there was no really good site to be obtained. Later we three made a short excursion south, and found that the whole of the country was mountainous and covered with bush, while, except for the road, which never went far from the sea, there was no possible means of communication. At Dover, on Port Esperance, there was a gap running through these mountains, and from Hope Island in the harbour a fair view could be obtained, giving for some 20° in azimuth a horizon not rising more than 3° above the horizontal. This was a possible place, but owing to the presence of Adamson Peak, 4000 feet high, in the field of view, there was a great probability of clouds even with the rest of the sky clear. We did not visit Bruni Island as the Australian expedition had chosen their site there, and also because the altitude of the sun was only 6½° at eclipse. Having found that the east coast offered no reasonable site for observation, the south-west coast was next visited. To do this it was necessary to take the train to Launceston and Burnie on the north coast, and the following day travel by Zeehan to Strahan, also by rail. Mr. Hughes, the manager of the Union Steamship Co.

FIG. 1.

records of the form of the corona. In connection with these instruments he took with him a large 21-inch siderostat and a 16-inch coelostat, to feed the above instruments with light from the eclipsed sun. In addition to these, he had several instruments of minor importance. With such a fine equipment and such willing helpers it is a pity that it was not possible to make an attack on the eclipsed sun.

It will be remembered that the eclipse track traversed the southern part of Tasmania. As the Australian party occupied Bruni Island, Mr. McClean, in order to obviate any local bad weather condition, set himself the task of selecting another site. This scattering of eclipse parties along the path of the moon's shadow on the earth is usually done when possible; but sometimes, as in this case, very considerable extra labour and difficulties are met with, as it necessitates the additional equipment of the expedition with all the requirements for camp, food, extra help, &c. Such impediments were not likely to deter Mr. McClean from roughing it in some lonely spot away from all civilisation. In order to give the reader some idea of the trouble he took in selecting a site and some details of the spot he finally determined upon, the following communication I have received from him will serve this purpose. I may, however, preface this account by stating the names of the members, up to the date of his letter, which formed his party:—F. K. McClean, England; Joseph

at Hobart, had communicated through to arrange for their steamer, the *Wainui*, to call in at Port Davey after leaving Strahan on its way to Hobart, and we were met by Mr. Eva, the local manager of the company, who did everything possible to assist in the arrangement. Accordingly, on the next day we started on the *Wainui* under Captain Livingstone, and early the following morning found ourselves in Port Davey, and were on shore before sunrise.

We first ascended the hills south of Bathurst Channel to get a general view of the country. In every direction rose hills and mountains from 600 feet to 2000 feet high, and between them were stretches of land-locked water leading out into Port Davey proper and the Southern Ocean. Some of the mountains were masses of almost bare rock, while others looked as though covered with smooth grass, which, however, when traversed, were found to be mostly scrub growth of 1 or 2 feet depth. The more distant mountains and those on the west side of the harbour were heavily timbered. In the valleys were patches of bush and small streams of water, brownish in colour. The place was without population, there being no food except that placed in a refuge for shipwrecked persons, and the country to the back being so mountainous and so thickly wooded that only a few persons have ever broken their way through to the east and north. There are said to be wallaby, wombats, and wolves (Tasmanian devil) in the neighbourhood, and also snakes; but we saw none, and fish are reported to be plentiful. We climbed to the top of Morning Hill and Mount O'Brien, and found that ground overlooking Davey Harbour and a sea horizon across the flat ground by Kelly Basin; but the slope of

the ascent made it impossible of access with instruments, as for part of the way the slope was from 35 to 40 degrees.

From the top it was possible to locate probable sites, and it was seen that there were only two, one at Spain Bay near Hilliard Head, and the other Hixson Point, on Sarah Island, in Bathurst Channel, the latter of which Mr. Brooks and Captain Livingstone were already examining. Spain Bay was open to the full force of the ocean, and was also very shallow, so that Hixson Point alone remained feasible. This on examination was found to answer all requirements. It was only 100 feet high, had deep water close in, and, except for a 6-foot bluff on the shore, had an easy gradient. It was protected from the sea by the Breaksea Islands, and from wind on the south by Morning Hill, and on the north by Mount Misery. There was water within a few hundred yards in a small bay where a camp might be set up, with a small amount of bush cutting. The top was flat for some 200 feet by

addition to tents, photographic materials, kitchen and dining utensils, &c. The danger that weather would prevent the steamer calling in made it advisable not to trust to outside assistance. This has kept us very busy, though we have been given every assistance. Mr. Hughes, of the Union Company, has made arrangements for the *Wainui* to drop us and our kit at Port Davey on April 9, and also to call in twice during our stay before it finally will take us away on May 10 or 11 to Melbourne.

Accompanying the above letter were several photographs of the region about Port Davey, with a large scale map of the vicinity. Three of the above photographs, which, when placed together, form a panoramic view looking towards the direction of the eclipsed sun (azimuth 123°), have been reduced, and are illustrated here in Fig. 1. From this the reader

FIG. 3.

100 feet, and the angle of view from it covered the horizon from west to north-west, the actual figures for the low horizon being:—

South limit of view ...	98°	azimuth from true south	} Angle 32°
Sunset on May 9 ...	114°	" "	
Eclipse	123°	" "	
North limit of view ...	130°	" "	

We therefore chose this spot for our eclipse observations, and returned to the ship by mid-day. From Port Davey we steamed along the south coast, passing through isolated rocks many hundred feet high, and along a coast-line of cliffs, sheer from the water's edge and crowned with trees, offering no possible landing, and of absolutely no use for astronomical observations.

Since there were no supplies at Port Davey we have had to arrange for provisions for the period of stay, in

will be able to gather an idea of the appearance of the neighbourhood and the open view in the direction of the eclipse from the observing station at Hixson Point.

Fig. 2 illustrates a general plan of the neighbourhood, and shows, by dotted lines, the various azimuths mentioned in the above letter.

Up to the present time no information is at hand regarding the erection of the instruments, the camp life, and the rehearsals. This will no doubt be received soon, and will form the substance of a later contribution.

In conclusion, it may be mentioned that in the *Westminster Gazette* for May 12, a Reuter cablegram from Melbourne records the observation of the eclipse made at sea on the Oceanic Company's steamer

Corinthic. It reads as follows:—"The eclipse of the sun was witnessed on board the Oceanic Company's steamer *Corinthic*, 480 miles south-west of Hobart. Totality lasted from 2h. 50m. to 2h. 54m. The corona was unexpectedly structureless, being equally distributed round the circumference. There were no prominences, rays, plumes, or streamers. The chromosphere was dark red and of exceptional depth."

WILLIAM J. S. LOCKYER.

SIR WILLIAM HUGGINS, K.C.B., O.M., F.R.S.

ONE of the pioneers of the new era of astronomy opened by the application of the spectroscopy and photographic plate to celestial bodies has just passed into silence, and though the memorial formed by his works remains with us, no new block can be added or detail elaborated by the hand of its builder. It is not given to many men of science to have their scientific careers associated so closely with new developments as was that of Sir William Huggins, whose death on May 13, at eighty-six years of age, we regret to record. It may almost be said that he was present at the birth of celestial spectroscopy; when he commenced his work nearly fifty years ago, he had a virgin field of study before him, so that "nearly every observation revealed a new fact, and almost every night's work was red-lettered by some discovery." It was inevitable that some lines laid down in this early survey required modification as more exact instruments and methods became available, but the observations served their purpose in showing that new regions awaited exploration, and Sir William Huggins lived to lead investigators into the realm thus gained for science, and to stimulate a new generation to study it in detail.

In 1901, a year after Sir William Huggins had been elected president of the Royal Society, an appreciative account of his work was given by Prof. Kayser in these columns as a contribution to our series of "Scientific Worthies." He was then seventy-seven years of age, and had crowned the edifice of his scientific publications by the production of a sumptuous "Atlas of Representative Stellar Spectra." In 1902 his achievements received the highest official recognition by the bestowal upon him of the Order of Merit. While president of the Royal Society from 1900 to 1905, he delivered four addresses in the course of which he described some of the work which the society has done, and is doing, for the nation. Selections from these addresses, with a short history of the Royal Society, were published in volume form in 1906, and the subjects with which they deal were thus brought under the attention of a wider public than that present at the anniversary meetings at which they were delivered. Two of the addresses were concerned mainly with scientific education, and the public interest excited by one of them led the Royal Society to appoint a committee to consider the subject and prepare a report, which was afterwards sent to the existing universities of the United Kingdom, with a resolution adopted by the president and council asking that steps be taken to "ensure that a knowledge of science is recognised in schools and elsewhere as an essential part of general education." It is a matter for regret that this manifesto, which was a sequel to Sir William Huggins's advocacy of the claims of science in modern life, led to no definite result. A fuller knowledge of the conditions at the public schools and universities, and greater precision in the recommendations of the committee, might have gained for him a place among educational reformers who see their causes triumphant.

There is no need now to refer in much detail to

Sir William Huggins's activities in the domain of astrophysics, for his work was surveyed in the "Scientific Worthies" article mentioned already. He began his spectroscopic studies with Prof. W. A. Miller in 1864, by the examination of the spectra of a few stars, with particular reference to the identification of their chemical constituents. Nine or ten terrestrial elements were found to exist in the atmospheres of Betelgeuse and Aldebaran, and other elements were suspected. While carrying on these investigations, he submitted a planetary nebula in Draco, close to the pole of the ecliptic, to a spectroscopic examination, and found the spectrum to consist of three bright lines, the brightest of which—the characteristic nebular line—he believed to be coincident with a line due to nitrogen. This identification was afterwards disproved, but there remains to his credit the fact that he was the first to observe the bright-line radiation of some nebulae.

Sir William Huggins was also the first to apply the Doppler-Fizeau principle to the measurement of radial velocities. He showed in 1867 that motion in the line of sight could be determined by measuring the displacement of spectrum lines in a star or other heavenly body; but though his work, and that to which it gave rise at the Royal Observatory, Greenwich, demonstrated the feasibility of the method, the results were too discordant to be of substantial service to science. Not until Vogel applied photography to the subject, about twenty years later, was real success achieved, and the value of the principle in astrophysical investigations realised.

Photography had been used by Sir William Huggins in cooperation with spectroscopy long before Vogel showed the precision with which radial velocities could be determined by its aid. He was probably the first to obtain a spectrograph of Sirius, in 1863, using a wet plate, though he failed to secure any impressions of lines in the record. After the invention of the gelatin dry plate, several years later, the attempt to secure photographs of stellar spectra was renewed, and success was attained. Using instruments placed at his disposal by the Royal Society, he photographed the ultra-violet series of hydrogen lines in the spectra of six "white stars," this being the first time the series had been revealed, either in terrestrial or celestial chemistry. It is a little surprising, therefore, that he did not anticipate Vogel in the application of photography to the determinations of radial velocities which have led to such valuable additions to our knowledge of binary systems and the gregarious movements of stars.

Not so much is known, perhaps, of Sir William Huggins's work in other astronomical directions as of that in celestial spectroscopy. With Prof. Stone, about 1870, he made some investigations with the object of measuring the heat received from stars, using a thermopile, and concluded that distinct indications of thermal effects due to stellar radiations were obtained; but the results are now known not to be trustworthy. Twenty years later, Prof. Boys, using his far more sensitive radiometer, was unable to find any definite effects from the brightest stars, and only when a more delicate radiometer was used by Prof. Nichols in conjunction with the great telescope at the Yerkes Observatory was it possible to secure distinct deflections due to radiation from stars like Vega and Arcturus.

Such revision as this of early observations is, we take it, a concomitant of scientific progress. However well an investigator may build, the iconoclast, with superior equipment and deeper knowledge of causes of weakness of conclusions, overthrows the edifice and erects his own pillar in its place. There

is frequently little left of the original foundation, yet each structure represents an advance upon that which it supersedes. Sir William Huggins recorded in 1867 that he had detected the presence of water vapour in the atmosphere of Mars, and re-affirmed his observation later at his observatory at Tulse Hill, but critical inquiry afterwards showed that the conclusions had been drawn too hastily. While, however, those observations must be discarded, we have the recent investigations at Prof. Lowell's Flagstaff Observatory giving clear evidence of the presence of aqueous vapour in the Martian atmosphere. So, like a coral on its base, rises the living body of science upon the monument of past effort. Cemented upon the rock of nature, Sir William Huggins stretched out his hands toward the stars, and if a succeeding generation is able to examine the secrets of the heavens more closely than was possible in earlier days, let it remember the patient pioneer work required to form the base of the pinnacle from which observations can now be made.

R. A. G.

PROF. STANISLAO CANNIZZARO.

BY the death of Cannizzaro, another link between the chemistry of to-day and that of the mid-Victorian era has been broken—a link which perhaps more than any other served to connect two well-defined and sharply differentiated epochs in the history of nineteenth-century chemistry. Cannizzaro was not a great discoverer in the ordinary sense of that word; the number of his published researches is few, and the field of inquiry he cultivated comparatively restricted. His greatest discovery, indeed, was his own countryman, Amedeo Avogadro. The fundamental conception of Avogadro that the gaseous laws of chemical combination—the laws associated with the names of Dalton and Gay-Lussac—could be explained by the simple hypothesis that equal volumes of gases, under identical conditions of temperature and pressure, contain the same number of molecules was as the seed which fell upon stony ground. Even the efforts of Ampère—a man of far more influence in his generation—to cause it to fructify had no immediate effect. Berzelius, for a time, dimly apprehended the potentiality of the supposition, but he eventually lost his way under the blind guidance of dualism, and led Europe wrong for a quarter of a century. The German school, it is true, mainly under the direction of Gmelin, gradually shook itself free from dualism, but it wandered still further from the true faith, and by the middle of the nineteenth century chemical theory was utterly befogged, and its doctrine bristled with inconsistencies, contradictions, and anomalies.

Cannizzaro appeared at the psychological moment, as the phrase goes. In its effect, the publication, in 1858, of his "Summary of a Course of Chemical Philosophy" created a revolution in chemical thought hardly less momentous than that which followed the appearance of Dalton's "New System." The publication of a syllabus of a lecture course is a simple enough occurrence, and perhaps never before marked an epoch. But its effect in this case was instantaneous and profound. Cannizzaro demonstrated that the hypothesis of his forgotten countryman constituted the means of placing the most important of all chemical constants on a definable basis; it rendered our conceptions of atoms and molecules, atomic weights and equivalents, gaseous volumes and valency, and all that is associated with or consequent upon these conceptions, logical and consistent.

It is not too much to say that Cannizzaro's intervention at this time saved the position of the atomic theory. The early 'sixties of the last century were a

period of much perturbation; there was then a sort of parting of the ways. Williamson laboured to stem the tide of infidelity, but many were unconvinced, and some even hardened their hearts. We hear little or nothing to-day of the scepticism which was fashionable among the young bloods of fifty years ago. It is largely due to Cannizzaro that our faith has been strengthened and purified.

There is something dramatic in the circumstance that Cannizzaro should have passed away at the time that all Italy is celebrating the achievements of Garibaldi and his never-to-be-forgotten Thousand in effecting the establishment of Italian unity, a cause in which Cannizzaro had himself struggled and suffered, and in which he was destined to take a share in shaping to a successful issue.

Cannizzaro was born at Palermo in 1826, where his father was president of the High Court of Chancery. He was originally intended for medicine, but under the influence of Melloni he began the study of natural science, more particularly chemistry, under Piria, in whose laboratory he became *préparateur*. The revolution of 1848 found Cannizzaro in Messina, and the youth of twenty-two an officer of artillery and a member of the Sicilian Parliament. For nearly nine months the revolutionaries held out against Ferdinand's army, but Messina was eventually bombarded and sacked, and Cannizzaro and what remained of his band were driven to Taormina. With the disaster of Novara and the abdication of Charles Albert, the Sicilian movement collapsed; the insurgents retreated to Catania, and thence by Castrogiovanni to Palermo, where Cannizzaro succeeded in getting on board a Sicilian frigate, and in escaping to Marseilles. He was now almost destitute, but friends helped him to Paris, and, thanks to Cahours, he found a place in Chevreul's laboratory in the Jardin des Plantes, and began the study of the amines in conjunction with Clœz. In 1851 he became professor of physical chemistry at Alessandria, in Piedmont, where he discovered benzyl alcohol and worked with Bertagnini on anisic alcohol. In 1855 he was elected to the chair of chemistry at Genoa, where he drew up the famous "Summary" of which mention has been made.

At this time the cause of Italian unity was in the ascendant, and by 1860, thanks to the affairs of Magenta and Solferino, the consolidation of Central Italy was complete. Sicily was once more ablaze, and before the middle of May Garibaldi and the "Mille" had effected its liberation. Cannizzaro immediately returned to Palermo, and threw himself into the work of organising the political future of the island and its relation to Italian unity. He then resumed his academic work at Genoa, but in the following year he was invited to the chair of chemistry at Palermo, where he remained ten years, taking an active share in the management of the University and serving for a time as rector.

In 1871 he was called to the University of Rome, and made a senator of the kingdom. As director of the Chemical Institute at Panisperma he gave, session after session, for nearly forty years, systematic courses of lectures on general and organic chemistry, and practically every Italian chemist of note now living passed through his laboratories and worked under his inspiration and direction.

Cannizzaro was a foreign member of many learned societies, and of nearly every academy in Europe. At the time of his death he was the oldest foreign member of the Chemical Society of London, having been elected in 1862. In 1872 he delivered the Faraday lecture to the society, giving a charming and graceful exposition of the genesis of the doctrine with

which his name will for ever be associated. In 1889 he was made a foreign member of the Royal Society, and two years later was awarded the Copley medal for his services to chemical theory. On the occasion of his seventieth birthday, NATURE published an appreciation of his labours, in the series of its "Scientific Worthies," accompanied by a portrait (No. xxx., 1897). From this account it may be permitted to give the following extract:—

"Cannizzaro, when compared with such men as Berthelot and certain of the leaders of the German schools of chemistry, or even with some of the younger generation of Italian chemists, cannot be called a voluminous writer. In all, about eighty memoirs have proceeded from his laboratory. It is on the special quality and character of his published work, rather than on its extent, or on the range and variety of its subject-matter, that his fame depends. In this respect he resembles the late August Kekulé. The names of both men will for ever be associated in the history of chemistry with the promulgation of generalisations which mark epochs in the development of chemical science."

T. E. T.

PROF. E. VAN BENEDEN.

EDOUARD VAN BENEDEN, who died on April 28, adds another to the already long list of illustrious zoologists who have left us since last summer. He belongs essentially to the epoch which brought forth Anton Dohrn and Alexander Agassiz, whose loss we have so recently mourned, and, like them, he participated in the triumphs of biological achievement which mark the 'sixties, 'seventies, and 'eighties of last century. If Dohrn may be called the founder of marine laboratories, and Agassiz one of the originators of modern oceanic research, van Beneden may surely be styled the father of modern cytology. For it was he who discovered the exact similarity of the male and female nuclei in fertilisation, and the halving of the number of chromosomes in gametogenesis.

Born at Louvain on March 5, 1846, he was the son of that distinguished zoologist Prof. P. J. van Beneden, of the Catholic University of Louvain. He was educated at Louvain in the university, and later he studied in Germany, especially at Würzburg under Kölliker. He succeeded the zoologist Lacordaire at Liège, and was put in charge of the course of zoology in the faculty of sciences in 1871, at the age of twenty-five. In 1872 he was appointed professeur extraordinaire, and in 1874 professeur ordinaire. This position he held until his death, and made full use of the opportunities it afforded him of advancing the interests of his favourite science. Though his principal achievements were in the domain of mammalian embryology and cytology, his work covered a wide field. He was the first to give an accurate account of the structure and life-history of those strange parasites of the Cephalopoda, the Dicyemida (1876 and 1882), and he founded the conception of a group between the Protozoa and the Metazoa, to which he gave the name of Mesozoa, a conception which has largely influenced speculative zoology. In conjunction with his pupil Julin, he carried out some interesting researches on the development of the Tunicata, and one of the last of his zoological works was an important memoir on the Anthozoa of the Plankton expedition. He is also the author of researches on Gregarines, Crustacea, Limulus, Cetacea, and other groups.

His work on mammalian embryology, to which he was apparently led by his researches on the ovum, chiefly concerns the rabbit and the bat. His first

papers on this subject, "La Maturation de l'Œuf, la Fécondation et les Premières Phases du Développement embryonnaire des Mammifères" (1875), and "Recherches sur l'Embryologie des Mammifères" (1880), were noteworthy for his description of the cleavage and for the comparison he instituted between the fully segmented ovum and the gastrula. Though these speculative views proved untenable, and were eventually given up by him, they had a considerable influence in stimulating interest in the subject, and so leading to further researches. Later (1884) he gave, in conjunction with Julin, the first complete elucidation of the fetal membranes of the rabbit and certain other types, and he was the first to name the pro-amnion and to explain its significance. He was, further, successful in making out the early stages of bats, and as far back as 1875 he directed attention, we believe for the first time, to the remarkable method of impregnation in these animals. His paper on the development of bats, published in the *Anatomischer Anzeiger* for 1899, contains the results of many years' observations, and is regarded by embryologists as the most far-reaching of all his mammalian work.

But although van Beneden's name will always hold a prominent position in the history of embryology, it is by his researches on the minute structure of living matter that he will be chiefly remembered. Of cytology, as this branch of science is now called, he will always be hailed as one of the fathers. He early directed his attention to the subject, and his first important published work, "Recherches sur la Composition et la Signification de l'Œuf, Mémoire couronné de l'Académie royale des Sciences de Belgique," published in 1870, dealt with it. This was followed in 1875 by his memoir, already referred to, on the maturation and fecundation of the ovum of the rabbit, and in 1883 by his greatest work, "Recherches sur la Maturation de l'Œuf, la Fécondation et la Division cellulaire." Then follows a lull in his activity, caused, no doubt, by the terrible accident which happened to him about this time on the Eiger, and as a result of which he was unconscious for three weeks and incapacitated from work for two years, and it was not until 1887 that he published, in conjunction with A. Neyt, his "Nouvelles Recherches sur la Fécondation et la Division mitotique chez l'Ascaride mégalocéphale." All his great achievements in cytological research are recorded in this series of remarkable papers. They prove, beyond all possibility of doubt, the right of Edouard van Beneden to take his place in that select band of great original observers to whom science owes her progress.

By his use of *Ascaris megalocephala* as the material of his investigation, he introduced a means of research which, in his own hands and those of his followers, led to the most important results. He was the first to show, for the ovum, that the chromatic threads are a portion of the network existing in the nucleus. He laid special stress upon the fact that the two daughter chromosomes were alike to the smallest detail, and he first pointed out that they pass to opposite poles of the spindle. He discovered the *corpuscule centrale* in 1876 (first seen, it is true, by Flemming in 1875), and first demonstrated its importance in cell division. He was also the first to show that it is in many cases, if not in all, a permanent organ of the cell (1885 and 1887). He also discovered the *sphère attractive*. Both these structures later received other names, the former being known as centrosome and the latter as centrosphere; but whatever names be applied to them—a matter of no importance—the fact remains that they

were discovered, and their importance appreciated, by van Beneden.

Finally, and this, perhaps, is the greatest discovery associated with his name, he showed, in 1883, that in the last gametogenic divisions by which the ovum is produced, the number of chromosomes of the nucleus becomes reduced to one-half the original number, and the like fact for the spermatozoon was discovered in 1884 by him, working in conjunction with J. L. J. van Beneden. Though it cannot be asserted that he was the first to give a complete account of the morphology of fertilisation, yet it may fairly be said that he went as near to that as any other worker, and that he was one of the three zoologists whose discoveries led to the complete elucidation of that phenomenon. Lastly, we must not forget to mention that he founded and edited the *Archives de Biologie*, in which some of his most important work was published.

Van Beneden was a strikingly handsome and distinguished-looking man. His splendid figure will not readily be forgotten by those who were present at the Darwin centenary celebration at Cambridge last year. He was a keen and active sportsman, and his proclivities in this direction often led him far afield—to Sweden for reindeer and, as we have seen, to Switzerland for climbing. He was a lauréat and correspondant of the Institut de France, correspondant of the Academies of Berlin, Vienna, and St. Petersburg, foreign member of the Académie "Dei Lincei" of Rome, and an honorary member of many other similar institutions in different parts of the world. He was an honorary doctor of many universities, including those of Oxford and Cambridge, and had many other titles and honours. A. S.

NOTES.

THE next meeting of the Royal Society will be held on Thursday, May 26, when the Croonian lecture will be delivered by Prof. G. Klebs on "Alterations of the Development and Forms of Plants as a Result of Environment."

OWING to the lamented death of King Edward, the Chemical Society's banquet to the past-presidents who have completed their jubilee as fellows has been postponed from May 26 to the autumn. We are also asked to announce that the conversazione of the Entomological Society of London, fixed for Friday, May 27, is postponed indefinitely.

THE annual May lecture of the Institute of Metals will this year be delivered by Prof. Gowland, F.R.S., vice-president of the institute, who will take as his subject "The Art of Working Metals in Japan." The lecture will be given on Tuesday, May 24, at 8.30 p.m., at the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W. Tickets admitting visitors may be had gratuitously on application to the secretary of the institute, Mr. G. Shaw Scott, Caxton House, Westminster, S.W., to whom applications should be made not later than Saturday next.

Two meetings—the first with Lord Verulam in the chair—were held on Friday in St. Albans to support the scheme of the society for excavating the site of Verulam during the ensuing summer and autumn. The site covers close on 200 acres, and although the Roman walls and other buildings were used as a quarry in obtaining materials with which to construct St. Albans Abbey, the greater part of Verulam is unique in that it has never been built upon. The beheading of the proto-martyr Alban, together with other circumstances, suggests that

remains of early Christian churches may be discovered; and, in any case, the theatre and forum are known to have been larger than any other similar buildings in England.

ON Tuesday, May 24, Prof. Love will begin at the Royal Institution a course of two lectures on "Earth Tides," the second to be delivered on Monday, May 30, and on Thursday, May 26, Dr. W. Rosenhain will deliver the first, and on Wednesday, June 1, the second, of two lectures on "Alloys"; on Friday afternoons May 27 and June 3 Dr. D. H. Scott will deliver the remaining two of his course of three lectures on "The World of Plants before the Appearance of Flowers." The Friday evening discourse on May 27 will be delivered by Captain R. F. Scott on "The Forthcoming Antarctic Expedition," and on June 10 by Dr. H. Deslandres on "The Progressive Disclosure of the Entire Atmosphere of the Sun" (in French).

FRANCE seems inclined to follow the example of Prussia in forming a Government Department for the Preservation of Natural Monuments. Last October an International Congress for the Protection of Landscape was held in Paris, the German Ambassador being one of the vice-presidents. The Prussian organisation for the preservation of nature—the term "Natural Monuments" referring to natural scenery and indigenous fauna and flora—was highly praised by French men of science, and it was proposed to take steps for the institution of a similar system in France. Prof. Miyoshi, of Tokyo, in a brochure laid before the conference, speaks highly of the Prussian movement, and invites Japan to take a similar precaution. Prof. Kumm, of Danzig, illustrated the working of the statute against disfiguration of scenery. Of particular interest was Dr. Hermann's paper on natural parks for the protection of animal and plant life, which have long been a German institution. The second Conference for the Preservation of Natural Monuments in Prussia has also just been held at Berlin. It is worth remark that the German Press and public take a keen interest in this useful work. There is, we may add, plenty of scope for such work in the United Kingdom; but it must be done soon, before the building speculator and the municipal engineer have quite exterminated nature in these islands.

THE number of *L'Anthropologie* for March-April, under the title of "Les Sofes chez les Abadites," of North Africa, contains the first portion of an important study of tribal sociology by Dr. J. Huguet. The vague term Sof is defined by the writer as "the reunion of all those individuals who, by reason of community of origin, needs, and political interests, have been forced to associate for purposes of attack and defence." The political influence of associations such as these has recently attracted much attention from the officers responsible for the control of these often unruly tribes.

IN the May issue of *Travel and Exploration* Miss E. C. M. Browne describes an adventurous journey by two ladies to the famous sacred lake Manasarowar, in Tibet, which has been hitherto visited only by a comparatively small number of Europeans. Evidently recent British action in Lhasa has borne fruit so far west as Manasarowar. The head Lama of the local Gomba was very friendly, and went so far as to allow the Bhotiya coolies following the camp to shoot birds in the holy waters, an unusual concession on the part of a Tibetan Buddhist, who, in theory at least, is much opposed to taking animal life.

IN *L'Anthropologie* for March-April MM. E. Cartailac and l'Abbé H. Breuil continue their survey of the paintings and engravings found in the caves of the Pyrenees. The caves described in this article are those of Gargas, not far from Montrejeau, and Bédailhac and Pradières, near Tarascon. The first of these contains a remarkable series of paintings and engravings, depicting hand-marks, animals such as the elephant, bison, horse, and what seems to be a rude human figure, resembling other European specimens of Palæolithic art, as well as that of the natives of Australia and the South African Bushmen. A similar collection of examples of primitive art from caves once occupied by Bushmen on Mt. Silozwana is described by Messrs. Mennell and Chubb under the title of "Some Aspects of the Matopos" in the first part of vol. viii. (1908) of the Proceedings of the Rhodesia Scientific Association, just received. The figures of the giraffe, guinea-fowls, and flying ants are particularly realistic, and supply excellent examples of primitive native art.

THE Choctaw of St. Tammany Parish, in Louisiana, the now scanty remnants of a once famous tribe, are described by Mr. D. I. Bushnell, jun., in the forty-fifth Bulletin of the Smithsonian Institution. They have now forgotten most of their characteristic industries—pottery and basket-making—and have lost the art of fishing, most of their needs being supplied from the nearest store; but though they have been for a long period subjected to Christian influences, they retain many of their primitive beliefs. Thus a solar eclipse occurs when the sun is resting and cleaning himself from the accumulated smoke of his fires. Thunder and lightning are produced by two great birds, and when the female is laying an egg in her nest in the sky there is a thunderclap. The good spirit, Aba, takes to his heaven the spirits of all tribesmen save those dying by effusion of blood and murderers. The evil spirit, Nanapolo, wanders in the recesses of the forest, and though he is feared, he never succeeds in gaining possession of the soul of a Choctaw. They have practically lost their belief in witchcraft, and have never assimilated the practices of Voodooism, so popular among the negroes around them. Mr. Bushnell has excavated a series of mounds which throw some light upon their primitive culture.

THE great flights of crossbills which visited this country and the Continent last summer and autumn have, in our islands at any rate, remained in many places to breed. In the May issue of Witherby's *British Birds* a large number of instances of such nesting are recorded, and it is confidently expected that many more will follow. The localities include the Southampton district, Wickham, the New Forest, Kent, Staffordshire, Suffolk, Surrey, and Sussex. The nests were mostly, or invariably, built in Scots firs, those near Burley, in the New Forest, being placed in the forks of horizontal boughs at a height of some 30 feet from the ground and a dozen feet from the stem. It is suggested that an unusual abundance of Scots-fir seeds may have led to the visitation.

DR. K. DENINGER, in vol. xviii., part i., of the *Berichte d. Naturf. Gesellschaft zu Freiberg*, has done good service in demonstrating the marked distinction between the babirusa of Boru and its relative of Celebes. The original *Sus babirusa* of Linnæus came, it appears, from Boru, but the *Babirusa alfurus* of Lesson's "Mammalogie," which was supposed by its describer to come from the same island, and to be identical with the Linnean species, is based on Celebes specimens. For the Boru species Dr. Deninger takes the name *Babirusa babirusa*, while for its Celebes representative he proposes the new title *B.*

celebensis, although in our opinion he ought to have retained Lesson's *B. alfurus*. Until the author brought home specimens, the Boru babirusa seems to have been represented in European museums only by a few skulls, the distinctive peculiarities of which were not recognised. It is distinguished by its nearly smooth hide, of which the colour in adult males is greyish-brown above and light brown below, and also by the thick coat of short bristly hairs, which becomes thickest at the root of the tail. The general colour is whitish-grey, tinged, especially on the head, with yellow. Females and young males are darker. The Celebes species, on the other hand, has the well-known rugged and furrowed hide almost naked, and brownish-grey in colour. The skull of the Boru babirusa is short and wide, with the extremities of the nasals not narrowing to a sharp point between the sheaths of the upper canines in the manner characteristic of its relative in Celebes, and there are also differences between the tusks of the two species. Dr. Deninger, who adopts Stehlin's theory that the bunodont dentition of the Suidæ is derived by degeneration from a selenodont type, concludes by expressing the opinion that Babirusa is nearly related to the Siwalik *Merycopotamus*, both genera agreeing in the parallel direction of the two lines of cheek-teeth, the general form and small size of the crowns of these teeth, the shape and direction of the tusks, and certain other features.

THE Board of Agriculture has taken advantage of the powers conferred upon it by the Destructive Insects and Pests Acts, and has issued an order affecting the following:—The vine louse (*Phylloxera vastatrix*, Planchon), the San José scale (*Aspidiotus perniciosus*, Comstock), the Mediterranean fruit fly (*Ceratitis capitata*, Wiedemann), the Colorado beetle (*Doryphora decemlineata*, Say), the large larch sawfly (*Nematus erichsonii*, Hartig), the potato moth (*Lila solanella*, Boisduval), the gipsy moth (*Liparis [ocneria] dispar*, Linné), the brown tail moth (*Euproctis chrysorrhoea*, Linné), the nun moth (*Liparis monacha*, Linné), the cherry fly (*Rhagoletis cerasi*, Linné), the narcissus fly (*Merodon equestris*, Fabricius), black knot (*Plowrightia morbosa*, Saccardo), wart disease or black scab of potatoes (*Synchytrium endobioticum*, Percival), tomato-leaf spot (*Septoria lycopersici*, Spegazzini), melon or cucumber canker (*Mycosphaerella citrullina*, Grossenbacher), and American pear blight (*Micrococcus amylovorus*, Burrell). Under the provisions of the Act any person selling or planting any seed, cutting, plant, &c., attacked by any of these pests is liable to a penalty of 10*l*. A like penalty is incurred if anyone fails to notify the proper inspectors when any of the pests appear in his garden, or if he omits to carry out the measures specified by the Board for the prevention of the spread of the pest. The inspector may enter any premises where he has reason to suppose one of these pests occurs and examine any plants. He may go further, and order the destruction of the plants affected if the local authority consents to pay compensation. This is the part of the Act that has been most criticised, and it still remains to be seen how much good is done when the most effective, if also the most drastic, method of treatment may be excluded. But the order shows that the Board is alive to the necessity for action, and it will no doubt discover a way of getting over this particular difficulty. If the order constitutes a new terror for amateur gardeners and careless nurserymen it also emphasises the necessity for horticultural instruction in the schools, and justifies the evening classes held in many of the counties.

A CURIOUS manna-like incrustation or wax collected on twigs and leaves of *Elæodendron glaucum* is described by

Dr. D. Hooper in the Journal of the Asiatic Society of Bengal (vol. v., No. 9). It has been identified as the secretion of *Phromnia marginella*, an insect passing in India under the name of the ghost bug. The substance contains sugar in the form of dulcitol, which the author refers to a special secretion in the plant.

An article in Engler's *Botanische Jahrbücher* (vol. xlv., part i.) by Dr. R. Knuth, on the formation of hybrids in the genus *Pelargonium*, should be interesting to horticulturists and botanists alike. The large number of *Pelargonium* hybrids contrasts greatly with the three hybrids known for *Geranium* and two for *Erodium*. It is strange to find that five sections of the genus furnish no hybrids, while crosses between species in different sections are not uncommon. The author remarks that, as a rule, there is no fusing of parental characters, but more often one supplies the leaf and the other the flower characters in the hybrid. The "English" *pelargoniums*, known in this country as decorative or fancy, are attributed to crosses between *grandiflorum* of the section *Polyactium*, and the species *cucullatum*, *cordatum*, and *angulosum* of the section *Pelargium*. Dr. Knuth recognises the excellent work of English horticulturists, and places a high value on the classic work of Sweet on the *Geraniaceæ*, published in 1815.

The composition of Indian rice has been investigated by Mr. David Hooper, and the results are published as No. 5 of the *Agricultural Ledger*. Rice cultivation is the most important of the agricultural industries of India, more than seventy million acres being annually under this crop. There are a number of varieties of grain differing in size, shape, colour, and other properties, not all being equally suitable for culinary purposes. Thus a variety known as *kauk-nyin* is so glutinous that it will not stand the boiling required by ordinary rice, but is made into various kinds of puddings and sweetmeats. It is frequently boiled in bamboo tubes, to be eaten cold by travellers; when required, the bamboo is peeled off, and a long roll of rice appears which forms a palatable substitute for bread. Taking the 159 samples as a whole, the percentage of carbohydrate varied between 92.2 and 82.2, of protein between 11.4 and 6.06, of fat between 3.6 and 0.11. The fibre rarely exceeded 1 per cent., and was usually round about 0.5 per cent.; the ash usually fluctuated between 0.5 and 2 per cent. This series of analyses of rice is probably the most complete that has yet been executed.

PROF. R. MAREK contributes an important paper on the position of the upper limit of the forest growth in the eastern Alps, and its relation to the elements of climate, to Petermann's *Mitteilungen* (p. 63). The general conclusion arrived at is that the importance of mean atmospheric temperature has hitherto been greatly overestimated, and that such factors as rainfall and direction and force of wind are essential causes determining the altitude of the forest line.

THE Proceedings of the Royal Society of Edinburgh (vol. xxx., p. 183) contain a paper by Dr. W. A. Caspari, of the Challenger Office, on the composition and character of oceanic Red Clay. Dr. Caspari gives the results of analyses of thirteen samples of Red Clay obtained from the different oceans in depths varying from 1900 to 3100 fathoms, and discusses the peculiarities of each. It is established, generally, that Red Clays originate, in the main, from the degradation of acid and basic volcanic glasses, and that the chemical processes involved cannot differ in essence from those associated with the sub-

aërial weathering of silicates. A feature of deep-sea "weathering" is that it takes place under conditions which admit of finality; in the Red Clay areas there is a temperature of 1° C. to 3° C., a pressure of 400 to 600 atmospheres, and a uniform medium, sea-water, which have scarcely changed for millions of years. As a result, a degradation product of much the same composition is found all over the globe, and it is to be observed that it is a more acid silicate than the corresponding continental material.

THE Bulletin of the Philippine Weather Bureau for August, 1909 (recently received), contains an interesting note on the frequency of local earthquakes in relation with atmospheric pressure in Manila in 1902-8. As "local earthquakes" are designated the so-called instrumental earthquakes the records of which traced by the micro-seismograph show that their point of origin was in the locality, or very close to it. During the years under consideration 796 such disturbances were recorded at the observatory, and a table showing graphically their mean hourly frequency exhibits clearly two principal maxima and minima, and one secondary maximum and minimum. When this curve is smoothed by showing the frequency for three-hour periods, its parallelism with that of the double daily oscillation of atmospheric pressure shows that "at Manila the highest pressures are more favourable to the occurrence of instrumental earthquakes than low pressures." Prof. F. Omori, the eminent seismologist, has attributed the reason of such parallelism to the fact that in all probability these local earthquakes have their origin at very shallow depths, and may be closely connected with daily changes of pressure exerted by the atmosphere on the earth's crust (see Bulletin of the Imperial Earthquake Investigation Committee, Japan, vol. ii., p. 105).

"THE CAUSE OF THE VERTICAL MOVEMENTS IN THE ATMOSPHERE" is the title of an interesting paper by Prof. W. Trabert in the *Sitzungsberichte* of the Vienna Academy of Sciences of December 2, 1909. The inquiry is based upon the observations of the upper air made at Lindenberg during the month of January, 1909. The diagrams, which exhibit, *inter alia*, the isotherms and lines of equal potential temperature up to an altitude of 5000 metres, show that at times tongues of low temperature extend downwards from the upper regions, and that others of higher temperature extend from below upwards, so that areas of high and low temperatures become intermingled. Among the results arrived at we may mention the following:—In a warm column of air the movement is upwards, and *vice versa*. The ascending movement causes the air-pressure to fall, and conversely. If cyclones and anti-cyclones are thus caused, the air already cooled is dynamically carried higher up, or the warmed air transferred further downwards, causing fresh vertical motion; the origin of cyclones and anti-cyclones is therefore thermic and dynamic. The pendulum-like upward and downward movement of the air is due to aqueous vapour, and the latent heat set free by its condensation furnishes the energy for the maintenance of the vertical circulation.

The importance of the coherer as a detector in radio-telegraphy amply justifies the large amount of attention which has been paid to it by experimenters during the last few years. Attention has been directed in these columns to the work of Mr. G. W. Pierce (*Physical Review*, vol. xxix., and references there) and of Mr. L. W. Austin (Bulletin of the Bureau of Standards, vol. v.). In the *résumé* of communications made to the Société française de Physique on March 18 there are abstracts of two further

papers by M. Tissot and M. Blein respectively. Both direct attention to the influences of the thermoelectric properties and the variation of the resistance with temperature of the materials used on their behaviour as coherers, but Dr. W. H. Eccles, in a paper read before the Physical Society of London on March 11, showed that the whole of the properties of coherers could be explained, both qualitatively and quantitatively, by the Joule and Peltier heat generated at the junction, and its effect on the resistances of the materials forming the contact.

VOL. vi. of the "Collected Researches of the National Physical Laboratory" contains 200 pages quarto, and consists of reprints of fourteen papers by members of the staff which have appeared in the pages of the technical Press or the proceedings of scientific societies, most of them during the year 1909. Several of these papers have already been noticed in these columns, but we should like to direct attention to the report of the committee appointed by the Institution of Naval Architects to carry out the scheme for establishing a tank at the laboratory in which the experiments necessary for the advance of British shipbuilding might be carried out. Ten experimental tanks are already in use throughout the world, Japan possessing one, but most of them are owned by private firms. An advisory committee of naval architects has been appointed, which will draw up a scheme of work to be done in connection with the problems now awaiting solution.

A SPECIMEN bottle of a concentrated combined toning and fixing bath, issued under the name of "Combino," has been sent for examination by Mr. P. F. Visick, 30 Finland Road, Brockley. It gives good colours, and as it is only necessary to place the print as taken from the frame into the solution until the desired colour is obtained, it makes the use of ordinary silver printing-out paper as simple as the self-toning papers now so common. It is a gold-toning solution, and the maker claims that it is stable when either concentrated or diluted for use, and that double-toning, that is, a variation of colour according to the depth of the printing, is impossible. It is issued in 4-oz. bottles at one shilling, and is diluted to five times its bulk for use.

THE changes undergone by stored coal are of considerable importance, both from the point of view of liability to spontaneous combustion and loss in calorific value. A recent Bulletin (No. 38, Series 1909) from the University of Illinois Engineering Experiment Station, by Messrs. S. W. Parr and W. F. Wheeler, is devoted to the consideration of this subject. A critical abstract of all the earlier work on the weathering of coal is given. This is followed by a detailed account of experiments made to determine the amount of disintegration and the changes in weight and calorific value occurring in the grades of coal found in Illinois and in the neighbouring States under different conditions of storage. The losses in calorific value for coal stored under water were found to be less than with the usual storage in air, but the differences were not great enough to warrant any changes in present storage methods from this point of view alone. Storage under water gives protection against spontaneously ignited fires, and also lessens breakage losses, and hence may be worth while resorting to in certain cases.

MESSRS. REYNOLDS AND BRANSON, LTD., have just issued a comprehensive catalogue of photographic requisites containing particulars of many new cameras and accessories.

A WORK on the birds of Dumfriesshire, by Mr. H. S. Gladstone, will shortly be published by Messrs. Witherby and Co. The book will give an exhaustive account of the present-day status and past history of all the birds of the

county, and will be illustrated by photographic plates and a map. It will be published by subscription, and in a strictly limited edition.

AN Aviation Association of Ireland has been formed, with Mr. J. B. Dunlop as president, Dr. W. E. Lilly and Mr. J. C. Peary as vice-presidents, and Mr. D. O'B. Gill, 19 Herbert Street, Dublin, as honorary secretary. A lecture was delivered before the association on February 11 by Dr. Lilly, and has now been reprinted by the *Motors News*, of Dublin.

MESSRS. J. AND A. CHURCHILL have a new edition of vol. ii. of "Allen's Commercial Organic Analysis" just ready for publication. This volume has been re-written under the editorship of Dr. H. Leffmann and Mr. W. A. Davis. The subjects are:—fixed oils, fats and waxes, special characters and methods, butter fat, lard, linseed oil, higher fatty acids, soap, glycerol, cholesterol, wool fat and cloth oils.

A NEW catalogue of lenses has just been issued by Messrs. J. H. Dallmeyer, Ltd. Among the new types of lenses of which particulars are given are a new series of Dallmeyer stigmatics, the single components of which are dissimilar and may be used separately; improved forms of the well-known "Adon" lens, which gives, for the same camera extension, a much larger picture than an ordinary lens; and a new telephoto combination working at $f/10$, and giving variable magnification. The capabilities of the various lenses and combinations are illustrated by some striking pictures.

OUR ASTRONOMICAL COLUMN.

HALLEY'S COMET.—The observations of Halley's comet during the present month have shown that, in brightness, it has at least come up to general expectation. Numerous amateur observers report having seen it as a fairly conspicuous object before dawn.

If Dr. Ristenpart's calculated time for perihelion is correct, the comet transited the sun between 3h. 4m. and 4h. 4m. this morning (May 19), and any special phenomena which could be caused by the passage should be fully reported to some competent authority. From Dr. Holetschek's results it appears likely that the brightest part of the tail would not extend so far as the earth, but meteors from the outlying, and possibly curved, extremity should be looked for, carefully noted, and reported. Recent observations indicate, however, that the tail is quite long enough to extend past the earth.

Mr. G. Gillman reports that he has continued his observations at Aguilas, Spain, on each successive morning, and found that at 3h. 20m. on May 13 the tail was particularly well defined. It was visible to the naked eye almost to a line joining θ Pegasi and α Aquarii, which means that the apparent length was some 43° . This is the greatest length yet recorded by him.

Mr. C. Leach also sends another sketch showing the extent of the tail as he saw it with the naked eye at 3h. 45m. a.m. on May 8. This shows the head of the comet in line with α Andromedæ, γ Pegasi, and Venus with the tail extending, nearly parallel to the south side of the Great Square, to a greater length than the distance between γ and α Pegasi; the tail was perfectly straight. Mr. Leach also sends a sketch and note, taken from a local paper, describing the comet as seen by Prof. Attilio Sesta, at Palermo, at 3h. 25m. on May 8. This corroborates Mr. Leach's own observation, and adds that the nucleus was very bright (visible until 5 a.m.), and that the diaphanous tail exhibited rectilinear margins which formed a small angle at the head.

A number of positions of the comet during November February are published by Dr. Rambaut in the *Monatliche Mittheilungen* (lxx., 6). The places were determined from photographs, taking astrographic stars for reference points.

In *Astronomische Nachrichten*, No. 4408, Herr J. Franke considers the passage of the earth through the tail and

the possibilities of meteor showers at the time. For different values of $1-\mu$ he finds that possible collisions may occur at May 19.442, 19.115, and 18.892. The corresponding radiants of possible small showers are near η Piscium, ρ Piscium, and β Arietis.

In the supplement to No. 4407 of the same journal a telegram from Prof. Pickering announces that Dr. Wright, at Lick, photographed the spectrum on April 29, and found the sodium D lines bright; this is announced as a recent development. An observation by Prof. Frost and Dr. Slocum on April 14 showed a distinct continuous spectrum for the nucleus, with no trace of bright lines or bands.

THE SPECTRA OF COMETS.—Further laboratory results bearing on the nature of cometary spectra are published by Prof. Fowler in a paper appearing in No. 6, vol. lxx., of the Monthly Notices.

Among other things, it is now shown more definitely that the tail spectrum is produced by an oxide of carbon, probably the monoxide. With sufficient density this compound gives the "Swan" spectrum, the most common feature of cometary spectra, whilst at very low pressures—0.01 to 0.005 mm.—the "tail spectrum" is developed. The addition of a trace of nitrogen introduces the cyanogen bands into the high-pressure spectrum, and the cathode bands of nitrogen, such as were found in the spectrum of the tail of Morehouse's comet, at the lower pressures. Hydrocarbons are regarded as variable constituents of comets because the characteristic band at λ 431 is only an occasional feature of their spectra.

The anomalous spectrum of Brorsen's comet, as observed by the late Sir William Huggins in 1868, is explained by supposing that it resembled the "tail spectrum," the differences of wave-length not being beyond the probable limits of error. If this is the true explanation, it appears that the heads of comets vary considerably in density, that of Brorsen's being about the same density as the tail of Morehouse's.

A new high-pressure (100 mm.) spectrum of carbon monoxide was discovered during the research, and it is suggested that the presence of this in cometary spectra is indicated by the anomalous positions of the carbon bands observed. Thus the blue carbon band in cometary spectra often occurs at λ 468 instead of at λ 473, the position of the brightest head; the superposition of the brightest band of the new spectrum, at λ 4679, would account for this.

Some interesting deductions as to the nature and the illumination of comets' tails are made on the assumption that the actual conditions are comparable with those obtained in the laboratory experiments. For example, it is shown that to come within permissible limits of mass the tails must be hollow, or must be made up of attenuated sheets or streams. The illumination is probably of electrical origin, but whether the negatively charged particles producing it proceed from the head of the comet or from the sun is still an open question.

OBSERVATIONS OF SOUTHERN NEBULÆ.—The positions and brief descriptions of five southern nebulae are published by Mr. Innes in No. 2 of the Transvaal Observatory Circulars. One of these objects, in R.A. 16h. 49m., dec. $-40^{\circ} 36'$ (1875), is very diffuse, and covers $10'$ in declination and $3m.$ of R.A.: its position was determined from a plate taken with the Franklin Adams star camera. Cometary, planetary, and ring nebulae are also included.

OBSERVATIONS OF THE AURORA.—In No. 3, vol. xxxi., of the *Astrophysical Journal* Prof. Barnard gives the details of all the observations of auroræ made by him during the period 1902-9. There are many points of interest too numerous to mention here, but it is evident that such carefully recorded data will prove extremely useful in discussing the probable relation of auroræ with solar outbursts, &c. Prof. Barnard outlines a scheme for systematic observations by observers some miles apart which would result in determinations of the height, &c., of specific auroræ. A tabulated statement of his results shows September and February to be months of prolific auroræ, but, as he points out, September is the month of clear skies, and the prominence of February depends largely upon the year 1907. July and December are especially low. There are indications of a maximum during 1907-8-9.

BRITISH SCIENCE GUILD.

FIRST ANNUAL BANQUET.

THE Right Hon. Lord Strathcona and Mount Royal presided at the first annual banquet of the British Science Guild, which was held at the Royal Institute of Painters in Water Colours, Piccadilly, W., on the evening of Friday, May 6. Amongst those present were the Right Hon. Lord Blyth, Col. Lord Kesteven, Sir Thomas Barlow, K.C.V.O., F.R.S., and Lady Barlow, Sir David Gill, K.C.B., F.R.S., Sir Norman Lockyer, K.C.B., F.R.S., and Lady Lockyer, Sir Alfred Keogh, K.C.B., and Lady Keogh, Sir Frederick Pollock, Bart., Sir William Ramsay, K.C.B., F.R.S., Sir Boverton Redwood and Lady Redwood, Sir Philip Watts, Sir Aston Webb, C.B., R.A., and Lady Webb, Sir William White, K.C.B., F.R.S., and Lady White, Colonel Sir John Young, C.V.O., Sir Henry Trueman Wood, Prof. Perry, F.R.S., Dr. W. N. Shaw, F.R.S., Prof. W. D. Halliburton, F.R.S., and Mrs. Halliburton, Mr. and Mrs. Carmichael Thomas, Mr. Roger W. Wallace, K.C., and Mrs. Wallace, Dr. A. D. Waller, F.R.S., and Mrs. Waller, Mr. A. Bruce Joy, Mr. Dugald Clerk, F.R.S., and Dr. F. Mollwo Perkin (honorary secretary).

After the Royal toasts, proposed by the chairman, "The Peace Organisation of the Empire" was proposed by Sir William Ramsay. He regarded it as a great honour to propose that toast—a toast given there for the first time. All he could do, perhaps, was to put before them some platitudes. He knew how little he knew, and he thought he knew a great deal when he had found that out. If he talked, therefore, in platitudes, he would be no striking exception to the rule. It was, he continued, generally supposed that science was something abstruse and abstract. It was not so. It was common sense, and common sense, as they all knew, was one of the rarest of commodities. What one learnt as one grew older was how little one knew about anything. How complex the simplest things were! His attention, he continued, had been turned to physical problems where the things he dealt with were comparatively simple. He had been working on the questions of liquids and gases—things more simple than social or economic problems; and yet those ideas, simple as they were, did not often find simple expression. He instanced the case of "the square of a temperature," which, like many other such phrases, conveyed no definite idea to anybody. If that was so in simple physical science, how much more complex were the problems that faced the social reformer. In this complex world of ours he (Sir William) had the utmost difficulty in making up his mind which of two political candidates was the one to vote for. He wished that Mr. Haldane, their president, had been there to illuminate that subject. It might even be desirable, continued Sir William, to get an elector like himself to vote against both candidates—to say that neither deserved his confidence; and if they could only get a sufficient number to vote like that, then no one at all would be returned to Parliament. Men of science, continued Sir William, had a uniform mode of procedure. They had a problem suggested to them which they thought worth investigating. They ascertained what had been done before on the subject, and then proceeded to try an experiment on a very small scale. The next stage was to try the experiment on a larger scale, and if that also promised well they might be encouraged to erect a large plant and increase it to the maximum of its production. Now, he asked, did they do that in politics? He thought not. The analogy was a close one. The problems which confronted the manufacturer were very much the same as the problem which confronted the Government. They both wanted to produce an article in demand. They had a permanent staff in both cases, and they wanted to provide an article that would meet with public approval. Men were constantly improving—at least if they were not progressing they were retrogressing, as it was impossible to stand still. In chemical manufacture what was chiefly wanted was brains. A well-known manufacturer declared that brains were indigenous to Cambridge, and that he only wished he could get a number of Cambridge men to work on the lines he would suggest. That was exactly the Government's difficulty too. Mr. Haldane recently stated he had made the discovery that not only in Parliament, but in other

places, there were brains, and that there were persons who, if they would, could solve those complex problems which were so costly, and yet for which one had to find some immediate solution. Now the intelligent manufacturer—just as a Government does—provides himself with a permanent staff to keep things going; but, further than this, he brings in other people in order to consult with them if anything goes wrong, or if he has reasonable grounds for believing he can make an improvement. The person thus consulted receives a retainer, perhaps—gets so much a year and so much a job. "It is suggested," continued Sir William, "and I think it is an admirable notion, that the same plan which has proved itself successful in helping our manufacturers should be applied by the Government. There is an enormous number of people in this country who could be got by a very small retainer indeed, or perhaps feel honoured by being chosen; and when required they would be at hand to help with their advice."

The question of dirigible balloons threatened our naval supremacy, continued Sir William. What was the best way to destroy them? The natural way was to project a shell at them; but our mechanical art had not grown so perfect as to enable us to time the explosion of a shell to the thousandth part of a second, while, on the other hand, the substance of the balloon would be too soft to explode the shell by concussion on contact with the balloon itself. "I was asked," Sir William proceeded, "what was the best way to destroy those balloons, and I made several suggestions. I am perfectly willing to put any suggestions I have at the disposal of the Government for the benefit of my country, and I am sure there are hundreds of thousands in the same position who are able and willing to do something for the benefit of this country without pay." Concluding, Sir William said that the practical solution of that problem was that there should be consultative committees formed in all branches of inquiry appertaining to the national welfare, and he saw no reason even why such parties called in for consultation should not be paid just as the ordinary consultee was paid by the manufacturer when called in to tender advice. The appointment of a large number of such consultative bodies, call them what they wished, would be of inestimable advantage to the nation in solving many of the complex problems which were so baffling to the ordinary advisory resources of a Government dependent practically altogether upon its permanent staff.

Mr. Frederick Verney, M.P., responding in the absence of Sir William Mather, said it was most interesting to hear a man of science speaking on politics. He heartily agreed with Sir William Ramsay in his main contention that the Government would be immensely helped and rendered far more efficient if they had at their disposal and took advantage of the enormous amount of latent wisdom which only required to be called forth to be put at the service of the country. If England could boast of one thing more than any other nation, there was one thing which we might safely say, and that was that in no other country was so much and so good unpaid work done to-day as was done in England. It was not so desirable to increase that work as to render it more efficient for the Empire at large, and he did not believe any member of the House of Lords or House of Commons would be against that proposal. Certainly no one in England would have welcomed more warmly Sir William Ramsay's proposal than Mr. Haldane himself, as there was no statesman who had shown himself more eager to avail himself of all the science put at his disposal than the Secretary of State for War. In any case, if there was any consolation for people to be killed scientifically, they would have abundance of chance of it in due time, and in the next great war he was afraid they would have too much of it. There was one essential difference between politics and science. In politics they had nothing but uncertainties to deal with, but in science they had perhaps something tolerably certain to deal with. In politics one had to deal with human nature—with character—and thus the uncertainties of political life were the hardest to foresee and the most difficult to deal with; and the man who could fight his way through the uncertainties of politics, and could do something for the good of the nation at large, deserved well of his country, and merited the name of British statesman.

Sir Alfred Keogh, K.C.B., also responded to the toast. As to the application of science to methods of government, he was glad to hear allusion made to their distinguished president, who was the great exponent of that idea. Regarding the possibility of war with Germany, we were at present engaged in real warfare with her, but that war was being waged in the laboratories of the two countries. The German nation deserved scientifically all the admiration we could give to it. It had recognised the relation of science, not only to industries, but to methods of government and the general education of the community. The great disadvantages in this country were that our rulers and governors did not appear to be acquainted with the fact that they had at their elbow men who, over and over again, would help them in all the problems they had to solve.

Sir William White, K.C.B., F.R.S., in giving the toast "The Armed Forces of the Empire," said that that toast was not a novelty, but although he had known it by many titles, it always meant the same thing—namely, that, as British citizens, they desired to honour and remember those who gave or were ready to give their lives for the service of the country and of the empire. Behind "the armed forces of the empire," he reminded them, lay the principle of personal service, and whatever else we could give, there was one thing we could all give to our country and empire, and that was personal service. In modern times war was a very complex thing. The day had passed when personal courage alone and readiness to do or die were an assurance of victory, because nowadays so much depended upon the equipment of war, in the perfecting of which every branch almost of art and science was laid under tribute; but although the material was important, it required the man and mind to utilise it; and when the man and mind were employed in competition with others struggling for victory, it was in the highest degree important that those who served in our armed forces should be equipped mentally, scientifically, and in every way possible so as to give the fighting unit an honest chance. Those were matters, however, which depended upon the central administration, and if it was not conducted on scientific lines, then there was little hope of that object being fulfilled.

Col. Sir John Young, in responding, concurred with the proposer of the toast in regard to the importance of science to the efficiency of the naval and military forces. He was glad to say that in Mr. Haldane, at any rate, true scientific principles have had a friend who understood thoroughly the job he had to accomplish.

Sir Boverton Redwood proposed the toast of "The British Science Guild in Greater Britain." Some misconception, he said, existed still as to what the guild really was. Many people thought it was only an addition to previous learned societies. He reminded them that the British Science Guild was not a scientific society in the ordinary acceptance of the term, but was an organisation intended primarily to bring about the adoption of scientific methods in all matters of daily life, and incidentally to promote and foster the study of science by people who were not what might be called "scientific people." The term "science," however, frightened and repelled many, although it had been defined over and over again as the organised application of common sense. He cordially endorsed Sir William Ramsay's opinion that the attention given to that organised application of common sense was lamentably lacking in many quarters, from the Government downwards. Now, that state of things must not continue if the British nation was to hold its dominant position amongst the nations of the world. The British Science Guild had shown them already what ought to be done, and how to do it, and it was not only in this country that there was scope for its work. From its inception there had been a gradually increasing number of members in Greater Britain beyond the seas, and that was an exceptionally good feature of the movement. Already some action had been taken in the direction of organising those members, and branches or committees had been formed with that object in Canada and Australasia. The effect of that was to stimulate the interest they took in the guild and to bind them to the common body, and generally they had evidences that there was the opportunity for great benefit from the work of those branches in the empire beyond the seas.

The chairman, in responding, gave an interesting account

of the remarkable progress of Canada since the visit of the British Association in 1884. Lord Rayleigh had, in allusion to that visit, described Winnipeg as the only city he knew where they ploughed up their streets to make them level. To-day Winnipeg had streets as good as those in London, and was thoroughly equipped in up-to-date institutions and modern conveniences of every kind. It was perfectly useless, he continued, for the unemployable, who could not or would not work, to go to Canada. There they would be absolutely lost, because everyone in Canada was a worker, but they gladly welcomed the genuine and willing worker in Canada, which was really as much England as was the Mother-country.

Sir David Gill, K.C.B., F.R.S., also responded, and said that in dealing with science and its application to practical affairs, there was not the least doubt that the temperament of men of science had been somewhat of a drawback in forcing scientific facts and principles upon the attention of mankind generally, as the man of science was apt to think he had done all he could do when he had found out scientific truths. He seemed to require something to aid him in forcing upon unwilling Governments that information which they were too ignorant to apply to national needs.

"The Guests" was proposed by Sir Frederick Pollock, Bart., and responded to by Mr. Roger W. Wallace, K.C., after which Sir Aston Webb, C.B., R.A., gave the toast of "The Chairman," to which the latter gracefully responded, thus concluding the proceedings.

CLIMATOLOGICAL REPORTS.

THE director of Chemulpo Observatory (Dr. Y. Wada) has issued the mean annual results of the valuable meteorological observations made at the Japanese stations in Corea in 1906-7 (see NATURE, April 1, 1909). The following are some of the results of air-temperature and rainfall for 1907:—

Station.	Chemulpo	Fusan	Wonsan	Mokpo	Song-chin	Yongamp
Latitude, N. ...	37° 29'	35° 6'	39° 9'	34° 47'	40° 40'	39° 56'
Longitude, E. ...	125° 32'	129° 3'	127° 26'	126° 22'	129° 11'	124° 22'
Mean max. ...	15.1°	17.5°	16.8°	17.7°	13.8°	13.4°
Absolute max. ...	34.6°	32.5°	37.5°	32.7°	32.9°	32.9°
Month ...	VIII	VIII	V	VIII	VI	VII
Mean min. ...	7.2°	9.8°	6°	9.8°	4.1°	4.3°
Absolute min. ...	-14.5°	-8.4°	-18.1°	-9.2°	-21.4°	-24.3°
Month ...	XII	II	II	II	II	XII
Adopted mean ...	10.8°	13.6°	10.3°	13.1°	8.2°	8.6°
Total Rainfall ...	667.3	1011.2	1576.5	811.6	627.3	1029.6

The instruments and method of observation are the same as those at meteorological stations in Japan; temperatures are given in centigrade degrees and rainfall in millimetres. The mean temperature was practically normal, but the rainfall fluctuated considerably; the data for the normals for these stations only go back to March, 1904.

The report of the Mauritius Observatory for 1908 shows that the mean annual temperature, 73.6°, was practically normal; the absolute maximum was 89.1°, minimum 53.8°, maximum in the sun's rays 166.2°, on November 12. The rainfall, 62.43 inches, was 14.5 inches above the average of 1875-1908, but for the whole of the island, obtained from reports from sixty-five stations, the mean was 90 inches, being 7½ inches above the average. Six cyclones occurred over the South Indian Ocean; during one, between February 28 and March 4, very heavy rainfall occurred over the whole island, ranging from above 45 inches at Curepipe to 9 inches at Port Louis; the tracks of three of the cyclones have been determined. Ninety-four photographs of the sun were sent to the Solar Physics Committee, and particulars of fifty-four earthquakes were sent to the seismological committee of the British Association.

The report by Mr. Ivengar of meteorology in Mysore for 1908 embodies the daily and monthly means for the second-order stations at Bangalore and Mysore, and the 8h. a.m. observations, with their monthly means, at the third-class stations at Hassan and Chitaldrug. Over the province, as a whole, the temperature of the year was practically normal; April was the warmest, and December the coldest, month. The absolute maxima and minima were 102.1° at Chitaldrug (in May) and 50.1° at Hassan

(in December). The rainfall was deficient and very unequally distributed, the defect varying from 13 to 43 per cent.; in November and December there was practically no rainfall.

The report issued by the Egyptian Survey Department on the rains of the Nile Basin and the Nile flood of 1908 states that during that year rainfall was measured at eighty-eight stations in the Nile Basin, while that recorded at 118 other stations in neighbouring regions was studied in connection with the meteorological conditions of north-eastern Africa. On the whole, rainfall was deficient to the south of the equator, and the country between the Victoria and Albert lakes seems also to have received less rain than usual. On the Bahr el Jebel the annual fall was usually in excess, and in the plains of the Blue Nile some months were wetter than usual. The tables show the monthly and annual rainfall for 1908, and the means for other years so far as data are available. We have previously referred to the flood of 1908, which again reached its normal value after a series of nine low floods. An interesting chapter on earth movements at Lake Victoria is added to the report.

The report of the chief of the U.S. Weather Bureau for the fiscal year ended June 30, 1908, shows that the important work of that department has been carried on with great activity. The tables, which extend over some 390 pages, include, *inter alia*, observations made twice daily during 1907 at twenty-nine stations selected to cover as nearly as possible all sections of the United States showing distinctive climatic features, monthly and annual summaries at 188 stations, and records of excessive rainfall in short periods at stations furnished with self-registering gauges. In our issue of October 21, 1909, we directed attention to several matters referred to in the administrative report, from an advance copy published in the annual summary of the *Monthly Weather Review* for 1908. We may add that this report states that the officials of the Bureau are encouraged in giving popular lectures with the view of eradicating superstitions prevailing with regard to the weather, and that instruments and charts are now exposed in kiosks at various suitable places. The instruments comprise special forms of maximum and minimum thermometers, air thermometer, hair hygrometer, thermograph, and a special type of rain-gauge with dial indicator.

The "Meteorological Year-book" of the Deutsche Seewarte for 1908, which has recently been published, contains the results of observations at ten stations of the second order, hourly observations at Hamburg, Wustrow, Memel, and Borkum, and storm statistics at fifty-seven signal stations in the North Sea and Baltic whenever a gale was experienced over a considerable area, embracing not fewer than three of the stations. The appendices include the hourly means of wind velocity at Pillau (a seaport in eastern Prussia) for the period 1899-1908. The mean monthly values exhibit a minimum in July (4.09 m.p.s.), rising gradually to a maximum (6.29 m.p.s.) in December, and gradually decreasing again to the minimum.

From an excerpt from the "Bavarian Meteorological Year-book" for 1909 we learn that registering balloon ascents made at Munich in connection with the international scheme for the investigation of the upper air were not so successful as in some previous years, owing to unfavourable weather conditions and loss of the instruments used. Nevertheless, eighteen successful ascents were made, and the results have been very carefully discussed. Among the several interesting features shown by a preliminary summary of the results for the years 1906-9 we may refer to the mean altitude and temperature at the beginning of the upper inversion, arranged according to seasons, which were found to be as follows:—winter, 10,650 metres, -61.5° C.; spring, 9870 m., -54.9°; summer, 11,770 m., -57.2°; autumn, 11,790 m., -58.2°. The mean monthly tables show that the lowest altitude of the "stratosphere" was in March and the highest in August. An extraordinary increase in altitude, practically without change of temperature, occurs from April to May, viz. from 9470 to 11,050 metres: but owing to the few and unequal number of cases available, the results deduced can only be accepted with caution.

The first part of a series of valuable contributions to the

climatology of South Germany appears in the "Bavarian Meteorological Year-book" for 1909, viz. investigations by MM. E. Alt and L. Weickmann on thunderstorms and hail, from observations made in Bavaria, Württemberg, and Baden during 1893-1907 at carefully selected stations. The discussion is carried out in great detail, with tables for geographical districts, isopleths for thunderstorm frequency in W.-E. and N.-S. directions, and by charts, but we can only refer to some of the more general results. The mean daily period of thunderstorm frequency for the whole of South Germany shows that the principal maximum occurs between 2h. and 5h. p.m., 39 per cent. of storms taking place about 3h. p.m. In the annual period the storms occur most frequently between April and September, the maxima being in June and July. With regard to hailstorm frequency, 70 per cent. of the storms occur between noon and 6h. p.m., the maxima being from 3h. to 5h. p.m. In the yearly period they occur most frequently between May and July, the maximum being in June, and, compared with the number of thunderstorms, hailstorms were comparatively rare. It may be mentioned that investigations as to a possible connection of thunderstorm frequency with the sun-spot period led to no result.

The results of the meteorological and magnetical observations for 1909 at Stonyhurst College Observatory, Lancashire, have been received. The tables are, as usual, plainly arranged, and the departures from very long averages being given render the data exceedingly valuable. The weather of the year was generally mild and quiet; the temperature of June was 3.2° below the average, and July and December were very wet, each having more than 4 inches above the average rainfall. The mean of the highest daily temperatures was 52.1° , of the lowest 40.6° ; adopted yearly mean, 46.2° (0.6° below the average for the last sixty-two years). The highest reading was 75.1° (August 15), the lowest 15.1° (December 21). The total rainfall was 48.77 inches (1.84 inches above the normal). The mean disc area of sun-spots (in units of $1/5000$ th of the visible surface) appears at 3.8, and the mean daily range of magnetic declination at $13.5'$; the mean for the year was $17^{\circ} 28.5' W$. Photographic copies of noteworthy seismographs were supplied to various authorities, and would be sent to any observing station on application.

THE PROGRESS OF AGRICULTURE IN INDIA.¹

It would be difficult to conceive a harder task than that set before the members of the staff of the Agricultural Department of India when they first set to work to improve Indian agriculture. The native methods of working were often primitive, their seeds were impure and their crops uncertain; the ryots were uneducated, poor, and without that ambition to rise that would have gone so far to lighten the work of the newcomers; but, in spite of all this, the Department has, in the space of a comparatively few years, done a vast amount of work; it has to chronicle failures as well as successes, but the successes have largely preponderated, and we can see some of the results in the various reports that have recently been issued.

The research institute for the Indian Empire is at Pusa, an estate of more than 1300 acres bounded on three sides by a loop of the little Gundak River. It is situated in the heart of a district where intensive cultivation prevails in consequence of the favourable climatic and soil conditions, which are also indicated by the density of the population—900 to 1100 per square mile. As, moreover, the district is largely controlled by a community of indigo planters, there is little fear that cultural improvements suggested by the staff should be unnoticed. The Phipps laboratory is said to be admirably suited for its purpose; it is provided with water-power and electricity, while the

soil of the experimental grounds can be made to grow practically all the important crops of the plains. The scientific staff comprises an agriculturist, a botanist, a chemist, two entomologists and a mycologist, with their supernumeraries and assistants.

In the botanical department Mr. Howard's work on wheat promises results of considerable importance both to India and to Great Britain. He has completed the classification of the Punjab wheats and has isolated some twenty-five pure types, the best of which will in time be available for general distribution. A survey on similar lines of the varieties grown in the Central Provinces, Bengal, Bombay, the United Provinces and Burma is in hand. This work is being followed by hybridisation to evolve new varieties possessing strength of straw, good cropping power, and resistance to rust. Some of the pure types which are being used as parents were found to be a great improvement on the mixed sorts previously grown, and we are not surprised to read that "large numbers of colonists came to see the plots and arranged for small supplies of seed for trial on their holdings." Not only is there the likelihood of an increased yield, but it appears that India can grow "strong" wheats such as are required in the English market, the common impression that Indian wheats are necessarily weak being erroneous. The economic results of a notable increase in wheat production of high quality can hardly be overestimated. An interesting physiological problem is also under investigation. It was found in 1908 that the same sample of Muzaffernaggar wheat sown at Lyallpur, Muzaffernaggar and Pusa gave rise to grain varying markedly in appearance, composition, milling and baking qualities. Mr. Shutt has observed similar variations in Canada. The cause can hardly lie in the amount of plant food in the soil, since no such variation is observed in going from plot to plot on the Broadbalk wheat field at Rothamsted; it must lie in some other of the factors constituting the general environment. Further investigations will be awaited with much interest.

Dr. Butler has continued the mycological work on the lines of previous years, very wisely concentrating attention on a few diseases, and carefully working out the life-history and general biology of the organisms involved. Of these, the chief are "red rot" in sugar-cane, the palm diseases, the wilt diseases of various crops, "white rust" and other diseases of citrus, the mulberry disease of Kashmir, and others. So successful has Dr. Butler been in combating the palm disease in the Godavari delta that he is considered on this work alone to have paid the cost of his department for many years to come! He has in preparation a book on Indian plant diseases that may be expected to help Indian planters considerably.

Dr. Leather was away on leave for part of the time, his place being taken by Mr. Annett. Work was continued on the losses of water from the soil, and the water requirements of plants, subjects that are obviously of fundamental importance in India. It was found also, in the first instance by pot experiments, and later by field trials, that certain soils benefitted notably by manuring with phosphates.

The task of controlling the insect pests falls to the lot of Mr. Maxwell-Lefroy, the Imperial entomologist, and Mr. Mason, with assistants for special work, but the staff is small for the work it has to do. The life-histories and habits of a number of injurious insects have been investigated, and also the influence of climatic changes on insect life and the problem of utilising beneficial insects. Attention has been devoted to sericulture and to lac. The second entomologist, Mr. Howlett, investigates Diptera. He has ascertained the life-histories of nearly all the mosquitoes occurring at Pusa, and has, in addition, found two species of fish capable of destroying large numbers of Anopheles larvæ. The number of Diptera injurious to crops and animals is very considerable, and fully justifies the appointment of an entomologist to deal especially with them.

The improvement of the livestock and poultry of India is undertaken by the Agricultural Department under the direction of Mr. Shearer. A large and remunerative export trade in Indian cattle has recently arisen, for which the Montgomery appears especially suitable. Careful attention is therefore being devoted to this breed.

Such is a brief outline of the main lines of work at

Pusa. The various provinces have also agricultural departments, with scientific staffs investigating problems of local importance and methods suitable for their own districts; an example of the kind of work they do is afforded by a study of the Madras report. The methods of bringing the scientific work to the notice of the cultivators were discussed by a committee of the Board of Agriculture and collected in their report—the second on our list. Whilst they vary somewhat in the different provinces, they may be classed roughly as (1) agricultural associations; (2) local demonstrations; (3) village agencies which hire out improved implements and demonstrate their use; (4) vernacular journals controlled by the Department, those run by private enterprise not being always satisfactory; (5) leaflets, circulars, and *communiqués* to the Press; (6) shows; (7) itinerant assistants, who, under suitable conditions and when working on one definite problem, have been found of considerable service; (8) seed farms and depots to do the work which seed merchants do here; (9) schools to train the sons of cultivators; (10) colonisation with expert cultivators. Like the cultivator of the soil in all countries, the ryot is conservative but not unwilling to take up a new thing that is clearly going to be of advantage; he suffers, however, sorely from lack of funds, and we are told that he often has to pay so much as 24 per cent. interest or more per annum for the money which he must borrow if he is to effect improvements. He must therefore get more than 24 per cent. return or he loses on the transaction, and so it may happen that an improvement which would be profitable elsewhere is of no advantage to him. This state of affairs can only slowly be remedied, and must for long remain a bar to the general improvement of Indian agriculture.

But when we turn to the large cultivators there is no such hindrance, and it may reasonably be expected that they will gain considerable benefit from the scientific work that is being done. To give only one instance, Mr. Bergtheil is investigating the problems of the indigo planters, and has already obtained results of value, a number of improvements having been effected of notable aggregate value. It has been shown, further, that the yield per acre can be increased very considerably by substituting the Java for the more common Sumatran variety. By selection and hybridisation it may be possible to get even better results. The belief is expressed in the report that the natural indigo will yet compete successfully with the synthetic product.

Such large works as irrigation are outside the scope of the present reports, although of great importance to the advancement of agriculture. Work is, however, in hand on the reclamation of *reh* or alkali land, a condition that may accompany irrigation unless drainage is also attended to. Mr. Henderson is making satisfactory progress in reclaiming the very salt soils of Sind. Other important improvements are going on, and we may in the near future look for great returns for the work that is now being done.

E. J. R.

THE MESSINA EARTHQUAKE AND ITS PREDECESSORS.

ITALIAN Government Commissions have recently issued two valuable reports on the earthquakes of Calabria and Messina. One of them deals with the earthquake of November 16, 1894, a shock of great interest, but overshadowed by the disasters of 1905 and 1908. The greater part of this report, of 350 quarto pages, consists of a detailed account of the earthquake by Prof. A. Riccò. Sig. E. Camerana considers the nature and distribution of the damage to property, and suggests methods of construction that should be employed in future; Dr. M. Baratta investigates the relations of the earthquake with its predecessors; and Dr. G. di-Stefano describes the geological structure of the district. The epicentral area includes the villages of San Procopio, Santa Eufemia, and Seminara, which lie near the west coast of Calabria and about twenty miles from Messina and Reggio. The number of persons killed at these and other places was 101, and the number of wounded about a thousand, the

highest death-rate, of about 5 per cent., occurring at San Procopio. The epicentre coincides nearly with that of the well-known Calabrian earthquake of February 5, 1783. The isoseismal lines of the two earthquakes were similar in form, both being flattened and compressed towards the east, and expanding in the opposite direction. The earthquake of 1783 was, however, much the stronger, the loss of life far greater (the death-rate at one place rising to 75 per cent.), and the after-shocks were five times as numerous as in 1894, were of greater intensity, and were spread over a longer interval of time. The earthquake of 1894 was, in fact, a replica, on a much smaller scale, of the greatest of all Calabrian earthquakes.

The Messina earthquake of 1908 is of far greater interest and importance than its predecessor of 1894, and it is satisfactory to find that the reports on it are being issued without undue loss of time. A Royal Commission, under the presidency of Prof. Blaserna, was appointed to investigate the sites best adapted for the re-building of the ruined towns. The report of the commission is of more than local value. As regards Messina, while recognising the unsatisfactory nature of the subsoil, it is realised that, for commercial and other reasons, the city must be re-built on its former site. It is recommended, however, that the building regulations adopted for districts of high seismicity should be rigorously enforced, and that no buildings intended as permanent dwellings should be erected on loose sands and gravels on sloping ground or within a hundred metres of the sea, and the commission also points out certain suburban districts in which the city might be allowed to expand.

Two or three of the appendices to the report are of considerable interest. In one, Sig. P. Marzolo, director of the Hydrographic Institute, compares the results of the soundings recently made in the Straits of Messina with those made in 1876-7. There are, he finds, no abrupt changes of level, but outside the Straits, to the north, the bathymetric curves of 200 and 300 metres are now much farther from both the Sicilian and Calabrian shores than they were in 1877, while the curve of 400 metres near the Calabrian coast no longer exists. Sig. Marzolo, however, refers the change to deposits from ocean currents rather than to elevation of the sea-bed. In the harbour of Messina, the bathymetric curves for the years 1903 and 1909 are practically coincident, and this is also nearly the case with the curves for 1908 and 1909 for the harbour of Reggio.

In another appendix Sig. A. Loperfido describes the results of new series of levellings, former series having been made along the same lines in 1907-8. In each case the new levellings were begun at points so distant that their altitude may be regarded as unchanged by the earthquake. In Calabria they started at Gioia Tauro (9 km. north of Palmi), and were continued round the south coast over a length of 87 km. The changes of level, at first inconspicuous, begin to exceed a tenth of a metre at Favazzina, and from this place to Saline they indicate a continuous lowering of the coast, amounting to 42 cm. at Villa S. Giovanni and 54 cm. at Reggio, with a maximum of 58 cm. about a kilometre south of Reggio. In Sicily three shorter lines of levelling were carried out, one from Capo Peloro to Messina, and the others inland from the latter city. They show a lowering of 65 cm. at the mareograph of Messina, a maximum of 71 cm. being attained about 3 kilometres farther north.

A paper by Sig. F. Eredia on Messinese earthquakes has appeared in the *Bollettino* of the Italian Seismological Society (vol. xiii., pp. 481-96). In this he describes a series of earthquakes which occurred in August, 1898, the centres of which were near Rometta, which lies seven miles south-west of Messina. Two of these shocks (on August 6 and 12) were strong enough to cause slight damage to buildings at Rometta, and before the end of the month they were followed by at least eighty slighter tremors. The centres of both shocks were beneath the Peloritan mountains. Comparing the areas most strongly shaken by them with others disturbed in April, 1893, and February, 1904, it would seem that, during the eleven years, there has been a continual northerly migration of the epicentres.

C. D.

MAGNETIC STORMS.¹

THE magnetic needle has been described with poetic licence as "true to the pole," and few, I suspect, are aware how little it deserves this reputation. The earliest known information on this point in England dates from 1580, when Boroughs, observing at Limehouse, found the needle to point $11\frac{1}{2}^{\circ}$ to the east of geographical north. During the next 2½ centuries it kept moving to the west, reaching its extreme position of $24\frac{1}{2}^{\circ}$ to west of north in 1818. It has since retraced its path, and now at Kew points only a little more than 16° to west of north.

Besides this slow secular change, there are daily changes, which are continuously recorded at a number of observatories. At a complete station there are three magnetographs, recording, respectively, declination, horizontal force, and vertical force changes. In the Kew pattern instrument each magnetograph has a separate drum and a separate sheet of paper, but the three drums are driven by a single clock, and two days' traces are usually taken on the same sheet.

In some foreign types of magnetograph, e.g. the Eschenhagen, which was used in the National Antarctic Expedition of 1901-4, the three elements are recorded on one drum, but only one day's record is taken on each sheet.

In my subsequent remarks I am obliged to employ a term having more than one meaning. It will be simplest to explain these by reference to the familiar daily variations of temperature. Suppose that in March we record the temperature at Kew at every hour and take a mean value for each hour of the twenty-four from all days of the month. We shall then find a regular rise from a minimum, probably at 6 a.m., to a maximum, probably at 3 p.m., and then a gradual fall to the minimum. The difference between this maximum and minimum is known as the *range* of the regular diurnal inequality for the month. On individual days, however, the hours at which the highest and lowest temperatures occur will vary, and if we take the mean of the differences between the highest and lowest temperatures of each individual day, irrespective of the hour at which they occur, we get a totally distinct range, which I shall call the mean *absolute range*.

The absolute range in any element cannot be less, and must usually be considerably greater, than the range of the regular diurnal inequality. At Kew, for instance, the mean absolute daily range of declination derived from the eleven years 1890 to 1900 was $13.6'$, while the corresponding range of the regular diurnal inequality was only $8.0'$.

The range of the regular diurnal inequality varies with the season of the year. Table I. shows its amplitude in the case of the declination at Kew, Batavia, and the *Discovery's* winter quarters.

TABLE I.

Range of Regular Diurnal Inequality (Declination).

Station	Lat.	Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Year
Kew	$51^{\circ} 28' N$	4.9	6.1	9.1	10.9	10.7	10.0	10.6	11.0	9.5	7.7	5.4	4.5	8.0
Batavia	$6^{\circ} 11' S$	4.2	4.8	3.6	2.9	2.4	2.0	2.3	3.2	3.8	4.5	4.5	4.2	3.0
Antarctic	$7^{\circ} 51' S$	58.6	69.6	47.4	35.4	27.3	28.1	29.2	35.8	52.6	45.5	60.1	85.2	45.5

Remembering that in the southern hemisphere June represents mid-winter, it will be seen that the range is in all cases larger in summer than in winter.

Allowance must be made for the fact that the disturbing force required to displace the needle $1'$ out of the magnetic meridian is proportional to the horizontal component H of the local magnetic force. Now the values of H in C.G.S. measure, at the epochs to which the data refer, were 0.183 at Kew, 0.367 at Batavia, and only 0.065 at the Antarctic station. Thus the disturbing force required to produce a range of $1'$ at Batavia would produce a range of $2'$ at Kew and of nearly $6'$ at the *Discovery's* winter quarters; but, even allowing for this, the Antarctic range is much the largest of the three.

¹ From a discourse delivered at the Royal Institution on Friday, March 4, by Dr. C. Chree, F.R.S., Superintendent Observatory Department, National Physical Laboratory.

The great increase apparent as we pass from temperate to Arctic or Antarctic latitudes is even more conspicuous in the irregular movements, which, when sufficiently pronounced, are known as magnetic storms. This is illustrated by Table II.

TABLE II.

Absolute Ranges of Declination.

At Kew from 11 years				Antarctic ($77^{\circ} 51' S.$) from 2 years			
Percentage of Days when Range				Percentage of Days when Range			
$0^{\circ}-10'$	$10^{\circ}-20'$	$20^{\circ}-40'$	over $40'$	$0^{\circ}-30'$	$30^{\circ}-60'$	$60^{\circ}-120'$	over $120'$
31	57	11	1	7	22	32	39

As already explained, the forces required to displace the needle $1'$ out of the magnetic meridian at Kew and $3'$ out of the magnetic meridian at the Antarctic station are approximately equal. If, then, the disturbing forces at the two places were of similar magnitude, we should expect ranges of less than $30'$ in the Antarctic to be as common as ranges of less than $10'$ at Kew, and ranges above $40'$ at Kew to be as common as ranges above $120'$ in the Antarctic. This, it will be seen, is exceedingly wide of the mark. A single year's records in the Arctic or Antarctic is likely to supply as many large disturbances as the records of a generation in the south of England. This is one reason why so much importance attaches to continuous magnetic observations in high latitudes.

The daily amplitude of irregular magnetic changes, like that of the regular diurnal inequality, is variable throughout the year, but the seasonal variation is usually different in the two cases. This is shown by Table III.

TABLE III.

Annual Variation in Inequality and Absolute Declination Ranges at Kew, omitting Highly Disturbed Days (1890-1900).

	Winter	Equinox	Summer
Inequality range	5.25	6.30	10.80
Absolute range	10.35	13.81	13.56

Each of the three seasons contains four months, March, April, September, and October being included under "Equinox."

If the days of large disturbance, averaging nineteen a year, had been included in Table III., the preeminence of the equinoctial value of the absolute range would have been greater. Kew, it should be added, is fairly representative of all stations in temperate latitudes.

When we pass to days of large disturbance, the prominence of the equinoctial season in temperate latitudes becomes accentuated. This is shown by Table IV., which gives the seasonal distribution of the 721 magnetic storms recorded at Greenwich from 1848 to 1903, as calculated from the lists drawn up by Mr. W. Ellis and Mr. E. W. Maunder, with corresponding results for Batavia from 1883 to 1899, obtained by Dr. Van Bemmelen.

TABLE IV.

Seasonal Distribution of Magnetic Storms.

Place	Epoch	Percentage of all Recorded		
		Winter	Equinox	Summer
Greenwich	1848-1903	32	42	26
Batavia	1883-1899	33	35	32

Out of every 100 storms recorded at Greenwich, forty-two occurred in the four equinoctial months.

The seasonal variation seems to diminish as we approach the magnetic equator, and but little remains of it at Batavia.

When we pass to high latitudes the preeminence of the equinox as a season for magnetic storms seems to disappear entirely. This is shown by Table V., which compares declination results at Kew and at the *Discovery's* winter quarters.

TABLE V.

Percentage of Days having Range above 20' at Kew, and above 120' at the "*Discovery's*" Winter Quarters (77° 51' S.).

Station	Mid-Winter	Equinox	Midsummer
Kew	12	16	9
77° 51' S.	24	31	81

At Kew, out of every 100 days at midsummer (May to July), only nine had an absolute range above 20', the corresponding figure for the four equinoctial months being sixteen, or nearly double; but in the Antarctic eighty-one out of every 100 days at midsummer had a range exceeding 120', while the corresponding figure for the equinoctial months was only thirty-one.

The phenomena of magnetic storms appear, at least at some stations, to be largely influenced by the hour of the day. Table VI. gives some figures for Greenwich derived from the hours of beginning and ending in Mr. Maunder's lists for the years 1848 to 1903, as well as some figures which Dr. Van Bemmelen has given for Batavia.

TABLE VI.

Diurnal Variation in Magnetic Storms.

Station	Local time	Percentage of Total Occurrences		
		1-8 p.m.	9 p.m.-4 a.m.	5 a.m.-noon
Greenwich ...	Beginning	60	22	18
	End... ..	9	45	46
Batavia ...	Beginning	30	25	45
	End... ..	18	55	27
	Maximum intensity	33	43	24

At Greenwich no less than 60 per cent. of the storms commenced during the eight hours 1 to 8 p.m., while only 9 per cent. then ended.

There is yet another influence on magnetic changes which requires to be considered, viz. sun-spots.

TABLE VII.

Connection between Sun-spot Frequency and Declination Ranges.

Year	1890	1891	1892	1893	1894	1895	1896	1897	1898	1899	1900
Sun-spot frequency (Wolfers)	7.1	35.6	73.0	84.9	78.0	64.0	41.8	26.2	26.7	12.1	5.5
Diurnal inequality range—											
At Kew	7.3	8.5	9.8	10.7	9.8	9.5	8.5	7.8	7.6	7.3	6.8
At Pavlovsk	6.3	7.3	8.7	9.6	8.6	8.2	7.4	6.8	6.3	6.0	6.2
Absolute daily range—											
At Kew	10.7	13.7	17.7	15.6	16.5	15.6	14.5	12.1	12.3	11.3	9.2
At Pavlovsk	12.1	16.0	21.0	17.8	20.4	18.1	17.5	14.6	14.7	13.1	10.5
At Pavlovsk—											
Mean range in month	28.2	46.3	93.6	48.3	84.1	47.4	52.4	43.8	46.6	38.3	32.8
Total range in year	42.1	92.3	194.0	87.1	145.6	73.9	88.7	101.1	118.9	63.8	94.2

While Prof. Wolfers's figures are given in Table VII. as a measure of sun-spot activity, it may be added that closely parallel results would be derived from the Astronomer Royal's figures for sun-spot areas. There was a well-marked maximum in 1893. The remarkable parallelism between the changes in sun-spot frequency and in the diurnal inequality ranges appeals to the eye.

Passing to the absolute daily range, we have a quantity which is considerably influenced by magnetic storms. Here, again, the ranges in the years of many sun-spots are conspicuously the larger, but the parallelism with sun-spot frequencies is less close. 1893, the year of sun-

spot maximum, shows at both Kew and Pavlovsk a distinctly smaller absolute range than either of the adjacent years, especially 1892. Of the last two lines in Table VII., the first gives the arithmetic mean of the differences observed at Pavlovsk between the extreme positions of the compass needle during each month of the year, while the second gives its total range during the year. In both cases 1892 occupies the premier, and 1894 the second, position. 1893 lags far behind; in the case of the annual range it even follows 1900, which had the smallest sun-spot frequency of the whole eleven years. The close parallelism visible between sun-spot frequency and the regular diurnal inequality becomes more and more obliterated as we pass from the regular to the less regular, and from these to the highly irregular daily changes of terrestrial magnetism.

A general parallelism between sun-spot frequency and the range of the regular diurnal inequality is far from proving any intimate connection between the two phenomena on the same day. Table VIII. gives the results of an attempt to find out whether the parallelism extends to individual days' results.

TABLE VIII.

Relation of Sun-spot Area (Greenwich) to Absolute Declination Range (Kew) on same Day and on Three Subsequent Days.

	Algebraic excess of range over mean from all days							
	10 days (each month) of largest spot area				10 days (each month) of least spot area			
	Same day	1 day after	2 days after	3 days after	Same day	1 day after	2 days after	3 days after
11-year mean	+0.17	+0.25	+0.48	+0.53	-0.32	-0.45	-0.38	-0.35
1894	+1.23	+1.55	+1.61	+1.69	-1.44	-1.92	-1.62	-1.36
1895	-0.85	-0.22	+0.06	-0.17	+1.19	+1.41	+1.29	+0.92

The days of each month were divided into three groups. The first group included the ten days in which the Greenwich sun-spot areas were the largest, the third group the ten days in which they were least. If any close parallelism existed between the solar and magnetic phenomena on the same day, we should expect the mean of the absolute declination ranges from the first group of days to be much larger than the mean for the whole month, and that from the third group to be much less. Taking all the months of the years 1890-1900, there is a difference in the direction indicated, but it is exceedingly small.

To provide for the possibility that the solar influence takes one or more days to travel to the earth, mean declination ranges were formed, not merely for the ten days of largest or smallest sun-spot area, but also for the ten days immediately following these, for the ten days separated by two days, and yet again for the ten days separated by three days, from the days constituting the sun-spot groups. The results appear in Table VIII., and are somewhat more favourable for an association between the magnetic phenomena and the solar phenomena two or three days previously than for an association between the phenomena on the same day. Individual years, however, e.g. 1894 and 1895, give conflicting results.

In the preceding discussion declination has been chiefly referred to, because it is the most familiar element. In some respects, however, declination records during magnetic storms are inferior in interest to those of horizontal force. Fig. 1 shows two successive days' records—November 12-14, 1894—of this element at Kew. The first day's trace, which was quiet, helps to bring out two important features. A little after 2 p.m. on November 13 there is a very small decrease of force (downward movement), followed by a much larger increase. These sudden commencements to storms are not unusual, and seem to occur simultaneously all over the earth. The type at most stations is very similar. The initial slight fall in force is only sometimes seen; the rise is generally substantial. In the Antarctic the oscillatory character is unusually prominent.

By 8 or 10 a.m. of November 14 the disturbance is

practically over, but the force shows a marked depression compared to its 'value' at the same time on the previous day. This is a very common after-effect of magnetic storms; the greater part of the depression usually disappears in two or three days. Fig. 1 is a good example of an ordinary disturbance in which the magnetic changes, though considerable, were seldom rapid. It differs conspicuously in this respect from the recent great storm of September 25, 1909. Many of the movements on this occasion were too rapid to be shown clearly in the photographic traces.

Dr. Schmidt, the leading German authority on our subject, assigns to this recent storm the first place of all recorded since the Potsdam Observatory came into existence some twenty years ago. Table IX. gives his estimate, on an arbitrary scale, of the intensity of the seven largest storms recorded at Potsdam.

TABLE IX.

Dr. Ad. Schmidt's Estimate of Intensity of Magnetic Storms.

Date of Storm	Disturbance at Potsdam	Date of Storm	Disturbance at Potsdam
September 25, 1909 ...	3800	September 11, 1908...	1520
October 31, 1903 ...	2860	August 20, 1894 ...	1410
February 14, 1892 ...	over 1800	February 9, 1907 ...	1340
July 20, 1894 ...	1580		

An old question which has received a good deal of recent attention is whether there is a cyclic period approaching

which the declination range conspicuously overtops the average is considerable. During these days there is usually a distinct fall in the horizontal force, a circumstance also indicative of magnetic disturbance. The following days were considerably disturbed:—August 29, 30, September 21, 25, 30, and October 18, 19, 23, 24; while a variety of other days, e.g. August 31 and October 2, 8, and 9, were decidedly more disturbed than the average. If we associate August 30 and September 25 we get a twenty-six-day period; if we associate August 29 and September 25, or September 21 and October 18, we get a twenty-seven-day period; if we associate August 31 and September 30 we get a thirty-day period; and we have any number of other possible combinations left. Disturbed conditions are seldom limited to a few hours of a particular day, and often extend over two or more days. Thus there is usually a good deal that is arbitrary in the value deduced by observation for the interval between two specified storms.

The disturbances of September 21, 25, and 30 led to a fall in the horizontal force, from which it is doubtful whether the element had entirely recovered even by the middle of November.

Mr. Maunder and Dr. Schmidt both associate their periods with that of the revolution of the sun relative to a point on the earth. This period exceeds the true period of the sun's rotation—which varies considerably with solar latitude—because the earth is travelling round the sun in the direction in which the sun rotates.

The view most in favour at the present time is that magnetic storms are due to some solar discharge, probably from sun-spot areas, and of an electrical nature. We

Kew Horizontal Force November 12-14, 1894. $\uparrow 100\gamma = 0.001 \text{ C.G.S.}$

FIG. 1.

a month in the occurrence of magnetic storms. J. A. Broun, an early pioneer of magnetic work, believed his observations to indicate a period of about twenty-six days. From an elaborate study of many years' storms at Greenwich, Mr. E. W. Maunder deduced a period of 27.275 days, and Mr. Arthur Harvey independently, from a study of storms at Toronto, deduced the remarkably similar period of 27.246 days. The latest result of this kind is due to the eminent German magnetician already mentioned, Dr. Schmidt, who believes in a period of 29.97 days. Schmidt found evidence of this period in a number of recent storms, and he declares that it exists in the case of very large storms even when separated by many years. He found that the dates of occurrence of five out of the seven largest storms recorded at Potsdam (see Table IX.) could be deduced to a high degree of accuracy from the expression $2410,000 + 3031.0 + n \times 29.97$, which counts time in days from the commencement of the Julian era.

Fig. 2, which serves as a chronicle of magnetic history at Kew from August 20 to November 16, 1909, will illustrate some of the difficulties in the way when one attempts either to prove or disprove the existence of a period in magnetic storms.

The upper curve shows the value each day of the absolute declination range at Kew, the lower the value at each midnight of the horizontal force. We see incessant variations from day to day, and the number of days in

may suppose a solar discharge to traverse space like a jet of water; when it overtakes the earth a magnetic storm begins, which continues until the full width of the jet has passed over. If the solar discharge continues long enough, it may sweep over the earth during several successive revolutions of the sun, and so give rise to a series of magnetic storms at nearly equal intervals.

Theories accepting a solar origin for magnetic storms differ as to the nature of the solar discharge.

Nordmann has suggested Röntgen rays, Birkeland kathode rays, and Arrhenius negatively charged particles. On Nordmann's hypothesis the terrestrial phenomena should follow the solar in a few minutes, on Birkeland's hypothesis in a few hours, while according to Arrhenius the interval might be two days or more.

The most elaborate investigation hitherto made into the supposed solar origin of magnetic storms is due to Prof. Kr. Birkeland, of Christiania, who believes kathode or analogous rays to be the vehicle by which the solar disturbance is propagated to the earth. He has made numerous experiments with kathode rays in a vacuum tube which contains a miniature earth or "terrella." By means of electric currents in wires wound on the terrella, a magnetic field is produced similar in type to the earth's field. It was apparently his experiments that suggested his explanation of a certain type of magnetic storm which he terms the "equatorial." These "equatorial" disturbances are,

he says, normally largest in the earth's equatorial regions, where they consist mainly of a change in the horizontal force, but they are also well marked in temperate latitudes. The cause postulated by Birkeland is a circular electric current in the plane of the earth's magnetic equator, at a

able to keep in action during the winter 1902-3. The characteristics of "polar elementary" storms are their comparatively simple character and short duration, and the fact that their amplitude—unlike that of Birkeland's "equatorial" storms—is much larger in the Arctic than elsewhere. These storms have at least a general resemblance to a special type of disturbance¹ of which I found numerous examples in the records of the National Antarctic Expedition of 1901-4.

Birkeland found that frequently, after an "equatorial" storm had been in progress for some hours, one or a series of "polar elementary" storms intervened. He obtained copies of the curves taken at a number of observatories on the days of the disturbances recorded by his Arctic stations, and he has reproduced these with his own records in a most valuable series of plates published in his recent monumental work, "The Norwegian Aurora Polaris Expedition, 1902-3," vol. i.

Whilst recognising to the full the devotion with which Prof. Birkeland has prosecuted his investigations into magnetic storms for more than a decade of years, and while admiring the beauty of his experiments, I have to admit that I do not find his explanations convincing. If "equatorial" storms are due, as he believes, to electric currents at great heights above the earth in the magnetic equator, the disturbing force, while approximately horizontal and in the magnetic meridian at places near the magnetic equator, should, even in temperate latitudes, have a considerable vertical component, and near the magnetic poles the vertical component should largely predominate. I am unable to see these phenomena in the curves of Birkeland's own plates.

Further, during the time of Birkeland's Arctic expedition the *Discovery* was at work in the Antarctic, and the simultaneous results obtained there do not seem capable of explanation on his hypothesis.

Fig. 3 affords one out of a number of examples of this.

FIG. 2.

height of several thousand miles. An objection to this explanation is that, according to Prof. Carl Störmer's¹ analysis, it is impossible for kathode rays emanating from the sun to reach the earth's atmosphere at all, except in a narrow band round each magnetic pole. The larger the mass and the greater the velocity of the particle for a given electrical charge, the nearer can it approach the earth in the equatorial plane, and the larger is the radius of the zone surrounding each magnetic pole within which the particle can actually reach the earth. The β particles of radium, from their higher velocity, have more penetrating power than ordinary kathode rays, and are, in their turn, eclipsed by the α rays, the lesser velocity of which is more than compensated by their larger mass! According to Störmer, the greatest angular distance from a magnetic pole at which average kathode rays emanating from the sun can reach the earth is only 2.4° , while the corresponding angular distances for β and α rays are respectively 4.1° and 12.7° .

Undeterred by these mathematical results, Birkeland assumes that a type of magnetic disturbance, which he calls the "polar elementary" storm, is due to kathode rays from the sun which get within a few hundred kilometres of the earth's surface at considerable distances from a magnetic pole. The paths of approach and retreat are supposed to be radial, and the connecting part horizontal. These "polar elementary" storms were observed on a good many occasions at four temporary Arctic observatories provided with magnetographs, which Birkeland was

FIG. 3.—Magnetic Storm in Antarctic.

It shows the declination (D), vertical force (V), and horizontal force (H) traces at the *Discovery's* winter quarters on March 22, 1903, during a magnetic storm which forms

¹ National Antarctic Expedition, 1901-4. Magnetic Observations, p. 186.

¹ Archives des Sciences physiques et naturelles, Genève, 1907.

the subject of Birkeland's Plate xx. Birkeland's curves, representing stations from $77^{\circ} 41' N.$ to $43^{\circ} 32' S.$ lat., all show two small but singularly distinct movements at about 1 p.m. and 2.45 p.m. G.M.T. These he ascribes to an "equatorial" storm. Now if these storms were due, as he supposes, to an overhead current in the plane of the magnetic equator, the vertical force disturbance, as we have seen, ought to have been largely predominant at the Antarctic station, which was only about 400 miles from the south magnetic pole. This is exactly what did not happen. Two movements occur in Fig. 3 exactly synchronous with those elsewhere, but the vertical force movements are much smaller than those in declination, and the disturbance in the horizontal plane is not smaller, but much larger than at the equatorial stations.

Interest also attaches to the large oscillation in vertical force between 9.30 and 11.30 p.m. G.M.T. with the accompanying considerable movements in the other elements. This is precisely the time of a "polar elementary" storm recorded at Birkeland's Arctic stations. A similar coincidence occurred on so many occasions that one can hardly suppose it to be accidental. This suggests a very intimate connection between magnetic phenomena in the Arctic and Antarctic.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. J. H. Jeans has been appointed Stokes lecturer in mathematics from midsummer, 1910.

Mr. W. B. Alexander has been appointed to the office of assistant to the superintendent of the museum of zoology.

The third annual report of the Forestry Committee refers to the work carried on during the past year. In June last the reader, Mr. A. Henry, commenced a series of experimental sowings of the different kinds of elms, which have yielded interesting results, showing that what were supposed hitherto to be varieties of one species, of unknown origin, are in reality combinations of two species, in which the Mendelian ratios are observed. Incidentally, these experiments have directed attention to the astonishing vigour displayed by certain first-crosses in trees, all of which hitherto had arisen in the wild state. An attempt is being made this year to produce artificially similar hybrids in the case of the more valuable kinds of trees, and for the first time, almost, the production of new breeds of forest trees is being tried. A plot on the University farm has been assigned by the Agricultural Department to the reader for forestry experiments, and about 5300 seedling trees, of known pedigrees, are now planted out. A small plot of *Eucommia ulmoides* has been established near Norwich. This tree, which was discovered in the mountains of central China, is perfectly hardy and fast in growth in this country. Its bark produces 5 per cent. of rubber, the quality of which, however, is still a matter of doubt, as only minute quantities have been tested.

GLASGOW.—In order to meet the necessity for increased teaching power in the faculty of arts, the University Court has decided to establish eight new lecturers and assistants in mathematics, natural philosophy, and the several literary and philosophical departments. A separate course in mathematics for students of engineering will be instituted, and better provision will be made for the tutorial instruction of students in smaller classes than have hitherto been practicable.

The annual report of the museums committee testifies to a considerable amount of work in the cataloguing and arranging of the collections under the care of Profs. Graham Kerr and Gregory. Gifts of entire collections, associated with the names of David Ure, Webb Seymour, and Mackenzie, have enriched the geological museum.

At the observatory a new house has been erected for the fine Corbett equatorial.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting M. Émile Cartailhac for the degree of D.Sc. *honoris causa* on May 10:—

"Nulli profecto ex eis qui hodie hominum naturae student posthabendus est Aemilius Cartailhac. Qui vir annos viginti quattuor natus commentarios in hoc genere apud Gallos eo tempore maximi habitos, in quibus gentium incultarum mores et vetustatis obsoletae reliquiae tractabantur, edendos suscepit. Quo munere viginti annos functus, cum res ex omni parte terrarum allatas scrutaretur, cum in ea loca ubi eiusmodi monumenta inveniendae sunt ipse multas peregrinationes faceret, adeo incendit civium suorum studia ut diversis auctoribus quasi symbolum conferentibus maxima illa Acta conflata sint, quibus edendis ipse multos annos praeiit, quibusque etiam nunc curam impertit. Academiarum quoque Gallicarum rectoribus persuasit ut discipulos in his rebus institui iuberent: ipse Tolosae in sua urbe atque Academia iuniorum studia dirigit. Nihil profecto his diebus magis admirati sumus quam rudes illas picturas in cavernis ubi habitabant homines pristini inventas. Huiusmodi monumentis, quibus maxime abundat Hispania septentrionalis et australis Gallia, hic noster maximam operam dedit, eademque pulcherrime expicta in medium protulit. Iure igitur hic vir tanta doctrina ornatus, scientiae tam deditus, apud ives suos iamdudum nobilis, ubicunque homines haec studia colunt insigni laude celebrandus est."

The first Halley lecture was delivered on May 10 by Dr. Henry Wilde, F.R.S., the founder. The subject of the lecture was "Celestial Ejectamenta." Dr. Wilde maintained that comets originated within the solar system, being the result of explosive discharges from planets, especially the larger planets, in process of cooling.

The Romanes lecture, postponed from May 18, will be delivered by ex-President Roosevelt on Tuesday, June 7. The subject is "Biological Analogies in History." The honorary degree of D.C.L. will be conferred on the lecturer on the same occasion.

The honorary degree of D.Sc., as already announced, will be conferred on Messrs. P. H. Cowell, F.R.S., and A. C. Crommelin, of the Royal Observatory, Greenwich, on Saturday, May 21.

AMONG many other matters of interest dealt with in the second volume of the report of the U.S. Commissioner of Education for the year ended June 30, 1909, special attention may be directed to the gifts and bequests made during the year to promote higher education in America. The total value of all benefactions recorded as having been received by the 606 universities, colleges, and technical institutions reporting to the Washington Bureau in the year under consideration amounted to about 3,561,000*l.* Of this amount, 806,000*l.* was given for buildings and improvements, and 2,244,000*l.* for endowment, the remainder being for current expenses. Thirty-six institutions each received 20,000*l.* or more, and together accounted for 1,972,000*l.* of the above total. Yale University, Connecticut, was helped most generously, having received some 254,600*l.* The University of Virginia was credited with about 157,500*l.*, while the University of Chicago, Illinois, Grinnell College, Iowa, Bowdoin College, Maine, and Washington University, Missouri, each received 100,000*l.* or more. We notice that the 606 institutions referred to employed a teaching force of 26,369, and had an aggregate enrolment of 308,163 students. Of the 606 institutions, 89 are under the control of States or municipalities and 517 are managed by private corporations. It will be noticed that several prominent universities supposed to have received very large gifts during the year are not mentioned in this summary of the official record of benefactions. The Commissioner of Education points out that the official statements of the amounts reported to have been received could not be obtained by the Bureau at Washington.

In the issue of *Science* for April 29 Prof. Guido F. Marx publishes a table showing the attendance of students at American and foreign universities during the session 1906-7. The figures of attendance were furnished to the U.S. Commissioner of Education by the editor of "Minerva." Prof. Marx recognises the probability that the totals he gives may understate, rather than overstate, the attendance in some of the countries which have no

published complete official statistics. The United States is placed first on the list with 212,956 students in institutions of higher education, or one such student to 394 of the population. Of the larger European countries France takes first place with 50,935 students, or one to 771 of the population. Germany comes next, where, including "hearers," the numbers are 73,020 and 830 respectively. Then we have in order Austria-Hungary, 51,691 and 909; Italy, 33,174 and 1014; United Kingdom, 41,305 and 1008; Spain, 15,642 and 1204; and the Russian Empire, 54,208 and 2754. Prof. Marx points out that the total in the case of the United Kingdom excludes 22,159 evening students, and that Prof. B. Menschutkin, writing to NATURE, claimed 76,900 students for the year 1908-9 for Russian higher educational institutions, with the surmise that possibly there were 20,000 more in private higher colleges.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, April 22.—Prof. H. L. Callendar, F.R.S., president, in the chair.—W. A. **Scoble**: Further tests of brittle materials under combined stress. A former paper described tests on cast iron, which is the brittle material which is most commonly employed in engineering practice. The tests described in the present paper were made on hardened cast steel. The specimens were $\frac{1}{2}$ -inch diameter and 30 inches effective length, and were tested under combined bending and torsion. Neither the maximum shear stress nor the maximum strain was constant at fracture, but the results indicated that the maximum principal stress is the best criterion of strength for a brittle material under combined stress. In general, the hardening did not affect the strength of a bar to resist bending, but it doubled the torque which was required to cause failure.—C. **Cheneveau**, with an appendix by A. C. **Jolley**: The magnetic balance of MM. Curie and C. Cheneveau. This balance is intended for the determination of the coefficient of specific magnetisation, susceptibility, and permeability of feebly paramagnetic and diamagnetic bodies. The body under investigation is suspended from one arm of a torsion balance, which measures the force exerted on the body when it is placed in the non-uniform field of a permanent magnet. The torsion balance is formed by a horizontal rod suspended by a long fine platinum wire, and carrying at one end a hook from which the substance under investigation can be suspended in a small enclosing glass tube. On the other end of the torsion arm a copper sector is fixed which moves between the poles of an auxiliary magnet, and thus provides efficient damping. A second branch arm is also provided, upon which may be placed suitable counterweights to balance the specimen. The suspension carries a mirror, and the movements are read on a translucent scale in the ordinary way.

Zoological Society, May 3.—Dr. A. Smith Woodward, F.R.S., vice-president, in the chair.—Dr. H. B. **Fantham**: (1) The morphology and life-history of *Eimeria (Coccidium) avium*, a sporozoon causing a fatal disease among young grouse. A detailed account of the morphology and life-history of the *Coccidium* which destroys the epithelial lining of the duodenum and caeca of grouse chicks, causing enteritis accompanied by diarrhoea. (2) Observations on the parasitic protozoa of the red grouse (*Lagopus scoticus*). Observations on some seven other protozoa parasitic in the blood or in the digestive tract of grouse. None of these parasites, however, could be said to be either numerous or very harmful to the birds examined. (3) Experimental studies on avian coccidiosis, especially in relation to young grouse, fowls, and pigeons. The results of many and varied experiments were recorded in this paper, relating to the time of ripening and duration of infectivity of coccidian oöcysts, their dispersal by insect larvae, &c., and the effects of various reagents on the oöcysts. The distribution of the parasites within the host was given, and the results of the transmission of grouse coccidiosis to young fowls and pigeons were set forth. (4) Observations on the blood of grouse. The

various blood-cells were described, and the results of blood counts (both of red cells and of leucocytes differentially) of healthy and diseased birds were set forth. Both coccidiosis and strongylosis produce anaemia, and the presence of various parasites is also associated with numerical differences in the leucocytic elements of the blood.—Prof. G. O. **Sars**: Report on the Ostracoda collected by the third Tanganyika expedition during 1904-5.—Dr. R. **Broom**: Tritylodont, and on the relationships of the Multituberculata. The author had re-examined the type and only known specimen of Tritylodont, and in one or two points came to different conclusions from Owen and Seeley. Gidley's recent paper on *Ptilodus* was criticised at some length, and an endeavour made to controvert his conclusion that *Ptilodus* is allied to the diprotodont marsupials. It was held that while the multituberculates are doubtless very unlike the living degenerate monotremes, they are more primitive than the marsupials, and not at all closely allied to them, and that until the evidence of their affinities is much greater than at present they may well be left as an independent order.

Linnean Society, May 5.—Prof. E. B. Poulton, F.R.S., vice-president, in the chair.—H. **Scott**: Eight months' entomological collecting in the Seychelles.—J. M. **Brown**: Some points in the anatomy of the larva of *Tipula maxima*; a contribution to our knowledge of the respiration and circulation in insects.

DUBLIN.

Royal Dublin Society, April 26.—Dr. J. M. Purser in the chair.—Prof. G. H. **Carpenter**: Injurious insects and other animals observed in Ireland during the year 1909. Among the species recorded are the chalcid fly, *Megastigmus strobilobius*, from silver fir-seed, in the county of Wicklow, and the root-knot eelworm, from tomatoes in a greenhouse at Belfast.—W. R. G. **Atkins**: The cryoscopic determination of the osmotic pressure of some plant organs. A number of fruits and underground organs were pressed, and the freezing points of the juices determined with Beckmann's apparatus. The mean molecular weights of the solutes were also obtained. The pressures in the same organs of different samples of the same species were found to be tolerably constant, as were also the mean molecular weights. Pressures ranging from 5.94 to 29.53 atmospheres were met with in fruits, and from 6.47 to 18.67 atmospheres in underground organs, while the mean molecular weights varied from 76 to 394 in the whole series.—Dr. W. E. **Adeney**: Studies of "streaming" of dissolved atmospheric gases in water.

PARIS.

Academy of Sciences, May 9.—M. Armand Gautier in the chair.—Gaston **Darboux**: A particular class of triple orthogonal systems.—M. Jean Bosscha was elected a correspondent in the section of physics in the place of the late M. Crova.—A. **Bernard** and P. **Idrac**: A second series of researches on Halley's comet and its spectrum made at the Observatory of Meudon. Details of observations following the changes in spectrum and structure commencing on January 7, and carried on to May 7.—J. J. **Landerer**: The polarisation of the light from the moon. A reply to criticisms of the method published in 1889.—M. **Coggia**: Observations of Halley's comet made at the Observatory of Marseilles with the 26-cm. Eichens equatorial. Positions of the comet and comparison stars are given for April 16, 17, 18, 21, 23, 26 to 29, and May 2 to 6. The comet could be seen with the naked eye on April 23 as a star of the third magnitude; on April 26 it had increased in brightness to the second magnitude, with a tail of about 1°. By May 5 the tail was about 10° long.—Paul **Pascal**: The magnetic analysis of some chromophoric groups. A double linkage always reduces the diamagnetism. The application of this to the study of some colouring matters appears to show that the existence of a marked coloration is nearly always correlated with a quinonoid structure, at least in bodies containing oxygen.—Daniel **Berthelot** and Henri **Gaudechon**: The chemical effects of the ultra-violet rays on gaseous bodies. Polymerisation reactions. The action of the ultra-violet rays from a quartz mercury arc lamp on acetylene, cyanogen, and ethylene, either alone or mixed with indifferent gases,

and contained in a thin quartz tube, has been proved to result in polymers being formed. The residual gas in all cases was pure, the polymers formed depositing on the sides of the tube in liquid or solid form. Oxygen under these conditions was proved definitely to give rise to ozone.—**Pablo-Martinez Strong**: The colloidal nature of the chromopolysulphuric acids. It is shown that these acids possess the properties of true colloids.—**V. Volmar**: Some trialkylacetophenones and their decomposition by sodium amide. Ketones of the general type

have been prepared. These are all split up by the action of sodium amide, the α isomers giving products corresponding to those obtained from the trialkylacetophenones, whilst with the β products the inverse reaction takes place.—**V. Grignard** and **L. Zorn**: The action of thionyl chloride on mixed organo-magnesium compounds. Aromatic magnesium compounds give rise to sulphinones; fatty compounds give a mixture of sulphinone, sulphide, and alcohol.—**P. Froundler**: The chloranthranilic esters and their condensation with nitroso-benzene.—**M. Tiffeneau**: The action of dehydrating agents on some α -glycols.—**L. Lutz**: The mode of formation of gum in *Tragacanthoides*.—**Raoul Combes**: The part played by oxygen in the formation and destruction of the anthocyanic red pigments in plants. The experiments described prove that when the anthocyanic pigments are formed the oxygen is retained by the organs in process of reddening, and there is at this time an increase in the activity of the oxidation phenomena in these organs. These results confirm those of Molliard.—**Vital Boulet**: The endotroph mycorrhizas of some fruit trees.—**Henri Coupin**: The growth of some moulds in oil. The growth of the moulds used in oil resembled the growth in water more than that in air.—**M. Marage**: The development of the energy of the voice. The energy of the voice is proportional to the volume of air expelled from the lungs and the pressure exerted upon it. Respiratory exercises are described for increasing the capacity of the lungs and for strengthening the muscles of the abdominal wall.—**Armand Dehorne**: The longitudinal division of the chromosomes in the spermatogonia of *Sabellaria spinulosa*.—**J. P. Bounhiol**: The thermic region of the Algerian coast. The distribution of the temperature of the sea off the Algerian coast has been studied with a view to the establishment of the sardine in these waters.—**G. Baudran**: The Koch bacilli. A glycerophosphate medium. Maximum doses of iron and alumina.—**C. Gerber**: The caseification of raw milk by the ferments from boiled milk.

DIARY OF SOCIETIES.

MONDAY, MAY 23.

VICTORIA INSTITUTE, at 4.30.—Heredity and Eugenics: the Rev. Prof. A. Caldecott.

TUESDAY, MAY 24.

ROYAL INSTITUTION, at 3.—Earth-tides: Prof. A. E. H. Love, F.R.S.

ROYAL STATISTICAL SOCIETY, at 5.

ZOOLOGICAL SOCIETY, at 8.30.—Observations on the Anatomy and General Biology of some Members of the larger Cetacea: D. G. Lillie.—Zoological Results of the Third Tanganyika Expedition, conducted by Dr. W. A. Cunningham, 1904-1905. Report on the Rotifera: C. F. Rousselet.—(1) The Marine Fauna of the Mergui Archipelago, Lower Burma, collected by Jas. J. Simpson and R. N. Rudmose-Brown, University of Aberdeen, February to May, 1907: The Hydroids; (2) Hydroids from Christmas Island, Indian Ocean, collected by Dr. C. W. Andrews, F.R.S., in 1908: J. Ritchie.

LINNEAN SOCIETY, at 3.—Anniversary Meeting.

WEDNESDAY, MAY 25.

ROYAL METEOROLOGICAL SOCIETY, at 4.30.—Daily Rainfall at the Royal Observatory, Greenwich, 1841-1903: W. C. Na-h.—Low Temperature Periods during the Winters 1908-9 and 1909-10: L. C. W. Bonacina.—The Rate of Rainfall at Kew in 1908: R. Corless.

GEOLOGICAL SOCIETY, at 8.—Dedolomitization in the Marble of Port Shepstone (Natal): Dr. F. H. Hatch and R. H. Rastall.—Recumbent Folds in the Highland Schists: E. R. Bailey.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

ROYAL SOCIETY OF ARTS, at 8.—Persia and the Regeneration of Islam: Bernard Temple.

THURSDAY, MAY 26.

ROYAL SOCIETY, at 4.30.—Croonian Lecture: Alterations of the Development and Forms of Plants as a Result of Environment: Prof. G. Klebs.
ROYAL INSTITUTION, at 3.—The Constitution and Internal Structure of Alloys: Dr. W. Rosenhain.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.
ROYAL SOCIETY OF ARTS, at 4.30.—The People of Burma: Sir Richard Carnac Temple, Bart., C.I.E.

FRIDAY, MAY 27.

THE LAST DAYS OF CHARLES II.

The Last Days of Charles II. By Dr. Raymond Crawford. Pp. 80. (Oxford: Clarendon Press, 1909.) Price 5s. net.

CHARLES II. died at midday on Friday, February 6, 1685, at the age of fifty-three. His last illness seemed to his courtiers to begin on the morning of Monday, February 2, with an attack of convulsions. He was bled, and became conscious and able to speak; on Thursday had more convulsions, with intervals of consciousness, and on Friday morning, after an attack of breathlessness, gradually became insensible, and so died without further convulsion. His body was examined after death; the blood-vessels of the brain were found distended, there was an excess of serum in the cerebral ventricles, the heart was large and firm, and, except an old pleural adhesion on the left side and a general engorgement of the liver, spleen, and kidneys, there were no other signs of disease. From these facts, as set forth in detail in contemporary evidence, Dr. Crawford arrives at the conclusion "that his death was due to chronic granular kidney (a form of Bright's disease) with uræmic convulsions."

Dr. Crawford's interesting book begins with an account of the authorities. These are the memoirs of Thomas, Lord Ailesbury, who was in waiting upon the king; the despatches of Barillon, the French Ambassador; those of the Dutch Ambassador; the diary and letters of Philip, Earl of Chesterfield; a letter to Mr. Roper, a Fellow of the College of St. John the Evangelist; the life of James II., based on his memoirs; the narrative of Father Hudleston, the priest who was brought in to the dying king; and the account of the illness written by Sir Charles Scarborough, the learned royal physician. Scarborough had received one of the highest honours which a physician could attain in that century, the friendship of Harvey, and his account of the progress of the illness and of each consultation, of the treatment and of the autopsy are unexceptionable evidence. Of equal value as regards truthfulness, though looking at what passed in an entirely different way, is the simple narrative of Father Richard Hudleston, a Benedictine to whom, by some slip of memory, Lord Macaulay has attributed a want of education which the narrative alone is sufficient to disprove. The accounts of Lord Ailesbury, Lord Chesterfield, and James II., and of Barillon, who were all present, supply further and, in the main, trustworthy details. The letter of the Rev. Francis Roper is less important, but shows the feeling of the time.

The king had excellent medical advice. Edmund King, who took the first step in treatment, was a man of great experience in all parts of his profession and had a scientific mind; Dr. Richard Lower was one of the first discoverers of the nature of dropsy; Dr. Frazier had been attached to the king, and attended him in poverty and exile as well as in prosperity; Dr. Walter Charleton had lived a long life among the learned; Dr. Martin Lyster had a mind attentive to every part of science, and a most tender heart; Sir

Thomas Witherby was the president of the College of Physicians. The greatest of English physicians thought so well of Dr. Thomas Short that he dedicated to him his treatise on gout and dropsy. Dr. Edmund Dickenson was a man of great general learning who had spent much time in chemical studies. Dr. Edward Browne had been trained from boyhood in literature, philosophy, and medical observation by his celebrated father, Sir Thomas Browne. Sydenham, in his account of the irregular smallpox, speaks of Millington as his friend and as a learned and candid physician, and Garth says of him—

"At your approach the baffled tyrant Death
Breaks his keen shaft and grinds his clashing teeth."

Barwick was devoted to the royal family, and was a very competent physician. Thus the king had the good fortune to be treated by a group of learned men, among whom were several first-rate observers.

At the present day, if the fourteen most distinguished physicians of the College were at the bedside of a patient afflicted by the convulsions which often terminate diabetes, the knowledge which they could bring to bear upon the problem of treatment before them would be but little more than that which their fourteen predecessors possessed of the last illness of Charles II. Since 1685 Blackall and Bright, and many other investigators, have made clear the whole morbid anatomy, and something of the pathology and treatment, of chronic granular kidney and uræmic convulsions, and thus Dr. Crawford is able to give good reasons for his opinion of the cause of the king's death. His hypothesis explains satisfactorily the king's intervals of consciousness, and is further confirmed by the entire absence in the accounts of the eye-witnesses of any evidence of paralysis such as would almost certainly have been noticeable had cerebral hæmorrhage been the cause of death.

Dr. Crawford shows that the facial paralysis imagined by Sir Henry Hallford to be represented in the wax figure of Charles II. at Westminster is not present. He is, perhaps, not quite just to the attainments of Wellwood as shown by his "Banquet of Xenophon" and other writings, and by the general opinion of his contemporaries. He is also unintentionally unjust to one of the physicians who signed the prescriptions given in the account of Scarborough, which he has printed in full. This is Dr. Christian Harel, manager of the Royal Laboratory, whose acquaintance Charles probably made at Aix-la-Chapelle, and who was a man of great perseverance and some ability. His name is erroneously transcribed C. Farwell, E. Farrell, C. Farel, and C. Farell. He afterwards became physician to Queen Mary.

MECHANICAL LITERATURE OF THE NINETEENTH CENTURY.

Royal Society of London. Catalogue of Scientific Papers, 1800-1900. Subject Index, Vol. ii., Mechanics. Pp. lxxiii+355. (Cambridge: University Press, 1909.) Price 15s. net.

THIS second volume of the Royal Society's subject index illustrates the difficulties, as well as the merits, of the undertaking. The vagueness of the

boundary between mechanics and mathematics, on the one side, and between mechanics and physics on the other, must have given some trouble, but this kind of problem seems to have been dealt with fairly satisfactorily. The difficulties of internal classification, on the other hand, are most perplexing and baffling. One constant source of difficulty is that the mere title of a paper often gives a wholly inadequate, or even a misleading, notion as to its real scope; the same paper may, moreover, contain matters which in any complete system of classification would fall under quite distinct headings. As regards papers published since 1883, the editors have attempted to deal with this point, and we are told that in all such cases the contents have been examined by experts. It is unfortunate that the same process could not be extended backwards so as to cover the whole century, but the labour involved would have been enormous, and the result at the best imperfect.

The schedules adopted as the basis of classification are those of the International Scientific Catalogue, but a number of subheadings have been introduced. These are printed in a somewhat aggressive type, and distract attention perhaps as much as they assist it; indeed, we have found that some little practice is necessary before the volume can be used with effect. It is possible to set oneself some rather interesting problems in hunting up known papers; we may suggest, for instance, a search for references to Hamilton's memoirs on varying action, Kirchhoff's theory of the vibrations of a circular plate, or his experimental method of determining elastic constants, and Hertz's paper on the pressure of elastic solids in contact. These are, of course, all in the book, but they may take some finding.

It would be ungracious to dwell further on imperfections which must occur on almost any practicable system. It is pleasant to turn to points which can be commended without reserve. The list of serials which have been used for the purposes of the work, and the indication of the more important British libraries where these are to be found, will save much trouble to scientific workers. Very welcome, also, as well as important from the point of view of scientific history, are the references to biographical articles; these seem to be especially full and complete. The lists of general treatises, tables, public addresses, and books on apparatus strike us, on the other hand, as somewhat meagre. Possibly they are merely receptacles for a few odd items for which place could not be found elsewhere.

When all is said, an index to the mechanical literature of the whole nineteenth century, drawn up on a consistent plan, cannot fail to be an enormous boon to students and investigators. These are once more under a deep obligation to the Cambridge University Press, which has undertaken the complete risk of printing and publishing the work. We would endorse the closing words of the preface, which express a hope that the scientific world generally will "use their best endeavours that this public-spirited action shall not result in financial loss."

SHELL-FISH INDUSTRIES.

Shell Fish Industries. By Prof. J. L. Kellogg. Pp. xvi + 361. (New York: Henry Holt and Co., 1910.) Price 1.75 dollars net.

IN this work Prof. Kellogg gives a very interesting account of the shell-fish industries of the United States, and also a very valuable summary of our present knowledge of the morphology and life-histories of the edible molluscs which form the material of those fisheries. The keynote of the book is the insistence on that waste of great natural resources, and indifference to the needs of the future which have characterised American exploitation. Past generations may have believed that the natural wealth of the continent was inexhaustible, but the present one, by mercilessly clearing up what remains, has established a record of waste which is probably without parallel in the history of peoples. The picture of wastefulness and lawlessness presented by the account of the great Chesapeake oyster fishery given in this book will seem almost incredible to European readers—even to those who know how State control of the sea-fisheries has generally given origin to a mass of futile and vexatious legislation. We read of insufficient surveys resulting only in insecure titles; of conflicting laws; of the utilisation of political machinery to secure immunity from State interference; and of an entirely inefficient fishery police. The earlier oyster-dredgers are described as being commanded by "as merciless a band of pirates . . . as ever ruled a deck on the high seas," and manned by "vagrants, thieves, and murderers," or by newly arrived and ignorant foreigners. The crews of these vessels suffered "abject slavery" and "unspeakable cruelties." They formed "one of the most depraved bodies of workmen to be found in the country." The Baltimore vessels "established a record of crime and cruelty such as has rarely been equalled." The fishery was entirely the exploitation of originally very rich natural beds, and it is not surprising that depletion of these has taken place to such an extent that many areas are now barren.

The natural reaction to such a condition of affairs is scientific investigation, competent and honest surveying, and the study of methods of cultivation. This side of the question is illustrated by an account of the great oyster fisheries in Long Island Sound and adjacent waters. Here State control has suppressed disorder, and has established security of tenure in the case of the partition of the sea-bottom among the holders. Methods of cultivation—seeding, culling, deposition of cultch, and destruction of starfish and other oyster enemies—have made the sea vastly more prolific than in natural conditions; and so we find an output of enormous proportions, and steam dredging vessels without parallel elsewhere among fishing nations. The same line of development is already indicated in the case of other American shell-fisheries.

The parts of the book dealing with these matters—the history of the industry and the methods of cultivation—will prove most interesting to general readers and to those who study fishery questions, but the purely scientific chapters in Prof. Kellogg's book are

also of great value. The first three chapters, and some later ones, give a good account of the life-histories of the oyster, the clams (*Mya* and *Venus*), and the scallops (*Pecten*). One chapter deals with the ciliary mechanisms in some of these animals, and, being based on original observations, contains much that will probably be new to most zoologists. There is also an interesting chapter on bivalve molluscs in relation to human disease. Prof. Kellogg's book may confidently be recommended to all biologists interested in the economic side of their science. J. J.

THE FAUNA OF CEYLON.

Über die Geschichte der Tierwelt von Ceylon. By F. Sarasin. Zool. Jahrbucher, suppl. 12, part i. Pp. 160. (Jena: G. Fischer, 1910.) Price 7 marks.

SINCE this elaborate piece of work embodies the results of the biological investigations undertaken by the Messrs. Sarasin in Ceylon during a protracted period, it has good claim to rank as the most authoritative attempt to explain the origin and relationships of the fauna of that island yet published. It is, however, really more than this, as it embraces a survey of the relationships and probable migrations of the faunas of south-eastern Asia generally, and their connection with that of Africa. Very valuable are the details given with regard to the geographical range of the various genera of mammals, reptiles, molluscs, planarians, and worms constituting the Ceylon fauna. Ceylon, which long formed a portion of "Gondwanaland," and is thus of great antiquity, appears to have been isolated from the Indian mainland during the whole or the greater portion of the Pleistocene period.

From this antiquity—in which the island presents a striking contrast to Celebes—the fauna of Ceylon displays unmistakable evidence of a very mixed origin, both as regards space and time. Not fewer than three epochs of connection between the Oriental region and Africa have left their impress on the Ceylonese fauna, one of these periods of union being pre-Cenomanian, while a second was Siwalik. Special emphasis is laid by the author on the part played during the Eocene in the evolution of the fauna of Ceylon by the irruption of the Deccan traps, which for a considerable period formed an impassable belt, dividing the peninsula into a southern area, including Ceylon, and a northern area. Even after the cessation of volcanic activity, communication between these two areas was greatly restricted, consisting of one track on the western and another on the eastern side of the peninsula, and even then practicable only to animals capable of withstanding a considerable amount of drought. The Siwalik connection the author considers took place by way of Baluchistan, Persia, Arabia, and Syria, or possibly to the south of Arabia by way of Socotra; and the author agrees with Dr. Arldt that the connecting area was originally clothed with forest, and that the affinity of the faunas of the African forest-zone, the Malay countries, and southern India and Ceylon may be accounted for by the subsequent deforestation of the tract, and the

retreat of the animals to districts where suitable conditions still remained.

Dr. Sarasin likewise admits a former connection between Ceylon and eastern Africa and Madagascar; but considers that a chain of islands will explain the facts of the case, and that recourse to a continental "Lemuria" is quite unnecessary. He likewise accepts a connection with the Malay islands, probably by way of the northern part of the Bay of Bengal, and has also something to say with regard to the South American affinities of the Indo-African fauna. In Ceylon itself the older forms of life, such as planarians, worms, and molluscs, have a very different distributional history from those of the later mammals, and thereby present another contrast to Celebes, where the advent of all was synchronous. A valuable digest of the previous literature concludes this excellent piece of work. R. L.

THE PHILOSOPHY OF EXPERIENCE.

The Principles of Pragmatism: a Philosophical Interpretation of Experience. By H. Heath Bawden. (Boston and New York: Houghton Mifflin Co., 1910.) Price 1.50 dollars net.

THIS is an altogether admirable exposition of the views which are usually associated with the names of Peirce, James, and Dewey in America, and Schiller in England. It does not claim to construct a system, but only to show how we may establish the basal conceptions of a new philosophy of experience.

Pragmatism is the reaction from a speculative philosophy which was out of touch with the affairs of men. The practical man follows with interest the development of a working hypothesis in science, but is impatient of speculations on the infinite and eternal. He values thinking, but he insists that thought shall keep close to experience. He has no use for empty abstractions. The metaphysician has spun a universe out of his own inner consciousness, and tries to make the facts fit his system. The pragmatist seeks the cooperation of the man of science in constructing a philosophy which shall be accurate in method and shall fit the facts.

Philosophy must start, not with a great First Cause or absolute, but with concrete, workaday human life. It must try to understand experience here and now, and from that as a basis proceed to work outward to the metaphysical problems. All the problems of origin and destiny need to be re-stated in terms of present experience. Such a procedure, if it does not much reduce the number of mysteries which lie about us, will at least save us from multiplying them unnecessarily.

The question of immortality, for instance, turns on the nature of individuality. In spite of all the arguments—theological, intuitional, revelational, ethical, and what not—most persons find their faith in a future life scarcely more than a wish. Why? Because the self for whose immortality they hope is an unreal abstraction.

"The self is conceived as a particularistic entity, with barriers to other selves. While, in society, indi-

viduals are recognised to be functions of each other, at death they are supposed to shrivel into isolated and alien units."

The only future that is possible is an immortality of function. An organism is nothing but a centre or focus through which the world-energy operates. When the organism is lost in what we call death, the function may well enough go on in terms of more subtle forms of energetic activity (*cf.* Prof. James's little book, "Human Immortality").

Perhaps, if a criticism may be ventured, modern "psychology-without-a-soul" has become *too much* afraid of being metaphysical. A function must be a function of something. If there is an act, there must be an actor who is, in a way, greater and more real than the act. A soul-entity, then, is justified. It is as reasonable to posit it as to posit a surviving "function."

But the volume is full of deep and careful thinking, and is suggestive and stimulating even in its more questionable doctrines. The analysis of consciousness, and the chapters on the test of truth and on mind and matter, are particularly good.

SOME GERMAN MATHEMATICAL TREATISES.

- (1) *Einführung in die Vektoranalysis, mit Anwendungen auf die mathematische Physik.* By Prof. Richard Gans. Zweite Auflage. Pp. x+126. (Leipzig: B. G. Teubner, 1909.) Price 3.60 marks.
- (2) *Die Vektoranalysis und ihre Anwendung in der theoretischen Physik.* By Dr. W. v. Ignatowsky. Teil I. Die Vektoranalysis, pp. vii+112. Teil II. Anwendung der Vektoranalysis in der theoretischen Physik. Pp. iv+123. (Leipzig: B. G. Teubner, 1909-10.) Price 6 marks.
- (3) *Vorlesungen zur Einführung in die Mechanik raumerfüllender Massen.* By Prof. Alexander Brill. Pp. x+236. (Leipzig: B. G. Teubner, 1909.) Price 8 marks.
- (4) *Funktionentafeln mit Formeln und Kurven.* By Prof. Eugen Jahnke and Fritz Emde. Pp. xii+176. (Leipzig: B. G. Teubner, 1909.) Price 6 marks.
- (5) *Die Zentrifugalkraft.* By Prof. Friedrich Poske. Pp. 80. (Berlin: Julius Springer, 1909.) Price 3 marks.
- (6) *Interpolationsrechnung.* By Prof. T. N. Thiele. Pp. xiii+173. (Leipzig: B. G. Teubner, 1909.) Price 10 marks.

(1) THE simplified system of vector analysis promoted by Gibbs and Heaviside has met with such general acceptance in Germany that treatises and memoirs on subjects of mathematical physics are now often hardly intelligible to readers who do not possess some familiarity with the notations and processes of the calculus in question. A demand has thus arisen for elementary expositions limited to what is absolutely necessary for physical purposes. The first book on our list, now in its second edition, is written mainly with a view to the electrical applications. It deals in a clear and simple fashion with the fundamental operations, and then passes on to the discussion of vector-fields. An interesting chapter on "tensors," which have a bearing on the theories

of stress and of quadratic moments, is added. The work closes with a few elementary applications to hydrodynamics and electromagnetism. It may be commended as giving in a very brief compass almost all that is of importance to the physical student.

(2) This work consists of two parts. In the first of these vector analysis is developed from its foundations as an independent discipline, without any reference to Cartesian or other special geometrical coordinates. The author claims some degree of novelty for his methods of exposition, we think with justice. In particular the intrinsic nature of Hamilton's operator ∇ , whether as applied to a scalar quantity, or by scalar multiplication to a vector, or by vector multiplication to a vector, is here explained with great insight and (we believe) originality. The passages in question may be recommended to the notice of those who have felt the inadequacy of the usual Cartesian treatment of the matter. The theorems of Green and Gauss naturally present themselves for discussion, and, as in the preceding work, a chapter is added on tensors. The second volume contains a number of applications to elasticity, hydrodynamics, electricity, and crystalline reflection.

(3) This is a course of lectures on the dynamics of continuous systems, written from a special point of view. The inspiration is derived from Hertz, but the author prefers to employ Gauss's principle of least constraint rather than the Hertizian law of the "straightest path." The treatment is somewhat academic, in the sense that stress is laid on unity of method rather than on the specific interest of the various topics discussed, but it is marked by clearness and great mathematical elegance. The subjects considered include the kinetics of rigid bodies and of fluid and elastic media, and, finally, the electromagnetic theory of light. On one point a protest should, in the opinion of the present writer, be entered. The notion that the apparent potential energy of a dynamical system may be accounted for as the kinetic energy of latent internal motions is here, as in many recent Continental writings, attributed too absolutely to Hertz. If nowhere stated so explicitly, perhaps, it must have been present to the mind, not only of Lord Kelvin, but of all students of his various expositions of the theory of gyrostatic systems, to say nothing of the well-known "kinetic theory" of elasticity.

(4) This is intended as a supplement to the ordinary tables of mathematical functions. Of recent years a great deal of work has been done, especially in this country, in tabulating the functions which occur in various important problems of mathematical physics, but the results are scattered in the proceedings of societies and in scientific journals, and are often unavailable, and even unknown, to those who have most need of them. The authors of the present treatise have collected a number of such tables, and have appended explanations of the notations, and lists of the important formulæ. The whole is brought within a moderate compass by restricting the entries to four significant figures; this is, of course, ample for most physical purposes, and more than sufficient for graphical representation. We are

glad to note that the author pays a tribute to the British Association Committee on Mathematical Tables, the activity of which has, unfortunately, in recent times somewhat slackened. The collection includes tables of the sine-integral, cosine-integral, and exponential-integral, the Fresnel transcendents, the gamma-function, the error-function, elliptic integrals, spherical harmonics, and the Bessel's functions of both kinds. Especially welcome are the tables of the latter function in which the argument is complex.

Every worker in applied mathematics will applaud this publication, and will wish it such success that it may be speedily followed by new and still more comprehensive editions.

(5) A "philosophical" discussion of the nature of centrifugal force is hardly suited for review in these pages. Such discussions are apt to resolve themselves into verbal questions, and we fear that the present one is no exception. The author insists, for example, on a distinction between "motive forces" and "resistances," the tension of a string being reckoned as belonging to the former category, the pressure of a smooth surface to the latter! The tract is lengthy and diffuse.

(6) A formal treatise on the theory of interpolation from the former professor of astronomy at Copenhagen is sure of respect. The present work is carefully written, and apparently from an independent standpoint. There is, indeed, hardly any explicit reference to the work of previous writers other than Newton and Lagrange, and novel notations are introduced freely without any reference to accepted forms which have long been in general use. The author claims for the subject an important place in schemes of mathematical instruction. To this we can hardly assent; processes of interpolation are, of course, constantly required, in one form or another, but a systematic study of the subject as an independent discipline would, in the case of most students, be an unnecessary infliction. The case of those who are training to become experts in certain special subjects is, of course, different.

H. L.

OUR BOOK SHELF.

An Introduction to Petrology. By F. P. Mennell. Second edition. Pp. viii + 204. (London: Gerrards, Limited, 1910.) Price 8s. net.

THIS is a plain and clearly written introduction to a branch of geology that has assumed much importance among students, and it has the merit of including a short description of the minerals that go to make up rocks. The author's personal studies, as is well known, have been carried on mainly in Rhodesia, and there is something pleasant in finding familiar facts illustrated from Bulawayo, Kimberley, or the Rand. The palisade structure of basaltic flows is thus well seen in the view of the Zambezi gorge on p. 92. In addition, we gain by the introduction of the results of tropical weathering on rocks; and the remarkable banded siliceous ironstones of South Africa (p. 180) are referred to the concentration of mineral matter in a stratified series near the surface.

Theoretical questions are touched on sufficiently to arouse interest, and a sane balance seems to be preserved between what can be seen in the field and what may be variously inferred. The discussion of

the absorption of schists and sediments by the granite of the Matopos and Mashonaland is sustained by evidence that seems convincing, and it has been our good fortune to go over something of this ground in the company of the author. The arguments derived from the amphibolites (p. 171) might have been supported by work of earlier date than that quoted, such as that done in Saxony and round Mont Blanc; but the introduction of matter of this kind, of chapter xiii. (on the origin and variations of igneous rocks), and of the well-reasoned chapter xix., on metamorphism, show that the author regards petrology as far more than the mere description of rock-specimens. Enough is said on each point to show what researches lie before the worker in the open country.

Simple and descriptive as the book is, it will undoubtedly encourage thought in all who read it. The illustrations are excellent, though we should like fewer rock-sections, and more landscapes, such as that on p. 101. Very few misprints—"Brux" for "Brüx," "Fougué" for "Fouqué," and "entectic" for "eutectic," twice on p. 89—have been noted. The formulæ of the silicates might be modernised in the next edition, since comparison is thus rendered more easy. On p. 70 the resemblance between kaolin and serpentine is unnecessarily obscured by a small difference of method. A comma is wanted in the dolomite formula on p. 75; but is not this better written $\text{MgCa}(\text{CO}_3)_2$? The change of appearance in a section of calcite when the polariser is rotated beneath it (p. 75) is due to differences in "relief" at the surfaces, and not to differences of absorption within the section. This well-printed book, as a whole, is a very pleasant one to read.

G. A. J. C.

Map of Eastern Turkey-in-Asia, Syria, and West Persia. Scale, 1/2,000,000, or 1 inch = 31.56 miles. (London: Royal Geographical Society, 1910.)

THE issue of this map occurs at an opportune moment. Public attention has been much directed lately to the once fertile strip of country that lies between the deserts of Arabia on the one hand, and the mountains of Asia Minor on the other. It is needless to dwell here on the visions of the past that a mere inspection of the names on this map will call up in the mind of the historian. Looking to the future alone, it is obvious that we have before us the representation of a piece of country destined once again to play an important part in human history, and to be the scene of a busy commerce and a thriving agriculture. Whatever be the political difficulties now blocking the way, it is certain that before very long we shall see the construction of the railway joining the Mediterranean with the head of the Persian Gulf, a route possibly extending through southern Persia and Baluchistan to India itself. In the more immediate future we shall see the rich land that lies between and about the great twin rivers wake from its sleep of four centuries and water again flow through canals and irrigation channels long choked with the desert sands.

The report on the irrigation system recently published by Sir W. Willcocks makes it clear that, with no great engineering difficulties, and even with no great expenditure of capital, some, at all events, of the old irrigation works can be reopened and a large area of land once more taken into cultivation. The enterprise and energy with which this work is now actually being taken up is the best evidence of the change that has come over the spirit of Turkish administration since the advent of constitutional government.

It is sincerely to be hoped that the prime importance of carrying out an accurate survey in advance of agricultural development will not be lost sight of. In

this matter the example of Egypt should be constantly borne in mind, both as showing the difficulties and loss incurred when survey is allowed to lag behind the necessities of land development and taxation, and also as an example of the methods upon which the cadastre of such a piece of country should proceed. The map before us is produced in the excellent style that its origin would lead us to expect, and the thanks of all geographers are due to its compilers and publishers.

E. H. H.

The Anatomy of the Common Squid, Loligo Pealii, Lesueur. By L. W. Williams. Pp. xv+92. (Leyden: late E. J. Brill, n.d.) Price 10s.

This work, published under the patronage of the American Museum of Natural History, but printed in Holland without date, is a very complete and well-illustrated description of the anatomy of one of the commonest Cephalopods. As such it should meet with a warm welcome from all serious students of the mollusca. We believe the squid is a type not usually dissected by zoological students in this country, but for the sake of comparison, at any rate, the work should find a place in the zoological laboratory.

We do not expect very much in the way of novelty in a memoir of this kind, but the author is to be congratulated on the important discovery of a pair of giant nerve-cells situated in the pedal ganglion, and each giving off a giant fibre. The giant fibres pass backwards to the centre of the visceral ganglion, where they cross one another, forming a "chiasma"; each fibre then passes on through the viscerostellate connective to the stellate ganglion of the side opposite its origin, where it divides into a number of branches, one of which enters each of the larger nerves given off from that ganglion. There appears to be no doubt about the facts of the case, which are sufficiently remarkable, but the term "chiasma" hardly seems suitable for the simple crossing of a single pair of fibres. According to the author, this is the first time such fibres have been described in any mollusc, though similar structures are, of course, widely distributed throughout the animal kingdom. We may mention that in the first text-figure we have what seems to be a variation of Lankester's well-known schematic mollusc which does not appear to us to be any improvement on the original.

The Siege and Conquest of the North Pole. By George Bryce. Pp. xvi+334. (London: Gibbings and Co., Ltd., 1910.) Price 7s. 6d.

As a record of a group of Arctic journeys which had the object of attaining the North Pole, this volume has a real value. It gives, usually in the explorers' own words, the most stirring stories of the Far North, many of which are now difficult to procure in the original form. The record only deals with the last hundred years, the three centuries of earlier efforts being dismissed in a brief introduction. The expeditions chronicled are those of Parry in 1827, Kane in 1853-5, Hayes in 1860-1, the German expedition of 1869-70, the *Polaris* expedition of 1871-3, the Austro-Hungarian expedition of 1872-4, the British expedition of 1875-6, the voyage of the *Jeannette* in 1879-81, Greely's in 1881-4, Nansen's in 1893-6, Sverdrup's in 1898-1902, the Duke of the Abruzzi's in 1899-1900, Peary's from 1886 to 1909, and lastly, Cook's in 1907-9. There were, of course, several other expeditions in the period covered, some, such as Andrée's, avowedly aimed at the pole; others, like the Jackson-Harmsworth, the Ziegler, and the Wellman expeditions, in which the attainment of the pole was at least as much an object of ambition as was the case with Nansen, and much more so than with Greely or Sverdrup. We are, indeed, inclined to

suspect that the hope of gaining the fame of first reaching the pole has animated a good many explorers whose ostensible ideals were more modest.

The author's comments and criticisms are few, but usually sound; and we are the more surprised to find that in the light of the adverse opinion of the University of Copenhagen he was able to say "it is impossible at present to pronounce a final judgment" on the story of Cook's journey in 1908. The summing up is strongly in favour of Dr. Cook's claim, and Mr. Bryce does not seem to be staggered by the coincidence of a group of highly improbable statements. He seriously reproduces, without comment or criticism, the absurd assertion that, after finding a latitude of $89^{\circ} 59' 45''$, the explorer advanced "a distance equal to the 15'." With the exception of the last chapter, however, we can commend the book unreservedly as giving in brief compass a graphic account of many of the greatest trials of human endurance. The sketch-maps suffer from the common fault of being over-reduced, but they help the reader to follow the narratives all the same.

The author does not point out, but the book itself bears abundant testimony to the fact, that the greatest results have been gained since the naval or military organisation of polar expeditions has been abandoned, and the personal ambition or scientific zeal of the leader has become the driving power of a small, well-equipped party, strong in the realisation of the lessons of past failure.

Les États physiques de la Matière. By Prof. Ch. Maurain. Pp. 327. (Paris: F. Alcan, 1910.) Price 3.50 francs.

This book is, as the title suggests, an exposition of the properties of matter in its various states. The author confesses, however, in his introduction, that he is principally concerned with the properties of crystals, the different states of solid bodies, liquid crystals and colloids. Thus we find only twenty-three pages devoted to the study of gases, and rather more than fifty to that of liquids. Prof. Maurain has found it convenient to preserve the old divisions of solid, liquid, and gas, but he points out that the distinctions are as regards degree only, and that no properties are peculiar to a particular state.

The treatment is practically devoid of mathematics. The contents of the book are mainly a collection of experimental facts, particularly those which have been brought to light by the use of the microscope and ultramicroscope. The former as applied to crystals, and the latter to emulsions and colloids, have recently widely extended the knowledge of these states of matter.

There are, in all, eleven chapters. The first is devoted to gases and gaseous ions. Reference is made to the kinetic theory, and estimates are given of the sizes and masses of the molecules. The second chapter deals with the properties of liquids. Much attention is paid to the question of the thickness of liquid films and its bearing on the molecular dimensions, and there is also included a discussion of the various methods of estimating the molecular weights of substances. In the next three chapters the properties of solid bodies are fully treated. The various systems of crystals are defined, and examples are given of their directed properties relating to thermal and electrical conductivities, elasticity, magnetism, and optics. The crystalline structure of solid bodies as seen through the microscope is described, and is applied to explain the various properties of metals. Chapter vi. deals mainly with the production of double refraction in isotropic bodies by external means, such as mechanical pressure and electric and magnetic fields. Liquid crystals form the subject of chapter vii. The special properties

of thin solid films are next treated, including Quincke's experiments on the range of molecular action. Chapter ix. is devoted to the behaviour of homogeneous mixtures, both liquid and solid, and chapter x. to heterogeneous mixtures, such as alloys and mixtures of salts. The concluding chapter concerns colloidal solutions, their preparation, structure, &c.

The book, as a whole, is very good. It contains a large fund of information, clearly put and in logical order. It is therefore both readable and instructive.

Aids to Microscopic Diagnosis (Bacterial and Parasitic Diseases). By Capt. E. Blake Knox. Pp. viii+156. (London: Baillière, Tindall and Cox, 1909.) Price 2s. 6d. net.

This little book is a *résumé* of clinical methods as applied in the diagnosis of bacterial and parasitic infections of man, and contains a large amount of useful matter in a small space. It is not meant to take the place of the ordinary text-books on these subjects, but to be used for revision purposes, and will be found handy by travellers who are unable to burden themselves with many books. Protozoal organisms, such as malaria, trypanosomes, and spirochetes, filaria, pathogenic bacteria, and the diseases they cause, pathological secretions, the opsonic index, and vaccine therapy are all dealt with, together with the methods required to demonstrate and isolate the causative organisms.

We have noticed a few slips and omissions, e.g. the *Streptococcus pyogenes* is spoken of as the *S. pyogenes aureus*; no mention is made of the fact that the *Staphylococcus pyogenes* group liquefies gelatin, while the *Staph. cereus* group does not; it is questionable if the tubercle bacillus can ever be detected in the blood; the term "subtertian," now commonly applied to the malignant form of malaria, is not mentioned; toxin and not dead culture is used for the preparation of diphtheria antitoxin; prophylactic vaccination in cholera is given under the heading "serum therapy," &c. Within the limitations stated by the author, we think a useful purpose will be served by this little book. R. T. HEWLETT.

Lift-Luck on Southern Roads. By Tickner Edwardes. Pp. xv+301. (London: Methuen and Co., 1910.) Price 6s.

HERE is a pleasantly written description of a journey, of some two hundred miles, through five southern English counties, on an unusual plan. Mr. Edwardes says, "My plan consisted in waiting by the roadside or strolling gently onward, until something on wheels, it mattered not what, overtook me . . . by dint of laying under use the whole gamut of country perambulation, at length, after many days of travel, I found myself at my journey's end." Having only a camera and a pack, the author was able to go into every byway he fancied and investigate any subject which presented itself. His account of his wanderings and his illustrations will delight all lovers of the country.

Praenunciae Bahamensis. II., Contributions to a Flora of the Bahamian Archipelago. By C. F. Mills-paugh. (Chicago: Field Museum of Natural History, 1909.)

THIS is the second fascicle of a contribution to a flora of the Bahamian Archipelago, issued by the Field Museum of Natural History. It contains observations on old species, the establishment of the new genus *Euphorbiodendron*, and the description of eleven novelties distributed among the genera *Dondia*, *Portulaca*, *Chamaesyce*, *Croton*, *Centaurium*, *Heliotropium*, *Varronia*, *Catesbæa*, and *Callicarpa*, collected in fifteen different islands of the group.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Halley's Comet and Magnetic and Electrical Phenomena.

HALLEY'S comet has been a source of interest to magneticians as well as to astronomers. The question was: Would the proximity of the comet's tail occasion a magnetic storm or would it not? If the tail consists of electrified particles, and if it were to envelop the earth, then a magnetic storm appeared a reasonable concomitant. It was thus with some expectancy that I consulted the magnetic curves recorded at Kew on May 19. The conclusion that will be drawn from these and similar records will, I suspect, depend somewhat on the temperament of the inquirer. A large magnetic storm unquestionably there was not, but there was disturbance.

The position may perhaps be best explained by reference to the international lists that are published as to the magnetic character of individual days. Days are classed as "0," "1," or "2," according as they are magnetically quiet, moderately disturbed, or highly disturbed. Taking the three years 1906, 1907, and 1908, the Greenwich and Kew lists, while differing in details, agreed in putting 39 per cent. of all the days in class "0," 58½ per cent. in class "1," and 2½ per cent. in class "2." No day practically is absolutely quiet, and a good many days are so near the line of demarcation of classes "0" and "1" that it is a good deal a matter of chance to which they are assigned. Again, there are an appreciable number of days so near the common margin of classes "1" and "2" that they may well be assigned to either. Thus while the Kew and Greenwich lists for the three years mentioned each assigned twenty-nine days to class "2," only nineteen days were common to both lists. If, then, a day is chosen by haphazard, it is most likely to be of disturbance class "1," while the odds against its being of class "2" are not so great that if it should prove to be of that class one is compelled to accept the coincidence as necessarily more than accidental.

In the present instance what was *a priori* the most probable event has happened; May 19 was undoubtedly of disturbance class "1." So far, indeed, as the declination curve was concerned, the choice between classes "0" and "1" was not very clear, but the horizontal force curve—while very far from being highly disturbed—was unquestionably up to the average class "1" level. The most rapid horizontal force changes occurred between 10 a.m. and noon, the range of the largest oscillation being about 50.7 (0.0005 C.G.S.). There were also changes of nearly the same size between 0 and 2 a.m., and again between 3 and 5 p.m. The largest irregular declination movements occurred between 0 and 3 a.m., the range being about 9'. Later in the day there were some oscillatory declination movements synchronous with those shown in the horizontal force curve, but their amplitude was only 2' or 3'.

As a rule, days of class "0" and days of class "1" disturbance occur in groups. The present occasion follows the general rule. From May 13 to 20 no day, except possibly May 16, was of class "0," May 13 being the most disturbed. There were horizontal force changes on the afternoons of May 17 and 18 similar in size to those on May 19. The afternoon of May 20 was also disturbed, though less so. The disturbances on May 18 and 19 were similar in magnitude to those which in 1902-3 accompanied what Prof. Birkeland termed "polar elementary" magnetic storms in the Arctic, and if Prof. Birkeland expected no more than a "polar elementary" storm from the passage of Halley's comet, then I have little doubt that the special observations he has been making in the Arctic will have supplied him with what he was looking for.

As it was conceivable that the intrusion of a comet's tail into the earth's atmosphere might exert a visible effect on the electric potential, I have also examined the Kew electrograms. The electrograms from May 19 to May 20

were throughout their greater part of the usual fair weather type, the potential being neither specially high, specially low, nor specially variable. There were, however, two intervals, between 8.40 and 9.20 p.m. on May 19, and between 1.30 and 3 a.m. on May 20, when there were rapid oscillations and negative potentials, which were not accompanied—as is usually the case—by a rainfall visible in the rain-gauge curves. Thunderstorms were, however, in active progress at the time at no great distance, a good many peals of thunder being audible in Richmond; there was thus nothing in the electrical phenomena that is not adequately accounted for by the observed meteorological conditions.

May 21.

The Magic Square of Sixteen Cells. A New and Completely General Formula.

THE ancient problem: *To construct a Magic Square with sixteen consecutive integers*, may be regarded as a special case of the general problem: *To construct a Magic Square with any sixteen positive integers, no two of which shall be identical*. The solution of the problem thus generally enunciated throws much new light upon the ancient special one, and will, in fact, enable us to classify and tabulate its 880 known solutions (8×880 , if we admit reversals and reflections of the same square to be "different") much more scientifically than has hitherto been done.

The following is the completely general formula for the Magic of Sixteen Cells:—

$A-a$	$C+a+c$	$B+b-c$	$D-b$
$D+a-d$	B	C	$A-a+d$
$C-b+d$	A	D	$B+b-d$
$B+b$	$D-a-c$	$A-b+c$	$C+a$

For (1) this formula obviously represents a Magic Square, since every row, every column, and both the central diagonals sum to $A+B+C+D$.

Also (2) it is a function of eight independent variables.

Let S be the sum of our sixteen unknown quantities; then the constant total of the square will $=S/4$. If three of the rows sum to $S/4$, the fourth row must do the same; similarly with the columns.

Hence only eight of the ten given conditions are independent; we have to solve eight simultaneous linear equations involving sixteen unknown quantities. The solution, if general, must thus involve eight arbitrary constants. Therefore the above solution, which does involve eight arbitrary constants, is a perfectly general one.

I proceed to a numerical example. If $A=10$, $B=12$, $C=8$, $D=5$, $a=8$, $b=-9$, $c=-10$, $d=2$, our formula gives us a Magic summing in every direction to 35:—

2	6	13	14
11	12	8	4
19	10	5	1
3	7	9	16

It will be noticed that the number 19 is used, and the number 15 is not.

We have here an example of a Magic in its simplest form, with none of the superfluous (accidental) relations such as appear among the components when those numbers happen to be consecutive; and we see that the "complementary pairs" (each summing to half the constant total) upon which previous writers have laid such stress are a purely adventitious feature, and have no real connection with the laws of construction of the square.

In the fourth volume of the "Récréations Mathématiques" of Edouard Lucas (Paris, 1894) are set out three theorems and three corollaries, enunciating various equalities which must exist between the component numbers of every Magic of Sixteen Cells. The proof of these takes up four pages and a half, and requires twelve illustrative diagrams. My formula proves them all by simple inspection.

If, in the formula, $a=b$, the square assumes the type which Frénicle designated by the letter δ .¹ If $a=-b$, it assumes the type which Frénicle, in his table, left unmarked. Of the latter type, there are exactly 120 in consecutive numbers. I append an example of each type:—

δ			
1	12	13	8
16	9	4	5
2	7	14	11
15	6	3	10

($A=7$; $B=9$; $C=4$; $D=14$;
 $a=6$; $b=6$; $c=2$; $d=4$.)

($A=4$; $B=15$; $C=10$; $D=5$;
 $a=3$; $b=-3$; $c=-4$; $d=1$.)

It must be borne in mind, however, that a complete numerical solution of the δ type necessarily includes the squares which Frénicle marked α and β , because both of these are, algebraically, particular cases of the δ form.

My formula readily supplies an infinity of solutions of the problem, *To construct a Magic Square with sixteen different prime numbers*. The following example (first published by me in the *Pall Mall Gazette* of February 26 last) omits two only out of the first eighteen odd primes, and sums to a far smaller constant than any other investigator has been able to obtain:—

1	47	13	53
61	17	31	5
29	7	59	19
23	43	11	37

($A=7$; $B=17$; $C=31$; $D=59$;
 $a=6$; $b=6$; $c=10$; $d=4$.)

It is obvious that every 4^2 Magic formed by the addition of two Latin squares is divided into equal quarters. No proof, however, has up to now been given of the "converse" of this proposition. I will deduce the theorem from my general formula.

Theorem.—Every 4^2 Magic in equal quarters can be expressed as the sum of two Latin squares.

That the form of the result may be more convenient, I

¹ "Ouvrages de Mathématique." Par M. Frénicle. (La Haye, 1731.)

re-state my general formula, with interchanged letters, as below :—

$A+d$	$C-a-d$	$B+a-b$	$D+b$
$D+c-d$	B	C	$A-c+d$
$C+b-c$	A	D	$B-b+c$
$B-b$	$D+a+d$	$A-a+b$	$C-d$

The condition that each quarter shall be equal to $A+B+C+D$ is obviously $a-c+d=0$. Substituting $-a+c$ for d , the universal formula for a square in equal quarters is therefore :—

$A-a+c$	$C-c$	$B+a-b$	$D+b$
$D+a$	B	C	$A-a$
$C+b-c$	A	D	$B-b+c$
$B-b$	$D+c$	$A-a+b$	$C+a-c$

which, by putting $A+a$, $B+b$, $C+c$, for A , B , C , respectively, becomes :—

$A+c$	C	$B+a$	$D+b$
$D+a$	$B+b$	$C+c$	A
$C+b$	$A+a$	D	$B+c$
B	$D+c$	$A+b$	$C+a$

This is the familiar traditional form, being the addition of one Latin square (A , B , C , D) to another (a , b , c). It is usually written (inaccurately) as if it involved eight arbitrary variables, instead of seven.

Magnetic Deflection of β Rays.

THE nature of the emission of α rays from radio-active bodies, and the mechanism of their absorption when passing through matter, are well known from the experiments of Rutherford, Bragg, and others.

As regards β rays, our knowledge is not so complete. Although in recent years a large number of experiments have been undertaken in order to study the laws of their absorption, there still remains considerable doubt concerning several fundamental points. From the study of the

absorption of β rays emitted from different radio-active substances, Otto Hahn and Lise Meitner arrived at the conclusion that the β rays, in the same way as α rays, are characterised by a definite initial velocity of expulsion. For different β -ray products the velocity may, of course, be different, but for a simple substance this velocity is characteristic of the rays. It was assumed by Hahn and Meitner that a homogeneous substance could be recognised as such by the exponential law of absorption by aluminium of the β rays which are emitted.

The experiments of W. Wilson were not in accord with this hypothesis. He found that the exponential law is not a measure of the homogeneity of the radiation, but, on the contrary, that homogeneous rays are absorbed according to a linear law.

In addition, the experiments of Kaufmann and Bucherer, who obtained a continuous magnetic spectrum of β rays in their determination of e/m and v for those rays, appeared to be contrary to the view of Hahn and Meitner. Such a spectrum could not be obtained on the assumption of groups of homogeneous β rays.

During the last few months the authors have investigated by a photographic method the magnetic deflection of β rays, and were able to show that in some cases very well-defined lines of deflection can be obtained. Experiments were especially successful when the active deposit from thorium served as source of radiation. As Hahn and Meitner have shown, this contains two groups of β rays (ThA and ThD). The authors obtained in this case two distinctly separated lines in the magnetic field. The line due to thorium A, which was further deflected, was nearly as well defined as if it were produced by α rays. Of course, by use of a stronger field, a third line, fairly well marked, was absorbed very near the ThA line, the source of which we are not yet quite certain.

But it is of interest that Hahn and Meitner recently discovered a new easily absorbed β radiation in ThX , and that the photographic impression, when using thorium X, really gave one more line as when using the active deposit alone.

Mesothorium gave a number of well-separated lines (about five or six). In this case the absorption experiments of Hahn and Meitner had already indicated a complex β radiation.

In the case of radium we have not, so far, been able to obtain single bands. This may perhaps be ascribed to the fact that the β rays from the radium products do not differ much in their velocities, and that the bands were consequently superposed, the intensity of the magnetic field being only about 80 Gauss. As a whole, the photographic impressions produced by the hard β rays are not very clear, since the rays pass through the photographic film without appreciable absorption, giving rise to a secondary radiation which fogs the plate.

The authors have proved by their experiments, at least for several of the radio-active elements, that these elements emit groups of β rays of definite velocity for which e/m and v can be separately determined.

A more detailed account of these experiments will be published elsewhere.

OTTO VON BAERER.

OTTO HAHN.

Berlin, May 1.

Peripatus papuensis.

At the end of last June I received from Mr. A. E. Pratt, the well-known naturalist, a number of fine specimens of *Peripatus* which he and his son, Mr. F. B. Pratt, had found in New Guinea on their recent expedition to that island. This is the first time *Peripatus* has been found in New Guinea. It was found by Dr. Willey in New Britain in 1897, and by Mr. Muir and Mr. Kershaw in Ceram last year (see *NATURE*, July 1, 1909, p. 17, and *Quarterly Journal of Microscopical Science*, liii., 1909, p. 737). The New Guinea specimens were found in January, February, and March at Sarayu, at an elevation of 3500 feet in the Central Arfak Mountains. Mr. Pratt, in describing his discovery, writes as follows:—"After my son found the first specimen amongst the roots of the grass, we at once showed it to the natives, offering them a large knife (which is most valuable to them) for every specimen. Quite sixty of the natives were searching for

the above months, and you have the results; so evidently they are not common in the part we were in. The curious thing is that, although we searched for weeks, we never found another specimen. The natives told me they found them at the roots of grass, under stones, and at the damp roots of clumps of bamboo."

Until the Ceram species was described it was quite uncertain whether the Papuan species would, when discovered, be found to belong to the Australian type or to the New Britain type, or to neither. Messrs. Muir and Kershaw's discovery settled that point. As a result of their work we know that *Peripatus ceramensis* belongs to the group *Melano-Peripatus*. It was therefore to be expected that the Papuan species would belong to the same type, as indeed it does. I propose to name the species *papuensis*, with the following characters:—

Peripatus papuensis, n.sp. Colour very similar to that of *Capo-Peripatus*, the principal pigments being a greenish-blue and an orange. Number of legs is variable, from twenty-three to twenty-nine pairs. Legs with three spinous pads. Nephridial openings of legs four and five on the proximal pad. Feet with three distal papillæ, of which one is anterior, one posterior, and one dorsal. Genital opening subterminal behind the legs of the last pair. Ovary small, with small ova (size not determined). Oviduct with a receptaculum seminis. Uterine embryos of very different ages in the same uterus. Spirit specimens which have been killed extended reach a length of $3\frac{1}{4}$ inches.

From this it seems fairly clear that we are dealing with a *Melano-Peripatus*. As the specimens are admirably preserved I hope soon to be able to work out the other characters.

A. SEDGWICK.

Imperial College of Science and Technology, May 13.

The Bibliography of the Biology of the European Seas.

MAY I through the columns of NATURE direct attention to the fact that the Bureau of British Marine Biology, which for some time past has been engaged in the preparation of an extensive MS. bibliography of the fauna and flora of the European seas, is now making the experiment of printing and circulating, in the form of a periodical, the records which are thus being brought together?

The number of scientific journals has increased so enormously of late, and the output of biological work has now become so vast, that there would seem to be a very real need of some means by which the student may keep more fully in touch with the published work of his colleagues than is possible with the aid of the existing bibliographies alone; it has already become quite impossible for the specialist to himself search through all the various journals, &c., as they appear (even should he be fortunate enough to have access to adequate libraries), and, at the same time, to accomplish any research work of his own.

The bibliography of European marine biology now in progress (the first part was published on April 2) in the "Contributions from the Bureau of British Marine Biology" aims at providing a full title-entry and summary of the contents of every publication as it appears which is in any way concerned with the biology of the European seas (including the North Atlantic, Arctic, and Mediterranean). These summaries will, in general, appear within a few weeks of the publication of the works to which reference is made, while entries in the existing annual bibliographies are, of course, necessarily at least one or two years behindhand. The analysis of works indexed by the Bureau is also carried very much further than is attempted in any existing bibliography; for instance, a separate entry is made for practically every mention of a species in the work analysed. In addition to the bibliography and analysis of current work, the MS. records of the Bureau also include extensive annotated lists of the marine fauna and flora, alphabetical reference lists of specific and sub-specific names and synonyms, particulars of type-localities, type-specimens, &c.; it is likewise intended to publish these records in the "Contributions." It may also be mentioned that all entries are being printed in such a form as will admit of their use as a card catalogue.

There is, of course, no desire to make a profit by the publication of these records, but, on the other hand, the

Bureau cannot afford to incur any considerable financial loss by the undertaking, and the publication of the bibliography will therefore not be proceeded with for any length of time unless there is by an early date distinct evidence that sufficient support will be forthcoming to meet the cost of printing. For this reason I would urge all who may be willing to assist the undertaking to notify as soon as possible their intention of subscribing. The bibliography will, I am sure, prove most useful to those interested in any department of marine research if only publication can be continued for a sufficient period to enable the "Contributions" to become established. Full particulars, forms for subscription, &c., will be forwarded upon application to the undersigned.

May 11.

An Improved Weight Dilatometer.

THE ordinary form of weight dilatometer is troublesome to dry and fill, and the filling takes much time. Air bubbles are removed with difficulty, and after cooling to a low temperature there is a risk of loss of mercury while weighing the dilatometer unless special precautions are taken.

To obviate these disadvantages the form of dilatometer here illustrated has been devised. The neck of the dilatometer is short and straight, and is enclosed in a cylindrical cup projecting a few centimetres above the neck, and sealed on to the body of the dilatometer.

To dry the bulb, the cup is fitted with a cork and a piece of tubing, and connected to the water-pump. By gently heating the bulb and exhausting, moisture is removed. In the second form (Fig. 2) air is drawn through the bulb by removing the clip and pad from the side tube.

To fill the simpler form, Fig. 1, dry mercury is poured into the cup; by gently tapping, the mercury falls into the bulb. The operation is repeated until the bulb is filled. To remove air from the neck the dilatometer is warmed, and when the mercury oozes out the cup is re-filled, and the dilatometer placed in ice water above the level of the

neck. After cooling, the excess of mercury is poured out of the cup. The dilatometer is dried and weighed, any mercury expelled by expansion being collected in the cup. After heating to a higher temperature, the expelled mercury is poured out, and the dilatometer weighed after cooling. In the form shown in Fig. 2 the filling is more rapid, as air is expelled through the side tube; when this is filled with mercury the clip is fixed, and the tube closed by a screw pad.

FIG. 2.

THE INTERNATIONAL ASSOCIATION OF ACADEMIES.

FOURTH MEETING, MAY 9-14.

IT is now ten years since the association was inaugurated in a preliminary meeting held at Wiesbaden, and since then regular triennial assemblies have taken place in Paris, London, Vienna, and finally in Rome, where the fourth meeting, conducted under the presidency of Prof. P. Blaserna, of the Accademia dei Lincei, has just come to a close. The representatives of the Royal Society were Sir Archibald Geikie, Sir Joseph Larmor, Prof. Schäfer, Colonel Prain, Prof. Turner, and Dr. Arthur Schuster. In judging of the past activity and the prospects of the association, it must be borne in mind that, having no funds at its disposal, its influence must be mainly

a moral one. It is intended to coordinate international enterprises, to initiate and encourage undertakings, and to act as an advisory body where advice is asked for, either by Governments or by the many special international organisations which have recently sprung up. The list of resolutions passed at each meeting may appear meagre to those who do not realise that they represent only the crystallised results of the discussions which have come to an issue, and that it often takes a considerable time before questions can be presented in a sufficiently definite form to admit of treatment by an international committee which can only meet at rare intervals; but those who have watched the proceedings of the association do not doubt that it has justified its existence, and that there is an important future before it.

That part of the association's work which prevents the overlapping of international enterprises has been illustrated in Rome by the manner in which the proposal of the Swedish Academy to take international action towards the prevention of the diseases of cultivated plants was dealt with. Everyone agreed that the subject was a most important one, and fell within the province of the association, but there is in Rome an International Agricultural Institute, which might be expected to include remedial measures against the diseases of plants within its range of activity. Apparently, however, there are difficulties which hitherto have prevented the Agricultural Institute from attacking the problem; these are partly financial, but partly also due to the terms of the convention under which the institute was founded. After a full discussion, the representative of the Swedish Academy accepted the following resolution, which was proposed by Colonel Prain, one of the representatives of the Royal Society:—

"The International Association of Academies of Science, while in entire sympathy with the proposal that further international cooperation in the study of plant diseases is necessary, considers that the question of deciding what ought to be done in the direction of combating these diseases might appropriately be entrusted to the International Agricultural Institute.

"In the event of its being found that the terms of the convention of 1905, under which it was established, prevent the International Institute from extending its activities so far as is desired in the interests of science and agriculture, this association recommends that the constituent academies bring to the notice of their respective Governments the desirability of conferring adequate powers upon the International Agricultural Institute."

A further question in which the association endeavoured to prevent a possible overlapping of enterprises arose out of the proposal to give the support of the association to an international committee formed to prepare tables of "physico-chemical" constants. Here a consultation with the International Scientific Catalogue Committee seemed advisable, and the following resolution was adopted:—

"The International Association of Academies gives its patronage to the International Committee of Physico-chemical Tables, and expresses the wish that this committee put itself into communication with the International Committee of the Catalogue of Scientific Literature."

The coordination of international scientific work which results from the extension of the patronage of the International Association of Academies to different independent enterprises is an effective method which deserves to be further extended. The International Union for the Study of Solar Phenomena has set a good example in this respect by asking the Association of Academies to nominate one of the three members of its executive committee. Prof. Riccò, of

Catania, was nominated two years ago as the member representing the Accademia dei Lincei when that body became the leading academy, and he will hold office until the end of the year, when a new member will be nominated by the academy which will next act as host to the International Association.

The scientific questions which are dealt with by the association are frequently handed over to autonomous committees which regulate their own proceedings and act very much like independent international bodies. All that appears at the meetings is a short report summarising the activity of the committee. One of these committees deals with the investigation of the functions of the brain, and works under the chairmanship of Prof. Waldeyer, of Berlin. The work of a number of institutes specially endowed in different countries for the study of this question is thus co-ordinated, and a more rapid progress is secured.

A very useful piece of work has been undertaken at the instigation of the Royal Society, with the object of introducing order into the chaos which reigns at present in the nomenclature of prominent features on the surface of the moon. The advice of all astronomers interested in the subject has been obtained, and a committee has been formed, under the presidency, first of M. Loewy, and since his death of Prof. Turner. Maps of the moon are being drawn by Mr. Wesley from maps supplied by the Paris observatories, and the details of the nomenclature, according to a definite scheme agreed upon, will then be prepared by Messrs. Saunders and Franz.

Questions which are of importance in the general theory of terrestrial magnetism have been under the consideration of a special committee almost since the foundation of the association. The general magnetic survey of the ocean basins which is being carried out by the Carnegie Institution of Washington is expected to prove of fundamental importance in this respect, and the work of the committee is dormant at present until that survey is more generally advanced.

The association has further interested itself in the publication of the collected works of Leibnitz, which is being promoted jointly by the Academies of Paris and Berlin, and in that of Euler's works, which has been undertaken by the Société helvétique des Sciences naturelles. The association has more especially approved at its recent meeting the decision to publish all memoirs in their original language. It may seem strange that such approval should be necessary, but it was called for by attempts that had been made to persuade the Swiss society to translate the Latin writings into a modern language.

A few words should perhaps be said on the literary side of the work of the association. The subjects dealt with included the preparation of an edition of the "Mahābhārata," and of an "Encyclopædia of Islam," of Greek documents, and of a "Corpus Medicorum Antiquorum"; further, the very difficult question of an international exchange—by way of loan—of manuscripts belonging to public libraries.

That a young association should still have to devote a considerable part of its time to matters of organisation is not surprising, and there is one question which is likely to occupy its attention very seriously before a definite conclusion is reached. At present the association has no legal status, not being subject to the laws of any country. It cannot, therefore, accept any legacies, and it is rumoured that it has lost in consequence a very considerable sum of money. The simplest manner to overcome the difficulty would be to establish a domicile in some country, such as one of the smaller States of Europe. It is claimed by some that other advantages would accrue to the association if it had a definite home, and its business matters could no doubt be carried on in a more satis-

factory manner; but at present there is still too wide a divergence of opinion to render a definite proposal generally acceptable. In order to evade the difficulty at present preventing the association from having funds of its own, the committee of the association, at a meeting held last year, at which nearly all the academies were represented, passed a unanimous resolution recommending that the different academies should declare themselves ready to accept legacies or gifts to be held in trust by them for the purposes of the association. When this resolution came up for discussion at the present meeting, objections were raised by several delegates, and the matter had to be referred to the several academies for an authoritative expression of opinion. Doubts were expressed in several quarters whether it would be advisable for the association to be in possession of funds, and at any rate one delegate thought that it would be more powerful if satisfied with its present "moral" force. Time, further reflection, and the force of circumstances will no doubt lead to a generally acceptable solution.

By the admission of the *Société helvétique des Sciences naturelles*, which was decided upon almost unanimously, the association has established the important, and, I believe, wise, principle that it attaches greater importance to the representation of countries in which important work is being done and of societies which take a leading part in such work than to the more or less exclusive tests of membership which a society may adopt. The Swiss society is not an academy in the old and perhaps proper sense. It may be the poorer for having no mediæval traditions, but it is the richer for not having adopted, without such traditions, a mediæval organisation.

Our association now consists of twenty-one societies, and fears have been expressed that our work would become more difficult if the number were to be increased substantially. These fears are not, perhaps, groundless, if the addition of a new society does not mean the inclusion of new interests and of independent directions of activity. Now, if we look at the proper balance of representation of such independent scientific activity, it seems altogether anomalous that the British Empire should only be represented by the Royal Society and the British Academy. The non-representation of India more especially denotes a gap which should be filled without delay. Both on the literary and on the scientific side our work has dealt with matters in which India is directly concerned. The publication of the "*Mahâbhârata*," more especially, cannot be carried out without substantial help from India, and at the present meeting in Rome it was announced that several of the Indian native rulers have subscribed to the undertaking. In the Asiatic Society of Bengal, India possesses a society of full academic rank, and without it the International Association of Academies is not complete. Some formal changes in its organisation, the dropping of the word "Bengal" from its title (I understand that its inclusion was purely accidental and not originally intended), and an increased activity on the scientific side may be desirable, but even with its present organisation there is no reasonable doubt that a proposal coming from the Royal Society to add the Asiatic Society to the list of academies forming the union would be generally welcomed.

In his introductory speech, Prof. Blaserna made a feeling reference to the death of King Edward, and several of the festivities prepared in honour of the meeting were modified in consequence of the Court mourning. A state dinner which the King had intended to give was changed into a private reception of the delegates, and in place of a garden-party arranged for by Queen Margherita, the Queen enter-

tained the delegates informally one afternoon at her palace. Soirées were given by the Syndics of the City of Rome in the Museo Capitolino, by Prince Teano and by Countess Lovatelli, but these were, as a matter of course, not attended by the British delegates. An interesting excursion by motor-car to Ostia, including a visit to the important excavations which are being carried out in that locality, concluded the meeting.

ARTHUR SCHUSTER.

HALLEY'S OBSERVATIONS ON HALLEY'S COMET, 1682.

IN the record-room at the Royal Observatory, Greenwich, are preserved nineteen manuscripts of Edmund Halley. In one of these, Halley's original observations of the comet afterwards called by his name were recently discovered by Messrs. Davidson and Burkett. The book is of about octavo size; it appears to have been originally a college notebook. On the cover Halley has written "Edmund Halley his Booke and he douth often in it Looke." Part of the book contains neatly written notes (in English) on geometrical conics, with carefully drawn figures, chiefly written on alternate pages. The observations (in Latin) and calculations have been jotted down subsequently wherever there is room, and in many cases have been written over the original contents of the book. By a strange coincidence (it can, I think, be no more than a coincidence) the observations, now identified as those of Halley's comet, are interspersed among notes on the parabola.

It will be recalled that Halley's researches which led to his discovery of the periodicity of this comet were not made until about twenty years after its appearance of 1682; in fact, the law of gravitation was not published until 1686. It is, however, well known that Halley saw the comet, but I believe that details have hitherto been lacking.

The observations now identified are given below in full, with practically no changes, except that punctuation has been added. In the original, symbols are used for the days of the week and the signs of the zodiac. The observations, which must have been made with the naked eye, are almost entirely alignments with stars; they are, of course, too rough to have any scientific value now, but are of historic interest. Calculations to determine the R.A. of the comet from these observations are intermingled with them. Although the observations can hardly be correct to 15', six-figure logarithms are used in the calculations! Halley, however, did not use his own observations in his determination of the orbit of the comet. The references to the "hand," "foot," "knee," "pastoral staff," &c., of Boötes are of some interest as illustrating the early method of specifying stars, based on the *Almagest*.

The year is not given, but as the observations are certainly those of Halley's comet, and the days of the week agree, we may supply the date, 1682.

Saturday, August 26, 7h. 29'. Culminante 277° A.R., Cometa visus in linea recta cum Arcturo et capite Ophiuchi; et ex altera parte cum Corde Caroli et secunda caudæ Ursæ Majoris; vel linea recta a cometa ad 1^{am} caudæ Ursæ Majoris relinquebat in consequentia stellam dictam Cor Caroli 30' A.R.

Wednesday, August 30. Culminante 280° A.R., visus est Cometa in linea recta quæ transiens genu præced.

he carried out his observations under weather conditions of the most trying and discouraging sort. Wind, rain, sleet, and intense cold companioned him throughout the—"unbrokenly wet and gloomy"—period of investigation—from April to July.

The eyrie where this royal mother established her nursery was situated on a narrow ledge of rock, 200 feet perpendicularly above a stream "in a dark gloomy corrie in a wild deer forest"—which, with excellent circumspection, the author does not more definitely locate—"in the heart of the Grampian range," into which "the sun penetrates for a few short hours during the long summer day." Here, with the aid of a very sympathetic stalker, the recorder constructed, within a few yards of the nest, a "bothy" as an observatory, so well disguised that it deceived the "eagle eyes" of the parents—into which he could just crowd himself and his

desire to read this diary for himself in its entirety, unspoiled by disjointed quotations. He will follow with unflagging interest the mother eagle sheltering her downy chick; feeding him at regular hours during its tenderest days; comforting him with wonderful solicitude on the approach of a violent thunderstorm; teaching him—when about a month old—how to feed himself for the first time. The diverting manoeuvres of the youngster, his games with himself, and his toilet operations as he grows older are interestingly recorded; how, also, after eight weeks old, when nearly as big as his parent, he began practising exercises by which he acquired strength in his wings and legs, and, in addition, a fierce hunger and vigorous appetite, which demanded a daily ration of two grouse, and the hindquarters of two full-grown hares; and, finally, how, under his mother's instruction, his tuition in aviation, which, every day, was

Father and Child. From "The Home-life of a Golden Eagle."

cameras. From April 23, 1909, when the mother eagle was found sitting hard on two eggs, to the end of July, eleven weeks in all, we are made part-takers, with Mr. Macpherson, of the most intimate privacy of the home-life of a member of a very exclusive set of bird society, and see every domestic incident performed naturally, and not through fear or suspicion, or under the distraction of an intruder. We feel, therefore, at the close of our vigils, that there is little we do not know about the upbringing of a prince of the avian blood royal, and the parental care and solicitude of the hen-eagle towards her offspring. About May 13 two eaglets were hatched; but one having mysteriously disappeared, the fortunes of its brother alone form the burden of this history.

It would be unfair to the author to extract, as one is tempted to do, the more intimate and touching episodes from his well-told story. Every ornithologist will

preparing him by short flights for his fast approaching supreme adventure, when he must fare forth for the first time into space "on his own." Mr. Macpherson must allow us to quote his own account of the eaglet's last hours in the eyrie:—

"At length he stepped forward to the edge of the cliff and gazed intently upwards, at the same time uttering the low cheeping note with which he has always greeted his parents' return. . . . Then suddenly a dark form flashed up the corrie and his mother swung past on silent wings . . . and tried to tempt him from his fastness. But the Eaglet was unwilling to obey. . . . Again and again she hovered round, then a wild, weird cry rang echoing down the glen. For the first time I had heard the yelp of the adult Eagle, the voice of the Queen of Birds calling to her young. . . . The Eaglet cheeped continuously till . . . he flapped to the very edge of the abyss . . .

listening to her call. And now he, too, changed his cry, his voice seemed to break, and the adult yelp . . . burst from his throat. The Eagles called to each other, yelp answered yelp. . . . The young Eagle gazed around him . . . spread out his giant wings and vanished for ever from my sight among the ledges below. . . . The Eaglet had left the nest and had flown."

This record is illustrated by thirty-two beautifully clear plates, reproduced from the author's photographs, which are splendid achievements when the difficulties of the situation and of the weather are considered. In them the eaglet's history is depicted from the egg to the day when it takes flight from the nest. Plate 18, "Father and Child" (Fig. 1), is here reproduced by courtesy of the publishers as a specimen of the series, every one of which is worthy of the ornithologist's careful study.

(2) This is the fourth report of the Migration Committee of the British Ornithologists' Club, appointed in November, 1904, for the purpose of collecting and collating evidence regarding the arrival and dispersal within England and Wales of some thirty strictly migratory species which winter abroad and nest within these limits. These reports are based on the records supplied by voluntary observers on land and on off-shore lightships and lighthouses, who have filled up and returned to the committee schedules of questions issued to them. Each report deals with the spring immigration and the chief autumn movements of the scheduled birds, the one under notice being for the autumn of 1907 and the spring of 1908. It opens with a summary of the weather reports from March to May, 1908, the period covering the spring immigration. The second section details the chief movements observed at the lights during the same period, and indicates the moon's phase and the direction of the wind on each occasion. Next are discussed the schedules of the thirty-three species, individually, each accompanied by a map, on which are plotted the more important data of their arrival and dispersion. Supplementary to this, the main and important portion of the report, are recorded observations on birds not specially scheduled. The migratory movements of the autumn of 1907 are then dealt with, but we regret to find no meteorological notes associated with this section, in which the weather conditions have a special bearing on the causes which impel the birds to start on their autumn journey southwards. A statement of the days and nights on which migration was recorded at the lights between Spurn Head and the Bristol Channel during the autumn of 1907, and a list of the observers, close the volume.

The report calls for little at this stage in the way of discussion, as it is not a final digest, but a further instalment of data towards the elucidation of the great mystery of bird-life, compiled with great care and labour, for which ornithologists generally will desire to offer their grateful thanks to the committee. Nor is there much in its contents deserving of criticism, except, perhaps, to direct the editor's attention to the rather irritating omission from the maps of the elucidatory legends which appeared on those of some of the earlier reports, especially as no explanation is given in the text of the various symbols employed in any of the maps in the report under review. In the two maps devoted to the "swallow," in the first report, for instance, we find that a date within a circle was employed as the symbol for "2nd migration" on the one map, as well as for "5th migration" on the other; while on that for "the nightjar" it stands for "main migration." In other maps the "5th migration" is represented by the date within a triangle. It would be a great advantage if in every map the

same symbols were used to indicate the same migration. Failing this, those used in each map should be printed upon it. On the map devoted to the black-cap in this report (p. 74), we find circles, squares, ellipses, and parallelograms, with no explanation of their import, the sole legend being "M=May; all other dates are in April." Further, on consulting the letterpress of the schedule for the same bird (p. 75) we read, "the earliest arrivals were reported from Gloucestershire on the 10th, 14th, and 21st of March, and these were followed by a pair in Devonshire on the 28th"; yet on referring to its map we discover no entry for any of these dates in the shires named; nor is the bird's earliest appearance in Wiltshire, on April 6, indicated on it, yet that of the 13th is entered, although it is stated in both cases that "the great proportion of the records were of single birds." Again, the same species is noted at St. Catherine's light on April 10 and 11, and the date is plotted on the map unenclosed by a line; its occurrences for April 27-30 are surrounded by an ellipse, while the dates of birds arriving four days later are enclosed in a parallelogram; yet the two records can hardly, we imagine, be assigned to a separate migration. Without, therefore, a legend or explanations in the text it is difficult to follow comfortably the map entries, the plotting of which must cost much in time and in money. Indeed, it may be a matter for consideration whether, at this preliminary stage of the inquiry, they might not be dispensed with, without much loss, seeing that the "chronological summary" under each species supplies all, and more than, they do.

The time is yet far distant when a digest of the valuable records in this report and its three predecessors can be attempted. It does seem, however, that, unless simultaneous observations can be taken over a far wider area than a portion of the British Isles, the true solution of the intricate and baffling problem of migration will not be greatly advanced. Besides ascertaining the flight-lines of the birds arriving in or departing from England and Wales, the state of the weather and the abundance or scarcity of food at these periods, we want to discover whence the individual birds that reach us in spring started; where those that nest within our shores in autumn actually spend our winter; why they adopt the particular routes they do; why they hasten to "change their skies" now to the north, now to the south; if the same individuals and their young invariably follow the same route in going and returning; and if they and their young drop out of the migrating flock every year at the same places in order to "build and brood in their old haunts." The pressing need in the migration inquiry is for the systematic marking in very large numbers, not only of nestlings, but of old birds, in this country and on the Continent of Europe, during both the summer and the winter visitation, but also, which is equally important, of those that spend our winter in southern latitudes, and at various halting places of the ranges of the species from furthest north to furthest south, in the Asiatic, Euro-African, and the American continents.

If the mark attached to the birds were a small faceted ring of aluminium, a light metal which long retains its brilliancy, it would often attract the eye by flashing in the sun, and thereby many birds would be detected as marked individuals by interested or chance observers on the look out for them, in districts especially where such labelling was known to have taken place. The birds could then be followed up, temporarily captured for their mark to be recorded, and then liberated, and the record thereafter promptly published. Until some such united action and extended system for identifying the movements

of individual birds—their actual routes of travel, their retreat during our winter, and their home in our spring and summer—is adopted, there appears little hope of our ignorance of the mystery of migration being quickly or greatly dissipated. We suggest this subject for consideration at the approaching International Ornithological Congress in Berlin.

(3) The "Catalogue of Canadian Birds," by the Macouns, father and son, is an endeavour, successfully carried out, "to bring together facts on the range and nesting habits of all birds known to reside in, migrate to or visit the northern part of the continent," including Newfoundland, Greenland, and Alaska. The authors enumerate 768 species as the avifauna of the region indicated. There is a full account of the distribution, nesting habits, and migration of each species, with many interesting notes on their habits and life-history. An introductory note by the director states that the present volume is an enlarged and to a great extent re-written edition of a previous catalogue, in three parts, which became exhausted immediately after publication. This is excellent evidence, not only of the interest taken by the public in the birds of their own country, but of the value to ornithologists generally of the work, for which we have nothing but commendation—except to say that it deserves a better binding—and to express the hope that the same fortune may be in store for the present edition which attended its predecessor.

(4 and 5) These two volumes belong to the series of publications being issued by the Field Museum of Natural History in Chicago. Both are by Mr. C. B. Cory, the curator of the Department of Zoology. The first of these, on "The Birds of the Leeward Islands," enumerates all the species inhabiting Aruba, Curaçoa, Bonaire, Islas de Aves, Los Roques, Orquilla, Tortuga, Blanquilla, Los Hermanos, the Testigos, and Margarita. The collections were chiefly made by Mr. J. F. Ferry and Dr. N. Dearborn. Each island is dealt with separately, the list of birds from each being prefaced by a short account of the island and a list of its ornithological literature. Dr. Hartert, now of Tring, had previously visited the larger islands of the group, and has described in detail their avifauna in the Hon. Walter Rothschild's *Novitates Zoologicae*, and in the *Ibis*, so that in few of them were there many novelties to be expected. Nevertheless, five new species and three new subspecies were discovered, chiefly on the smaller islets which Mr. Cory's energetic collectors were the first to visit.

Mr. Cory's second book is a much more pretentious volume, and includes, "as far as known, all species and subspecies of birds that occur in Illinois and Wisconsin," the total number being 365 (not 398, as stated in the preface), with descriptions of their various plumages, nests, and eggs, and geographical distribution, together with more or less brief biographical notes concerning them. It is more, however, than an avifauna; it is, in addition, an ornithology for less advanced students. The book is divided into two parts, the first devoted to a key to the families and species, and the second to biographical notes on the species. No fewer than 274 pages are given to the key, which is constructed on a series of highly artificial characters. In the first place, the birds are divided into two great divisions—water birds and land birds. In the former, Mr. Cory includes landrails, herons, golden plovers, and peewits (because they may sometimes be found feeding near water!); yet ospreys, sea-eagles, and kingfishers, which find their food chiefly in that element, are classed as land birds. The collector with a bird in his hand must first decide whether it is a land or a water species, and, having determined this (not, per-

haps, as Mr. Cory would), he must, in order to run down the family, enter tables prepared for him according to the length of the wing. "A large series of specimens has shown," says Mr. Cory, "that while adult birds of the same species differ considerably in length, the wing measure is very constant." Recent investigations have, however, showed this statement to be far from true. Wings vary greatly, not only in actual length in different individuals of the same species, but the wing feathers, the primaries, for instance, vary in length in different proportions. Even Mr. Cory's tables show this. The species *Passer herbulus* (1) *caudacutus nelsoni* is to be found in a group with wings from 1.75–2.5 inches; also in a second, with wings from 2.15–2.37 inches long, as well as in a third, with wings from 2.37–2.75 inches! Examples of the same sort are numerous. Another species appears in one group as having "belly clear yellow," in a second with "underfronts yellow or greenish yellow," and in a third with "under-parts pale greenish yellow."

A curious error occurs on p. 114, where an illustration entitled "first five primaries emarginate. Bald eagle," is drawn with six primaries! The author here adheres also to a method of enumerating the primary quills which has long been given up by all modern ornithologists, who number these feathers from the carpal-joint outwards, and not from the point of the wing inwards.

The second and really valuable portion of the work deals with the history of the 365 species found in the two States, in which the very numerous (and excellent, be it said) illustrations appearing in the key are all needlessly repeated, thus adding greatly to the cost and to the bulk of the book. The volume is beautifully printed on a fine-surfaced paper, and is worthy of a better binding than the flimsy paper covers in which it is issued; but it would be greatly improved by having the system of keys to the families and species remodelled and much condensed.

PORTUGUESE ZAMBEZIA.¹

FOR the pictures alone this book is worth purchasing. We have rarely seen in any similar work dealing with Africa a better collection of admirable photographs which are apt illustrations of the text. The book is not written round the illustrations nor are these photographs stuck into the work without relation to its text and purport. If Mr. Maughan had further confined himself in his text to his own personal observations of this relatively vast region of Portuguese Zambezia, and to his own theories based on his personal observations and experience, there would be nothing in the book to criticise unfavourably. But he has conceived it necessary to borrow largely from the works of other writers, borrowing which he frankly acknowledges in the preface, by which, one might plead, were quite unnecessary his purpose in view.

Somehow or other, a mischievous idea has spread amongst many writers on Africa of late years that it is not sufficient for them to relate their own experiences and to describe a portion of the country they have visited, but that their work must make an attempt at being encyclopædic. If they write the histories of their own personal researches, then they feel obliged to give summaries of linguistics, natural history in general, or botany, which they extract from already published works, and again set forth either

¹ "Zambezia: a General Description of the Valley of the Zambezi River from its Delta to the River Aroangwa, with its History, Agriculture, Flora, Fauna, and Ethnography." By R. C. F. Maughan. Pp. xiv+408; with maps and illustrations. (London: John Murray, 1910.) Price 15s. net.

is due to their own original research, or, quite fairly (as does Mr. Maugham), as the work and conclusions of other people. But in this transposition, not having sufficient technical knowledge, perhaps, they allow themselves or their printers to mar these summaries with ridiculous mistakes in names, English or Latin, or they repeat the few errors of the persons from whom they borrow. Mr. Maugham does more. He adds a little acid to his work by recounting the theories of his predecessors or fellow-travellers (and very often misinterpreting them in the repetition) and then holding them up to ridicule; while at the same time it is patent to a specialist that he has not taken the trouble to understand what appears to him absurd. I pointed out the same tendency in an earlier work of his, in which he chose—one does not know why—to ridicule theories of the origin of the Bantu languages set forth by English and German philologists, while by his own confession (and certainly by the evidence in his text) he was without special knowledge of the subject.

If it were not for this desire on his part to have a dig at all and sundry who have at one time or another written on the countries of South-East Africa, he would have given us a most agreeable, as well as a most interesting, book; for when he confines himself to his own researches and observations he arouses the interest of the reader and secures the attention and respect of those who know Africa as well as he does, or even better. The reader's attention should be directed to the author's sensible remarks on pp. 157-9, as to the proportions of the European hold over the southern half of Africa. These should be a corrective to any excessive exultation. In several directions also he renders service to the very few persons in the United Kingdom, and to the three or four individuals in the southern half of Africa, who are foolish enough to care for the preservation of big game and of interesting birds and beasts. He points out with absolute truth the nonsense of the theory that connects the spread of the *Glossina* tsetse-flies with the abundance of big game: the theory which is quoted by the officers of the British South Africa Company, and of other great companies controlling South Central Africa, and by the thousands of "sportsmen" now swarming over Africa and slaying everything right and left, as their justification for spurning game regulations and mocking at the attempts of a few "fanatics" who think that at any rate a selection of the big and interesting wild beasts

might be preserved for the intelligent appreciation of later generations. He cites this example of the falsity of the theory.¹ There is a considerable region of desolate country lying between the west bank of the Shiré River and the north bank of the Zambezi up to the vicinity of Tete. In this district, across which passes the Cape-to-Cairo telegraph line, there are few human inhabitants, and there is absolutely no wild game. Yet here the tsetse swarms, as it does, possibly, nowhere else in Africa; in fact, its extraordinary abundance has driven away most of the human inhabitants because they have found it impossible to keep any form of domestic animal. Now, if this district swarmed with game, one would be justified in supposing that by destroying the game one might drive away the tsetse. But apparently the *Glossina* flies have made life unbearable for all creatures that do not fly or burrow in the ground, and yet they continue to swarm.

Mr. Maugham, however, is not always consistent

Zambezian Goldsmiths: and Huts built upon Piles. From "Zambezia."

in his desire to create a little tolerance for the existence of beasts and birds, not as yet of interest to South African settlers or sportsmen. He says contemptuously that "the rhinoceros will have to go," but gives no justification for such an utterance. To the intellectual interests of the world the two forms of existing African rhinoceros are quite as important as (let us say) the moderate prosperity of a few European settlers.

But, of course, the only proper solution of this question in Zambezia, as well as elsewhere, is the marking off of game preserves which shall grow by degrees into national parks, and shall harbour and sustain the wild fauna. In the intervening regions the land must be given up to exploitation by man, black or white, and any game straying beyond the reserves should receive no protection. But, of course, the

¹ Further support is given to his remarks in the very interesting article on the flora and fauna of Ngamiland (by Major Lugard) just published in the Kew Bulletin and deserving special notice.

farce of the "reserve" system at present is, first, that the local white and black population do not obey the law, and the local authorities seldom enforce it, and second, that the Government is somewhat too ready to set aside the law in favour of distinguished sportsmen.

In no book which the reviewer has yet seen have the great beasts, the landscapes, and the people been more admirably photographed than in this work on Zambesia, while at the same time due justice is done to the Portuguese towns, the Portuguese officials, and generally to such civilisation as Portugal has been able to introduce into these lands.

H. H. JOHNSTON.

PELLAGRA AND ITS CAUSE.

A GOOD deal of notice has been taken lately in medical journals and in the newspapers of the disease pellagra. It is difficult for British folk to realise the scourge this disease causes in many countries, but chiefly in Italy, Roumania, Spain, Tyrol, and other countries in south-eastern Europe. In the United States of America, pellagra has spread recently to an alarming extent, and in several British colonies and protectorates, markedly the West Indies and Egypt, pellagra is a serious ailment. Persons who contract the disease present a train of symptoms which may be summarised as follows:—"sunburning" of face, neck, chest, and hands is an early and very prevalent manifestation; stomachic and intestinal catarrh; feverishness; skin rash; lassitude and weakness. Spring and autumn recurrences continuing for years further tend to mental excitement and bodily weakness, leading all too frequently to lunacy and a fatal issue.

The disease has hitherto been attributed to eating damaged maize, which is so largely consumed as "polenta," the "porridge" of Italy. In the United States maize is termed Indian corn, and under various names it is used in many countries. In 1905 Dr. L. W. Sambon, at a meeting of the Tropical Section of the British Medical Association, criticised the accepted theory, pointing out that pellagra did not seem to be a food disease or due in any way to unsound maize, but that in all probability it was due to a parasite—a protozoan. Dr. Sambon supported his theory by arguments based upon the well-established principles applicable to protozoal infections, and put in a form which appealed to men of science. His theory gained adherents until it gradually came to be considered a duty to humanity and to science that the question should be fully inquired into. With this object in view, a Pellagra Investigation Committee was formed in London by Mr. James Cantlie, and Dr. Sambon was sent to Italy on March 20, 1910.

At present the field commission in Italy, consisting of Dr. Sambon and his assistants, is engaged in inquiring into the epidemiology of pellagra. Many pellagrous districts in northern Italy have been visited and the banks of the streams searched for possible carriers of the disease. The field commission has come to the conclusion that pellagra occurs amongst the cultivators and not amongst the consumers of maize; that it is the agricultural labourer, not the town dweller, who suffers from pellagra, and that it is whilst working in the field that the labourer becomes infected. In a telegram dated Rome, May 13, and published in the *Times*, May 14, Dr. Sambon states that it "has been definitely proved that maize is not the cause of pellagra." In addition the telegram assures us that "the parasitic conveyer is the *Simulium reptans*."

The *Simulium* is a species of fly commonly called "sandfly"; its larvæ are met with on the rocks and stones along the streams in pellagrous countries, and Dr. Sambon seems to connect this fly with the spread of pellagra.

So far as we know, Dr. Sambon has not found the parasite, nor is there direct proof that the *Simulium* is the actual carrier. That he has found cause for the statement that eating maize is not the cause of the disease is highly probable, for several men of science, such as Babes (Roumania) and Alessandrini (Rome), have declared in favour of Sambon's theory, and have been working on the lines suggested by him for the elucidation of pellagra. Even with the announcement above quoted, stating what work has been done, there is much yet to do. Questions of the kind are not settled in a day, and it may take years of inquiry before we have finally settled what Dr. Sambon has so well begun.

The fact that it is a duty to humanity and to science that pellagra should be investigated does not provide the necessary money, and the committee in London has endeavoured to keep the inquiry going by appealing to friends to help. So far some 245 have been actually collected, and further sums have been guaranteed; but even should the Government favour the work by contributing the 150*l.* which the committee was led to believe might be the case, the sum is quite inadequate, and unless further donations are speedily to hand the field commission must be recalled from Italy in a fortnight. Sir Lauder Brunton, Bart. is the chairman of the committee; Prof. F. M. Sandars, with vice-chairman; the bankers are the London and South-Western Bank, Great Portland Street branch, and donations may be sent to the treasurer, Dr. Clement Godson, 82 Brook Street, W., or to Mr. James Cantlie, 140 Harley Street, London, W., honorary secretary, Pellagra Investigation Committee.

NOTES.

FOR some time past a scheme for the distribution of time signals by wireless telegraphy has been mooted with the view of assisting navigation and for the determination of longitude. The Eiffel Tower in Paris and the summit of Teneriffe have been proposed as suitable sites for the emission of these signals, and we now learn that the plan for which M. Bouquet de la Grye and Commandant Guyot are more especially responsible is so far complete that the first signals were dispatched from the former station at midnight on May 23. The Paris correspondent of the *Morning Post* states that Paris time was transmitted from the observatory by way of the Eiffel Tower by wireless telegraphy to all wireless stations and ships fitted with wireless apparatus within a radius of between 2500 and 3000 miles. The system is an automatic one, and a Morse sign is sent into space first at midnight, again two minutes after midnight, and, finally, four minutes after midnight. Thus, steamers furnished with wireless telegraph apparatus will no doubt be placed in a more favourable position, but the suggestion that has been made in some quarters, that chronometers can be dispensed with, seems premature. The receipt of a signal will not enable a ship to determine its position or even its longitude. All it will do is to give the error of the chronometer. The ship's officers will not be able to forgo the use of Sumner lines and other devices, and for these the knowledge of local time and the use of a ship's chronometers will be convenient. It may be desirable to point out here what is the kind of error in longitude to which in these days of accurate navigation a ship is liable, or what is

amount of error which the employment of télégraphic signals can correct. Of course, the error accumulates with the time at sea, but a ship that carries three chronometers, the usual number in a well-found ship, should not after 100 days be in doubt about the longitude by a greater quantity than twenty seconds; usually it is much less. At the equator this would amount to an uncertainty of about five miles, in the longitude of Paris correspondingly less; but the number of time signals scattered over the world is now so large that every steamer has the opportunity of correcting its chronometers much more frequently than is suggested here. While, therefore, we welcome every advance which increases accuracy and demonstrates the value of scientific application, we cannot consider that the practical benefits of the scheme will be immediately apparent.

MR. J. B. TYRRELL has been elected president of the Canadian Institute, the oldest scientific society in Canada.

WE regret to see the announcement of the death, on May 23, at eighty years of age, of Mr. J. B. N. Hennessey, F.R.S., late deputy surveyor-general in charge of the Trigonometrical Surveys, Survey of India.

IN consequence of the death of King Edward, the council of the Institution of Civil Engineers has decided not to hold a *conversazione* this year. The eighteenth "James Forrest" lecture will be delivered at the institution on June 22, at 8 p.m., as already announced.

PROF. R. W. WOOD, of the Johns Hopkins University, Baltimore, will spend the coming autumn, winter, and spring in England and on the Continent. He has accepted invitations to deliver the Thomas Young oration of the Optical Society and the Traill-Taylor lecture before the Royal Photographic Society, and will arrive in London early in October.

ON Tuesday next, May 31, Mr. C. J. Holmes will begin a course of two lectures at the Royal Institution on "Heredity in Tudor and Stuart Portraits"; on Thursday, June 2, Major Ronald Ross will deliver the first of two lectures on "Malaria"; and on Saturday, June 4, Prof. J. A. Fleming will commence a course of two lectures on "Electric Heating and Pyrometry" (the Tyndall lectures).

THE King, on the recommendation of the Home Secretary, has approved of the reconstitution of the Royal Commission on Mines for the purpose of an inquiry into the health and safety of persons employed in metalliferous mines and quarries. The new commission will consist of Sir Henry Cunynghame, K.C.B. (chairman), Mr. R. A. S. Redmayne, Dr. J. S. Haldane, F.R.S., Mr. John S. Ainsworth, M.P., Mr. R. M. Greaves, Mr. R. Arthur Thomas, Mr. R. T. Jones, Mr. W. Lewney, and Mr. U. Lovett.

DURING the Whitsuntide excursion of the Geologists' Association to Swanage, Mr. John Newton obtained a well-preserved upper jaw of the small mammal *Triconodon* from the Lower Purbeck beds. The specimen was found in the fresh-water limestone above the well-known mammal-bed, which was carefully examined at two places in Durlstone Bay without success. It appears to be the first discovery of a mammalian fossil in the Purbeck beds since 1880, when Mr. Edgar Willett obtained the lower jaw of *Triconodon* now in the Museum of Practical Geology. Mr. Newton has placed the new fossil in the British Museum (Natural History), where it will be exhibited with the Beekes collection.

DURING the next few weeks the Somersetshire Archaeological and Natural History Society will commence the excavation of the lake village at Meare, three miles north-west of Glastonbury. Besides interesting mediæval buildings, such as the Fish House and the Manor House, the parish contains the remains of a lake village much larger than that of Glastonbury. Trial excavations have already disclosed many interesting objects, and the thorough examination of the site will certainly prove to be of much importance in elucidating the history and antiquities of the late Celtic period, dating back a century or two before the Christian era. Assistance, which is much needed in support of the excavation fund, will be gladly received by the secretaries, Taunton Castle, Somerset.

THE series of aeronautical calamities which figures so prominently in the issue of the *Deutsche Zeitschrift für Luftschiffahrt* for April 20 is continued in the issue for May 4, where the destruction of the *Zeppelin II.* at Weilburg, and that of the Delitzsch balloon, which was struck by lightning on April 6, are described and figured. In addition, there are figures and references to accidents to Rougier's and Chavaz's machines at the Nice aviation meeting, the former having fallen into the sea and been picked up by a steamer.

M. JACQUES DE LESSEPS, grandson of the engineer of the Suez Canal, crossed the English Channel on May 21 in a Blériot monoplane. Instead of a three-cylinder Anzani motor of 25 horse-power, such as was used by M. Blériot, M. de Lesseps employed a seven-cylinder Gnome rotary engine of 50 horse-power. He started from Les Baraques, near Calais, at 3.40 p.m., and landed close to Wanston Court Farm, near St. Margaret's, at 4.17 p.m. According to the French Press, the crossing took thirty minutes, as compared with M. Blériot's thirty-one minutes' flight. M. de Lesseps reports that he travelled at a height of from 350 to 400 metres to avoid the fog, which obscured his view, and that he was unable to make use of a compass on account of the effect of the great vibration upon the instrument. By his successful flight M. de Lesseps wins the Ruinart prize of 500*l.* and the 100*l.* cup offered by the *Daily Mail* for the second aviator to cross the Channel in the air.

IN an article on the London to Manchester flight (*NATURE*, May 5) reference was made to the desirability, now that the possibility of long-distance flights has been clearly demonstrated, of devising means for encouraging the pursuit of aviation without taxing the physical endurance of aviators or subjecting them to risks more than was necessary. From an article in the *Deutsche Zeitschrift für Luftschiffahrt* we gather that the arrangements made at the Nice aviation week afforded an excellent example of what could be done in this direction. In the first place, the long-distance flights were performed mainly over the sea between Cap Ferrat and Cap d'Antibes, where steamers were available (in the language of the *Zeitschrift*) to "fish out" any aviator who descended, and this actually happened to Latham; in the next place the prizes offered included a cumulative prize for the longest total distance covered, excluding individual flights of less than 5 kilometres, and prizes were also offered for the quickest flight performed on each day, the best start and the best landing, so that the chances of success were less dependent on meteorological conditions than they would have been if competitions at fixed hours had alone been provided for. That progress is being made in aérotechnics was shown by the fact that while at Berlin last year flights were only made when the wind velocity was less than 3 metres per

second, the anemometer at Nice often showed velocities of 7 to 10 metres per second without interfering with the flyers. It is interesting to note that the starting place was close to the mast where the late Captain Ferber made his early experiments. The writer also refers to the liberality of the citizens of Nice and others in contributing to the prize funds.

A spell of really warm weather occurred over the British Islands, and the weather report for the week ending May 21, issued by the Meteorological Office, shows that the mean temperature was everywhere above the normal, the mean for the period ranging from about 3° to 6° in excess of the average in different parts of the kingdom. The warmest district was the south-east of England, where the mean was 58° , and the absolutely highest temperature was 83° , at Hillington, in the east of England, on May 20. The lowest shade temperature anywhere was 37° , but slight frost occurred in the open in several places. The mean temperature of the sea was considerably higher than during the preceding week on many parts of the coast, and was generally higher than in the corresponding week of last year. The rainfall was mostly in excess of the average, and the aggregate measurement since the commencement of the year is largely in excess of the average, the excess being more than 3 inches in several of the northern and western districts. There was a good deal of sea fog and mist along the east and north-east coasts of Great Britain. Thunderstorms were very common in England, and rather so in Scotland and the south of Ireland. On May 20 and 21 they occurred over a wide area in Great Britain, and several persons were killed by lightning.

IN our issue of December 2 last full particulars were given of the eighth International Zoological Congress which is to be held at Graz (Austria) on August 15-20 next, under the presidency of Prof. Ludwig von Graff. We have received a second circular in connection with the congress which gives much practical guidance to foreign visitors. It is pointed out that as the most direct route to Graz is *via* Vienna, many of the scientific institutions of that city have made arrangements to receive foreign visitors during August 12 and 13. Arrangements are being made to secure a reduction of fares on the Austrian railways. The circular also provides full details of the numerous excursions which have been arranged. We may remind zoologists that all inquiries relative to the congress should be sent to the Präsidium des VIII. Internationalen Zoologenkongresses Graz (Österreich) Universitätsplatz 2.

It is with great regret that we have to announce the death of M. Bernard Brunhes, the director of the observatory of the Puy de Dôme. M. Brunhes died at the early age of forty-seven, and had been in charge of the observatory for only the last nine years, but he brought to its administration a high reputation for capacity and industry, qualities which were recognised while a student at the Sorbonne, and had been further developed during his occupancy of important scientific positions both at Dijon and Clermont-Ferrand. Under his directorship the observatory won a prominent position for researches in the several departments of terrestrial magnetism, the physics of the earth's crust, and the exploration of the upper atmosphere. M. Brunhes will be particularly remembered for his researches in meteorology, in which mechanical contrivances could be employed to elucidate physical phenomena. With considerable ingenuity he discussed the mechanical action exerted by a horizontal current of air upon a whirlwind, having sinistrorsal and dextrorsal motion about a vertical axis susceptible of lateral displacement.

Another subject which engaged his attention was the effect of a want of symmetry in the action of running water, as exhibited in the erosion effects upon opposite banks of rivers. His reputation must, however, rest mainly on the work of weather forecasting, to which purpose the activities of the observatory were chiefly directed. He held in scorn those who attempted forecasting without any knowledge of the general movement of the atmosphere, and on the occasion of the proposal of the sensational scheme for competition in weather forecasting, his denunciation of those who to acquire a little brief notoriety, were willing to run the risk of bringing science into disrepute was both merited and timely. As a writer of scientific treatises intended to make science popular, he was exceedingly successful. In crystallography, terrestrial magnetism, and meteorology, his books have been welcomed as models of clearness and accuracy, while his latest work on "*La dégradation de l'Énergie*" has won a well-deserved approval.

THE scientific side of geographical exploration has suffered a severe loss by the death of Lieut. Boyd Alexander, in the Sudan, at thirty-seven years of age. From information received at the Foreign Office it appears that Lieut. Alexander was killed at Nyeri, about seventy miles north-east of Abeshr, the capital of Wadai, on April 2, a few days before the French troops met and defeated the native bands opposed to the French occupation of the country. Lieut. Alexander began his career as a traveller-naturalist in 1897 by an expedition to the Cape Verde Islands, and in the following year he made expeditions to the Zambezi and Kafue Rivers. In 1904 he visited Fernando Po, and made some valuable ornithological observations. His most important work, however, was accomplished during the Alexander-Gosling expedition of 1904-7, which crossed the African continent from west to east. One of the objects of this expedition was to study the distribution of the fauna between the Niger and the Nile from the point of view of zoological relationships between the west coast region and the Nile basin. The expedition mapped a large area, made systematic observations of the natural history and ethnology of the region traversed, and secured collections of great value to science. For this achievement Lieut. Alexander was awarded the gold medal of the Royal Geographical Society. Toward the end of 1908 he left England for further zoological and geographical explorations, and was in the German Kamerun Colony during the great earthquake in that part of Africa about a year ago, and the subsequent eruption of the Kamerun Mountain. He then passed to the Lake Chad region, and at the time of his death appears to have been making his way to the Nile by the north of Wadai and Dafur. It is greatly to be deplored that this adventurous journey has deprived science of an explorer and naturalist of such great distinction and promise.

WE learn from the *Builder* for May 21 that next year, in connection with her International Exhibition, Italy will inaugurate the great national monument to Victor Emmanuel, which has been a quarter of a century in building, and has cost an immense sum of money. By its importance, and, on the whole, by its artistic excellence, it is worthy of the patriot king. The breadth of the monument is 460 feet and its depth 480 feet. Standing on a spur of the Capitoline Hill, it is one of the most prominent objects in the City of Rome. On a lofty pedestal in the midst of a stately lay-out of steps and terraces stands the colossal equestrian statue of "*il régalant'uomo*" by Enrico Chiaradia. It is approached from below by a stair 130 feet wide in four flights of convex plan, and as a background it has a gigantic

colonnade of concave plan backed by a wall parallel to it. At either end of this are square open halls decorated internally with coloured marbles, and supporting quadriga groups. Among the many works of sculpture by Italian artists is a fine series of statues personifying the provinces of Italy—Latium, Lombardy, Venetia, and so forth. The architect was Count Giuseppe Sacconi, who died in 1906 without having seen the completion of the monument.

In the *Cairo Scientific Journal* for February Mr. Harold Sheridan gives an account of that curious musical instrument, the *rabāba*, which was introduced into Europe by the Crusaders, and, with a slight modification of the original name, is now known as the rebeck. It has certainly been evolved from the one-stringed lyre of the early monuments, the single string twanged with the finger developing into the present double-stringed instrument played with a rude bow and provided with a body. Even in its present state it is a most primitive instrument, made up in the rudest way out of a long iron nail, a cocoa-nut, a few strands of horse-hair (that of the living animal being most in request), a piece of fish-skin, and sundry pieces of wood. The last are coarsely glued together, and the body is made of half the cocoa-nut, over which a piece of moist skin—that of the Nilotic fish known as the *bayad*—is tied tightly until it dries. The tone is regulated by incisions made in the body, those being most numerous when the tone is intended to be loud, and this is further regulated by moving the bridge. The *rabāba* is thus of considerable interest as marking an early stage in the evolution of the modern violin.

A MEMOIR issued in the Eugenics Laboratory Series (Dulau and Co.), by Miss Ethel M. Elderton, assisted by Prof. Karl Pearson, discusses the influence of parental alcoholism on the physique and ability of the offspring. The memoir is based on two series of data, the one contained in a report of the Edinburgh Charity Organisation Society, the other in an unpublished report, by Miss M. Dandy, on the special schools of Manchester, and relating only to families in which one child was sufficiently defective to be educated in such a school. Very little trace of any unfavourable influence of the parental alcoholism is found. The mean heights and weights of the children of sober parents are, on an average, slightly greater than those of the children of alcoholic parents, age for age, but the difference is extremely small, and the general health of the children of intemperate parents appears to be rather the better of the two; cases of tuberculosis and of epilepsy are stated to be markedly less frequent than amongst the children of sober parents. No marked relation of either sign is found between parental alcoholism and the intelligence of the child. The data of the Edinburgh report as regards the extent of parental alcoholism are rather remarkable. A school of a "widely representative character" was chosen for investigation, and the fathers of more than half the children in this school, and the mothers of more than one-third, are classed under the headings "drinks" or "bouts," i.e. are judged to be drinking more than is good for them or their homes.

ACCORDING to the report for 1909, the Field Museum at Chicago extended its operations, and at the same time largely increased its collections, by the dispatch of expeditions to Tibet, the South Sea Islands, and the Philippines, and smaller parties to Guatemala, New Guinea, Fiji, &c., while important collections have been acquired by purchase from Egypt and New Guinea. To make room for these, obsolete and unsatisfactory specimens have been removed from the exhibition galleries, while economy of

space has been gained by re-arrangement of the store-collections. Among striking additions to the public galleries, special reference may be made to the Tonopah meteorite from Nevada, weighing nearly two tons, to a pair of African elephants mounted in striking attitudes, and likewise to a fine male gorilla.

AFTER mentioning his regular attendance, when Prince of Wales, at the meetings of the trustees at the Natural History branch of the British Museum, the *Field* of May 14 states that in the early 'nineties, when Sir William Flower commenced to replace the old specimens in the mammal galleries by well-selected examples of modern taxidermy, the late King gave instructions that a series of rats, rabbits, and hares should be trapped on the Sandringham estate and forwarded to the museum, and it is these by which the species are still represented in the British saloon. To the late King the museum is also indebted for the skull and the mounted heads of three Spanish draught oxen, an Indian wild boar, and, in some degree, the makhna (tuskless) male Indian elephant, Jung Pershad. King Edward's last gift to the museum was the skeleton of Persimmon. The only specimen in the bird gallery presented by his late Majesty, when Prince of Wales, is a fine Reeves's pheasant, shot in the Sandringham coverts in 1890. It was, however, at the late King's suggestion that Mr. Andrew Carnegie presented the model of the skeleton of *Diplodocus* to the museum.

IN the May number of the *American Naturalist* Dr. W. J. Holland, director of the Carnegie Museum, Pittsburgh, discusses the views recently expressed—particularly those of Dr. Tornier—with regard to the proper position and pose of the limbs of *Diplodocus* and other sauropod dinosaurs. Early in his criticism the author takes occasion to emphasise the marked distinctness of the Dinosauria from all other reptiles, a circumstance which is of itself in some degree sufficient to render it probable that their limbs may have approximated to the mammalian type in regard to the relative position of their bones. Important evidence in support of this is afforded by the compressed, instead of depressed, form of the thoracic cavity, which appears absolutely incompatible with limbs arranged after the crocodilian fashion. It is also shown that if the femur is placed, as Dr. Tornier suggests, in a horizontal plane, its head cannot be made to enter the acetabular cavity of the ilium, while, on account of projections, no movement would be possible. Further, in this mode of restoration the distal articular surfaces of both humerus and femur would project at right angles to the axes of the bones of the lower segment of the limbs without being opposed to the corresponding articular surfaces of the latter. After a reference to the extraordinary position which would be assumed in certain circumstances by the fore-limbs of *Diplodocus* according to the new restoration, Dr. Holland maintains that the form given to the limbs in the skeleton in the Natural History Museum is in all essential features correct.

EGGS with two yolks occur not uncommonly, but eggs with three yolks are exceptionally rare. Such an egg was recently laid by a barred Plymouth rock pullet at the Maine Experiment Station, and is described in some detail in a Bulletin recently issued. The egg was somewhat above the average size, but no other abnormal feature was noticed.

IN past years, when sugar cultivation was the only industry of importance in Barbados, it was customary to issue annually a bulletin on sugar-cane experiments, but now that the cotton industry is developing so rapidly, it

has become necessary to issue a report on similar lines to those already sent out from other West Indian colonies. The first of these, which has been sent to us, contains an account of the sugar experiments which are still being continued, of experiments to find more suitable types of cotton than those at present in cultivation, and on important food crops such as sweet potatoes, cassava, eddoes, and tannias.

THE March number of the *Journal of the Board of Agriculture* contains an article by Mr. A. D. Hall summarising the results of trials at Rothamsted on the new nitrogenous fertilisers, cyanamide and calcium nitrate ("nitrate of lime"). Both proved equally as effective as sulphate of ammonia and nitrate of soda in increasing the yield of grain, but the nitrates were perhaps the better for straw production. Sulphate of ammonia and cyanamide gave somewhat less offal corn than the nitrates—10 per cent. of the total, against 13 per cent.—but the differences throughout are so small that they may be disregarded. The choice between the manures will therefore be dictated by their relative price and by the character of the soil.

THE results of the experiments carried out by the scientific staff of the Royal Agricultural College, Cirencester, have hitherto appeared in the *Agricultural Students' Gazette*, but it has now been decided to publish them in a separate journal, the first issue of which has reached us. Summaries are given by Prof. Kinch of the experiments on grass land carried on continuously since 1888, the general result being that nitrogenous and phosphatic manures are particularly necessary, and the addition of potassium salts desirable, over a long series like the present. The cereal experiments (barley from 1885-91, oats from 1894-5) are also described, together with others that have gone on for a shorter period. A meteorological summary would add to the interest of these papers. Whilst there are many advantages in separate college bulletins for the publication of demonstration results, we hope that all papers of general interest bringing out new facts will appear in the recognised journals, where there is no risk of them being overlooked.

IN the Bulletin of the Cracow Academy, 1909 (June and November), Dr. Maryan Smoluchowski discusses the instability or "buckling" of elastic plates and its applications to problems of mountain formation.

IN the Journal of the Royal Statistical Society, lxxiii., 1 (1910), Mr. G. Udny Yule gives a solution, based on probability considerations, of the problem of the distribution of deaths with age, based on the supposition of a succession of causes of death which act cumulatively, and he considers applications to deaths in man caused by disease and to the extinction of bacteria by successive applications of disinfectants.

IN the *Popular Science Monthly* for March and May Prof. John B. Smith gives an address on "Insects and Entomologists: their Relations to the Community at Large." While the first article deals with insects in their economical aspect, the second consists of a collection of biographical notices, with portraits of the principal entomologists of America.

DR. JEAN MASCART, of the Paris Observatory, has issued a list of errata which he has discovered in Borda's classical tables of logarithms. It is interesting to note that the tables were completed by Borda by the year 1792, but were not all in print at the time of the author's death. The publication was concluded by Delambre, who carefully checked them with the help of Briggæ, Vlacq, Véga, Hobert,

and Ideler, and the present list evidently represents purely typographical errors which escaped notice, and which would probably in most cases be obvious to anyone who happened to take these particular logarithms from the tables.

THE assessment of income-tax is a question which does not, as a rule, fall within the purview of a scientific journal. We have, however, received a reprint from the *Daily Telegraph* of an article on this subject by Mr. William Schooling (London: Constable and Co., 1910), in which the author proposes a substitute for the present illogical and unscientific system of graduation. According to his system, the tax which a man pays would increase continuously with his income, as shown by a continuous graph. Under the existing system the tax increases discontinuously at certain points where the rate becomes infinity in the pound, and the amount of the tax depends, not only on a man's income, but on whether this income falls on a lucky number such as 4999 or on an unlucky number such as 5001, the man in the latter case paying more and receiving less than in the former. Mr. Schooling's system is much more rational and scientific, and has all the advantages which he claims for it.

THE illustrated catalogue of microscopes and accessories recently issued by Messrs. Flatters and Garnett, 32 Dover Street, Manchester, provides a very full list of apparatus by leading English and foreign makers for which they act as agents, and numerous sundries, some of which are the special designs of the firm. Among these are the hand microtomes provided with discs for regulating the thickness of sections and arrangements for keeping the paraffin blocks steady. The firm also specialises in turn-tables, water-baths and ovens, and slide cabinets.

WE have received separate copies of several contributions from the Jefferson Physical Laboratory of Harvard University which appeared in the March number of the *Proceedings of the American Academy of Arts and Sciences*. Amongst them is one on certain thermal properties of steam by Mr. H. N. Davis, in which the author, after a critical examination of the experimental work on the subject done during the last twenty years, comes to the conclusion that the total heat of saturated steam up to 190° C. is best represented by the expression

$$H = H_{100} + 0.3745(t - 100) - 0.00099(t - 100)^2,$$

where H_{100} has the most probable value 639.11. Outside this range of temperature the latent heat L is best given by an equation of the form suggested by Thiesen, i.e. $L = 92.93(365 - t)^{0.315}$, in which 365° is the critical temperature of steam. The question of the true value of the specific heat of steam at constant pressure cannot be settled on the contradictory experimental data at present available.

MESSRS. A. GALLENKAMP AND CO. (19 and 21 Sun Street, E.C.) have just issued a circular containing a description of a technical series of physical apparatus. The majority of the items described are connected with the subject of heat, and relate to the determination of coefficients of expansions of solids, liquids, and gases, vapour pressures, and specific heats. A simple apparatus for the rapid determination of specific heats consists of a Dewar flask which contains a hot liquid; into this the cold body under test is dropped, and the fall of temperature is noted; the procedure is therefore the converse of that usually adopted in the method of mixtures. The use of the Dewar flask enables this to be done without sensible error. A lecture apparatus to illustrate Carre's ice machine is designed to

overcome the difficulty experienced by lecturers in causing water to freeze by its own evaporation. A glass tube 50 cm. long and 5 cm. diameter is closed at both ends and filled with coarse glass-wool to give more surface. A lateral tube near one end connects with a round-bottomed flask (or, better still, with a Dewar flask); another lateral tube near the other end connects with an exhaust pump. The flask is first half-filled with water, and the glass wool is saturated with fresh strong sulphuric acid. The formation of ice is very rapid. Grace's apparatus for determining the mechanical equivalent of heat also deserves mention as being a cheap pattern of the modern rotating cylinder form of apparatus for this purpose.

THE May number of *Knowledge* appears under new auspices. The editors are now Mr. Wilfred Mark Webb and Mr. E. S. Grew; and Hardwicke's *Science Gossip* is incorporated with the journal, as well as *Illustrated Scientific News*. In an introductory note Principal Miers gives encouragement to scientific amateurs to pursue their observational work in spite of the gulf that may exist between them and the trained specialist. In astronomy and natural history particularly, the work of amateurs is often of great value to science, and any efforts made to stimulate it must be appreciated by professional men of science. The new number of our contemporary should be of assistance in this direction. There are several fine illustrations in the form of plates and other figures, and the articles are by contributors who write with authority and not as the scribes. Among the astronomical articles we notice one on Halley by Mr. T. A. Bellamy, a characteristic contribution by Mr. J. E. Gore on counting the stars, and a description of Prof. Lowell's observations of Martian canals. Dr. D. H. Scott, F.R.S., writes upon the earliest flowering plants—a subject which he has made his own—Prof. F. Cavers upon liverworts, and Prof. A. W. Porter upon electromagnetic mass. There are also the usual notes upon recent advances in the various departments of science, and reviews of books. We offer our congratulations to the editors upon the attractive character of their first number, and trust that their efforts to promote and extend intelligent interest in science will meet with success.

BOTANISTS alone; so far as we are aware, have a journal dealing purely with the jests and humours of their subject. The first number of the *Sportophyte*, edited by Dr. Marie Stopes, emanates from Manchester University, and is to appear yearly. It contains anecdotes, verse, and articles parodying serious journals, of which the highly technical and friendly humour will appeal to professional botanists.

THE first part of a catalogue of books on natural history, to be obtained from Mr. Francis Edwards, 75 High Street, Marylebone, W., has been received. It is concerned with miscellaneous and general books and those dealing with ornithology and oology. The second part of the catalogue will deal with works on botany, gardening, ichthyology, and other subjects.

OUR ASTRONOMICAL COLUMN.

TOTAL SOLAR ECLIPSE OF MAY 9.—According to the *Daily Mail* of May 19, Mr. Driffield, a surveyor, reported to Mr. Baracchi, director of the Melbourne Observatory, that he observed the solar eclipse of May 9 at Queenstown, Tasmania, in clear weather. According to him, the corona appeared regular in form, concentric with and evenly distributed around the moon's disc, except in the

south-eastern quadrant, where two streamers were seen running straight for some distance, and then curving downward like a plume. The extent of the corona was more than half a degree from the limb. Its structure was striated, the colours merging gradually from deep orange to pale green. The streamers were two moon's diameters in length. Mr. Baracchi is recorded to have said that this is the best observation which was obtained.

SOLAR ACTIVITY.—After a period of quiescence the sun has, during the past week, exhibited a recrudescence of spot activity. Several moderately sized groups have been observed containing well-defined extensive umbræ.

COMET 1910a.—According to an ephemeris published by Prof. Kobold in No. 4410 of the *Astronomische Nachrichten*, comet 1910a is still almost stationary to the west of the Great Square, and its estimated magnitude is about 12.0. For May 27 its position is given as

$$\alpha (1910.0) = 22^{\text{h}}. 31.5^{\text{m}}., \delta = +29^{\circ} 29.8'.$$

THE PROBLEM OF THE RESISTING MEDIUM.—In No. 4408 of the *Astronomische Nachrichten* Mr. Selig Brödetsky, of Cambridge University, discusses Prof. See's assumptions concerning the possible part played by a resisting medium in the capture of satellites. In conclusion, he shows that the arguments employed by Prof. See will not stand close analysis, and are such as to render the possibility of capture, with an assumed resisting medium, very uncertain. That such a satellite as the moon was captured in the manner suggested appears to be extremely improbable; while some of the larger planets have apparently been able to capture a number of comets, rendering them periodic, there is no known case in which the earth has been able to perform a similar operation.

THE CALCIUM BANDS AT λ 6382 AND λ 6389.—In the spectra of sun-spots the calcium bands with heads at $\lambda\lambda$ 6382 and 6389 are an important feature, to which attention was directed by Prof. Fowler, but their precise origin is not quite settled. Investigations on this point have been carried out by Prof. Barnes at Bryn Mawr College, who describes his latest results in No. 2, vol. xxxi., of the *Astrophysical Journal*.

In dry air at atmospheric pressure, and with pure metallic poles, these bands do not appear in the arc spectrum, but with the pressure reduced to 3 cm. of mercury, or less, they come out strongly. In atmospheres of dry hydrogen and pure dry nitrogen the bands do appear, but not so strongly as when the arc is run in *vacuo*; with the arc burning in SO_2 they do not appear.

It has been suggested that these bands are due to a compound of calcium and hydrogen, but, from his experiments, Prof. Barnes concludes that they may be considered as true metallic radiations, a conclusion which is important in discussing the probable origin of the sun-spot spectrum.

STARS WITH VARIABLE RADIAL VELOCITIES.—In No. 2, vol. xxxi., of the *Astrophysical Journal*, Mr. O. J. Lee publishes the results of recent observations of radial velocities with the Bruce spectrograph at the Lick Observatory. For α Cygni a range of 9 km., from -9.0 to $+0.1$ km., was found, but the observations do not suggest a period. Two members of the Taurus stream of stars discovered by Prof. Boss, Nos. 1007 and 1092 in his catalogue, have also been shown to vary their radial velocities. The first is 58 Tauri, the range of its velocity being from $+41$ to $+15$ km., and the second is B.D. 7° 681 Tauri, which exhibits a range of from $+34$ km. to $+17$ km. θ Pegasi is also shown to be a spectroscopic binary with a range of from -32 to $+19$ km., and on one plate shows a very faint component at $+62$ km.

OCCULTATION OF MARS BY THE MOON ON APRIL 13.—Through a break in the clouds Dr. W. Krebs was able to observe the last contact during the occultation of Mars by the moon on April 13, and, in No. 4407 of the *Astronomische Nachrichten*, he gives the time as 10h. 49m. 30s. $\pm$ 15s. (G.M.T.).

OBSERVATIONS OF HALLEY'S COMET.

Observations at the Madrid Observatory and Malta.

IN a communication which has been received from Dr. F. Iñiguez, the director of the Astronomical and Meteorological Observatory of Madrid, a brief account is given of the visual observations of Halley's comet made at that observatory, accompanied, not only with several excellent photographs showing its general appearance, but with a photograph and drawing of the spectrum of the nucleus and tail.

According to Dr. Iñiguez, the nucleus underwent many variations in size, and these changes can be gathered from the following figures which he gives. Thus on April 21 it had a diameter of 10"; on May 5, 7"; on May 7, 8"; and on May 10 it was only 5" in diameter. During May the nucleus was comparable with a star of the first magnitude, that of May 10 being a little brighter.

From photographs taken with a doublet of 5 inches aperture, the first view of the comet only indicated a tail a few minutes of arc in length. On April 25 it extended to one degree. On April 28 it was increased to four degrees. By May 5 it had reached a length of ten degrees;

FIG. 1.—Photograph of Halley's Comet taken at the Madrid Observatory on May 11.

on May 11 its length was thirty degrees, and on May 14 it is described as extending about sixty degrees. The accompanying illustration (Fig. 1) shows the comet as photographed on May 11, the exposure lasting from 2h. 58m. a.m. to 3h. 44m. a.m. official Madrid time.

On May 7 and 8 the comet was photographed with a prismatic camera, using a Grubb lens of 8 inches aperture and a prism of twenty degrees angle. The photographs obtained displayed a spectrum which was continuous, but crossed by three monochromatic bands. On May 9 and 10 visual observations of the comet's spectrum were also made, and these also indicated a continuous spectrum crossed by three bands. The wave-lengths of the bands in the spectrum of the nucleus are given as 561 λ , 510 λ , and 472 λ , while those in the tail are 550 λ , 505 λ , and 461 λ . The forms and positions of the bands are given in the accompanying drawing (Fig. 2), which is a reproduction of that sent by Dr. Iñiguez.

The second communication is from Mr. C. Leach at Malta, dated May 16, who writes:—

"Enclosed is a sketch of what was seen here between 2.45 and 3.15 a.m. of May 13 and 14. The position and

size of comet were easily noted owing to the clear sky. The chief thing noticeable was the great change in position since May 10, on which date I sent you a sketch of same. The position of the head on May 14 was as shown, forming a rough parallelogram with β , α of Andromeda and γ of Pegasus; in fact, the head was below γ to the extent of the distance α , γ . The tail was quite distinct to ζ of Pegasus and γ of Aquarius, and just filled the space between them. A star was seen through the tail at its extremity.

"The width of the comet at the head was about one seventh of side γ , α of Pegasus, and the tail about one third of same at broadest part, roughly speaking, 2° and 5° respectively. By referring to a star-map, I made out the head to be near to ϵ of Pisces, so that the length must have been nearly 45°.

"We must have been in a very favourable position and have had ideal conditions, as I see Greenwich observations on May 10 make out the tail only 45 minutes.

"I am sorry I cannot sketch better, but I have a difficulty in representing just the correct degree of light in the tail, which is much fainter after α of Pegasus.

"The nucleus was equal to α of Andromeda in brightness.

"The reflection of Venus on the sea was splendid.

"I think there can be no mistake about the length of the tail of the comet being great enough to allow the earth to pass through it, in spite of statements to the contrary.

"It was seen by several people here; in fact, the general appearance of the comet is summed up exactly in the comparison used by several, 'Just like a searchlight from the fort.' It was not seen on May 15 and 16 owing to a sirocco haze."

Mr. Leach's drawing is here reproduced (Fig. 3) on a

FIG. 2.—Spectrum of Halley's Comet observed at the Madrid Observatory.

reduced scale, and illustrates very clearly the comet's form and position among the stars.

Passage between the Sun and Earth.

The possibility of the mutual interaction of the comet and earth when the former passed directly between the earth and the sun on May 19 aroused great interest. A telegram from the Kiel Centralstelle gave the time of the comet's passage across the solar disc as ingress 3h. 22.7m. a.m. (G.M.T.), egress 4h. 22.5m. a.m., but, with one exception, all the reports yet to hand state that no trace of the comet was seen during the passage. The exception was at the Munich Observatory, where, according to Reuter's Berlin correspondent, the observers "succeeded in catching a glimpse of the comet as it passed across the sun's disc"; until official confirmation is forthcoming, this statement should, we think, be accepted with reserve. At other German observatories no trace of the comet was seen, and at Munich the sun would not rise until the commencement of the passage; its altitude, therefore, would be very small.

The greatest hope for detailed observations of the comet during its passage was centred on the Kodaikanal Observatory, in southern India, where careful preparations had been made for visual, photographic, and spectroheliographic observations. *Inter alia*, it was proposed to take photographs with the spectroheliograph, with the primary slit set on one of the strongest cyanogen bands, in the hope that the cometary radiations might thereby become differentially intensified in the image, just as the hydrogen or calcium radiations ordinarily are. But, according to a telegram sent by Prof. Michie Smith to the *Daily Mail*,

the results were negative; neither the visual nor the photographic observations revealed any certain trace of the comet during its transit of the sun's disc. The day was cloudy, but the definition was splendid, and the comet's tail had been easily seen in the early morning. It therefore seems certain that the tenuity of the matter forming the head of Halley's comet has not been overstated.

In England the sun did not rise until, according to computation, seven-tenths of the passage was effected, and bad weather effectually prevented any possibility of observation. In a telegram to the *Daily Mail* Prof. Dyson reports that the sky was clear, on May 19, from 1 a.m., but no meteors, aurora, or other unusual phenomena were seen at the Edinburgh Observatory. The reports from the African and Australian observatories are similarly negative.

The Rev. Dr. A. Irving writes, however, from Bishop's Stortford on May 18 as follows:—

"We are here at about 250 O.D. and well away from the London atmosphere. The day has been overcast until

about 4 p.m., but the later hours have been clear. I have looked for anything abnormal, but have not been able to observe anything beyond a slight and diffused haze, which seemed to be perhaps more continuous than usual into the upper strata of the atmosphere. At sunset the western sky was clear of clouds, but the glow was quite an ordinary occurrence, except that it seemed somewhat fainter than usual with such a sky. But I do not recollect having ever seen a sunset in such a sky with such feeble after-effects. It may be said that there was no after-glow at all: merely a dull grey effect, as if the comet's tail had no effect beyond acting as a sort of screen to the sun's rays. It might be interesting to know if similar 'naked-eye' observations were made by others."

The time of the passage of the earth through the extremely tenuous tail was, and apparently still is, uncertain. A week or so before the passage was due there appeared to be some doubt whether the tail was sufficiently long to reach the earth, but this was dispelled by the later observations. Prof. Barnard, on May 18, traced it to a distance of 10^7 from the head, which implies an actual length of more than fifty million miles, more than three times the necessary extent.

But the actual curvature of the tail could not be determined, and in that lay the uncertainty as to a passage taking place; for the same reason the time of the earth's passage was indeterminate, although Dr. Franz calculated that it should occur some time later on May 10. Observations at Johannesburg indicate that the earth passed under the tail on Saturday morning.

The possibility of this occurrence appears to have incited a great deal of fear and excitement, despite the explicit statements of well-known astronomers that any catastrophe was improbable in the extreme. The fear of poisoning by cyanogen seems to have been the best defined,

and to have led to some eccentric precautions, such as an oxygen-supplied sealed room, &c. The accounts of prayer-meetings held by negroes in the southern States, and of general absolution being given by Italian priests, vividly recall the Biela scare of 1882, when Holmes's comet was discovered.

Unfortunately, astronomers and sensationalists alike have been disappointed. According to Johannesburg observations on Thursday, the tail was seen still well above the ecliptic, and observations generally failed to indicate any phenomena which might assuredly be connected with an encounter. Careful preparations were made to observe possible magnetic disturbances, aurora, and meteors, all or any of which might be produced by the earth's passage through a charged, meteoric agglomeration. The magnets at Greenwich indicated no abnormal disturbance on May 19, but, according to Reuter, Prof. Birkeland's instruments at Fimarken registered a well-marked magnetic storm on that day, although the days before and after were exceedingly quiet. Prof. Birkeland ascribes this to

FIG. 3.—Halley's Comet as seen at Malta on May 14 by Mr. C. Leach.

electrical effects produced by the passage of the earth through the charged cometary matter, and has secured excellent magnetograms and earth-current curves, as well as valuable electrical and meteorological observations.

The reports received at the Meteorological Office contain no references to unusual meteorological phenomena which may be associated with Halley's comet. Thunderstorms occurred on each day of the week in some part of the United Kingdom. A sharp storm in the south-east of England in the early morning of Thursday, May 19, just about the time of the calculated transit of the earth through the comet's tail, attracted much attention. It would, however, be rash to attribute their electrical manifestations to cometary influence, for the general meteorological situation, which was characterised by high pressure over Scandinavia and low pressure over the Bay of Biscay, was of a type which in summer is generally associated with thunderstorms over the British Isles. The results of the kite and balloon ascents carried out on May 19 have not yet come to hand.

The Comet and its Spectrum.

M. Coggia, in No. 19 of the *Comptes rendus* (May 9, p. 1165), gives positions for, and descriptions of, the comet for a number of dates between April 16 and May 6. On April 16, 17, and 18 the comet was seen to have a large nucleus, ovoid in shape, but no tail. Seen with the naked eye on April 21, it was of about the third magnitude and yellowish in colour; telescopically, the enveloping coma showed two jets in position-angle 120° . With the moon nearly full, a 3° tail was seen on April 23, and was bifurcated. On April 26, with the moon at full, a 1° tail was seen, and a telescopic view showed that the nucleus was smaller than formerly, but was extraordinarily brilliant and decidedly stellar. May 5 found the comet as a second-magnitude object with a tail $10''$ in length having a curved, plume-like form at its extremity. Seen in the telescope, the nucleus was round and very bright, and was surrounded by a coma containing two aigrettes. These were broad and were symmetrical with regard to the nucleus, from which they emerged in directions perpendicular to the axis of the tail. On May 6 the nucleus was yet brighter, and the aigrettes had disappeared, but there was a very bright sector turned towards the sun.

A circular from Kiel announces that observations at the Lick Observatory, on May 20, showed the length of the tail to be $140''$, that is to say that, were it all visible, it would traverse more than three-quarters of the visible hemisphere. The observations were made in the morning in the eastern sky, and showed the tail to lag far behind the radius vector, so it was suggested that the earth would not pass through it. On the morning of May 21 the tail was fainter, but was traced to beyond Aquila.

A correspondent, Mr. E. Clegg, at Morenas, near Pernambuco, reports that during the early days of this month the comet was seen very plainly at about 4 o'clock each morning by a number of people.

Despite the smoke and cloud near the horizon, and the full moon, the comet was seen as a conspicuous object by thousands of people in various parts of the country on Sunday evening last. At Gunnersbury it was first picked up at 8.45, although the sky was by no means dark, but, probably owing to the bright moonlight, the tail was only suspected. Mr. W. E. Rolston reports that, to the naked eye, it appeared as a white, nebulous cloud, of appreciable size, having a bright centre. By averted vision 2° or 3° of the tail was glimpsed at intervals.

The results of a number of spectrum observations, made at the Meudon Observatory during the period January-May, are published, by MM. Bernard and Idrac, in No. 19 of the *Comptes rendus*. In January the cyanogen band at λ 388 dominated the spectrum of the head. The photographs obtained on February 9 and March 2, 3, and 4 show, in addition, the blue "carbon" band at λ 474 and others, more feebly, near λ 408 and λ 438; in the later spectra the bands at λ 388 and λ 474 were nearly equal in intensity. A visual observation by M. Giacobini on April 17 showed the nucleus to be stellar in character with a circular nebulosity surrounding it, but to the Meudon observers on April 25 the condensation was planetary in character, with uniform luminosity over a circle some $5''$ in diameter. A nebulosity of $30''$ diameter surrounded it, and showed two short jets on the opposite side to the sun. Photographs taken on April 26 showed that the tail was developing in the form of two jets about 1° in length separated by an angle of some 8° or 12° .

Spectrograms obtained on April 26 showed only the band at λ 474, but others, secured on May 4, showed the continuous spectrum of the nucleus, and, in the head, the bands at λ 474 and λ 388. It is interesting to note that, probably owing to the differential absorption of the earth's atmosphere at a low altitude, the band at λ 388 was much fainter than that at λ 474.

On May 7 the comet was much brighter, its estimated magnitude being 0.5, and a tail 1° long was easily seen with the naked eye. The head of the comet exhibited several modifications, the nucleus now being elongated in the direction perpendicular to the sun-comet line, and having a luminous jet at each extremity of its major axis. Spectra, taken on 2 and Wratten and Wainwright's orthochromatic plates, show the intense continuous spectrum of

the nucleus extending from λ 660 to λ 395. The band at λ 474 is very intense in the spectrum of the head, which also shows condensations at $\lambda\lambda$ 516 and 563; the cyanogen band at λ 388 is much weaker than on the earlier plates.

Messrs. V. M. Slipher and Lampland also give a good preliminary account of the comet and its spectrum in Bulletin 47 of the Lowell Observatory.

Photographs were secured on every morning between April 14 and May 1 inclusive, except April 28, and indicated some remarkable changes in the form of the comet. On April 30 it was seen that the bilateral symmetry of the earlier photographs of the tail had disappeared; the northern edge was now nebulous, whilst the southern was bright, well defined, and showed several sharp bends. On May 1 the tail was gently curved, first to the north, then to the south, for seven degrees from the head, and then became nebulous, with a number of brighter condensations. This outer part indicates the action of some shattering, perturbative agency, and the proximity of Venus is tentatively suggested as a possible cause. The lengths of the tail, shown on the photographs, range from 1° on April 15 to $18\frac{1}{2}^\circ$ on May 1.

The photographic spectra cover the whole range from the red to the ultra-violet, and show many interesting features. One of the most striking is the intensity of the continuous spectrum of the nucleus, the solar origin of which is indicated by the presence of many Fraunhofer lines. More than a dozen emission bands were photographed, the typical cometary bands 3883, 4737, 5165, and 5635 being generally the most prominent. The cyanogen band at λ 3883 is the strongest, and shows progressive intensification. Other notable bands are at λ 4000, prominent in tail; 4214, strong and increasing; 426, prominent in tail; 455, apparently composite, and prominent in tail; 570, faint and narrow; 5893, sodium (emission) lines, varying in intensity; $630\pm$; the continuous band is photographed to a short distance beyond B. The study of the sodium lines from day to day indicated that they fluctuated in intensity.

The objective-prism photographs show that the head and tail are not alike in composition, a point brought out in the study of Morehouse's comet. Two bands, in fact, at $\lambda\lambda$ 4000 and 4260, were first recognised in the tail; 4550 is also prominent in the tail, but inconspicuous in the head. The cyanogen bands at $\lambda\lambda$ 4214 and 3883 are practically absent from the tail.

Other observations of the comet are recorded by M. Esclanlon and M. Borrelly in No. 20 of the *Comptes rendus* (May 17).

While visual observations show the tail as straight and bifurcated, photographs show it to be more of the intricate form exhibited on photographs of Morehouse's comet. According to the *Times*, a splendid photograph was secured by Mr. Evershed, with the 9-inch reflector at the Kodaikanal Observatory, on April 22. This shows the nucleus as surrounded by a parabolic envelope, from which radiate a number of streamers in the form of a fan. Instead of the simple bifurcated extension seen visually, this photograph represents the tail as a number of disturbed, bent streamers, one of the brightest of which actually crosses the others. The photograph certainly suggests energetic disruptive action rather than a steady streaming forth, and demonstrates the danger of comparing modern photographic representations of comets with the earlier drawings.

An excellent series of photographs has also been secured at the Helwan Observatory, and copies forwarded to the Royal Astronomical Society.

The complicated structure of the tail is also shown on photographs taken at the Transvaal Observatory on April 16. Describing them in No. 4411 of the *Astronomische Nachrichten*, Mr. Innes says that they show a tail 3° long, divided into five rays, one set of which cross over the others. In the telescope, on the same date, the nucleus was seen to be double, the secondary nucleus being in position-angle $48^\circ 11'$. No. 4413 of the *Astronomische Nachrichten* also contains numerous reports of observations of the comet.

The following is part of an ephemeris published by Dr. Ebell in No. 4411 of the *Astronomische Nachrichten* :—

Ephemeris for 12h. Berlin M.T.

1910		R.A.		Decl.
		h.	m.	
May 30	...	9 45 ⁰	...	+2 53 ⁰
" 31	...	9 50 ⁹	...	+2 23 ⁵

" 3	...	10 4 ³	...	+1 13 ⁴

The estimated brightness for May 30 is about 0.5 mag., and for June 2, 1.0 mag.

HALLEY AND HIS COMET.¹

WHAT do we know of the nature of a comet's tail?

Near the head we notice that there is a dome-shaped envelope which suggests that something has been spouted from the head and turned back by some repelling force of the sun, much as water spouted from a jet into the air is turned back by the attraction of the earth. The shape of a fountain is, in fact, closely like that of a comet near the head. The same curve, a parabola, characterises both, and accordingly the adopted view of the nature of the tail is on these lines. But Mr. Eddington has recently directed attention to a grave difficulty; he has calculated from comet Morehouse, which appeared eighteen months ago, what must be the magnitude of the sun's repelling force to accord with this view, and he finds it almost inconceivably great. The suggestion was made, accordingly, that possibly a different view might fit the facts better, viz. that the matter was not spouted from the comet's head and turned back by the sun, but came from the sun and was turned back by the comet. Mr. Eddington has done something already to examine this view, and finds several striking facts in its favour. In the first place, the shape of the curve, the parabola, which has been taken as good evidence for the former view, equally fits the latter. Secondly, since the matter is streaming out from the sun, and the comet is moving across it, we must take into account the motion of the matter relative to the moving comet. It should be possible to test the correctness of the view by observing the direction of the comet's tail, which should not lie accurately in the line away from the sun, but should be slightly inclined to it. Measurements of several photographs seem to support this view.

Besides the particles of solid matter which exist in the tail (whether spouted from the comet or from the sun), there are also certain gases. Sir William Huggins found with his spectroscope, as early as 1881, that there were certain carbon compounds in the head of a comet which are doubtless also present to some extent in the tail. Some very interesting spectroscopic observations made on the daylight comet showed that there was sodium vapour, not only in the nucleus, but extending out into the tail on either side. The strong yellow lines in the spectrum have been thought to have possibly some other origin, perhaps helium or a carbon compound. It may appear curious that there should be any doubt, but it must be remembered that when an object is in motion the lines in its spectrum never correspond *exactly* with the lines of a terrestrial substance. They are displaced to one side or another according as the object is moving towards or from us. However, in the present instance measures made at the Lick Observatory seem to identify the lines as sodium lines when due allowance is made for the comet's motion away from the earth. Prof. Fowler has recently made an interesting identification of the spectrum of a comet's tail with that of some substance which at present he has not completely recognised, but which he believes to be a compound of carbon, hydrogen, and oxygen in a state of great tenuity. He can obtain a spectrum in his laboratory when the pressure is reduced to less than 100,000th of atmospheric pressure.

The particular interest of Halley's comet lies, not in the fact that we shall pass through its tail, not in the magnificence of the spectacle which we hope to see (for this will be much less sensational than, for instance, the comet of 1858, or even of 1882), but in the circumstances

which first brought its existence to the knowledge of the world. It was the first comet of which the return was predicted with success. Halley reaped this reward, the great reward of having an enduring monument in the skies, as the well-deserved outcome of his devotion to science. He was one of those men who seem to have an instinct for discerning at any particular moment the most important thing to be done, and the energy to do it, such a man as would have made a great general or a great statesman, or succeeded in many other walks of life, and such a man as is only too rare in the history of science. When an undergraduate at Oxford (Queen's College) he was struck by the fact that our knowledge of the stars was practically limited to those of the northern hemisphere, and he determined personally to rectify this at the earliest possible moment. Accordingly, he did not wait even to take his degree, but started for St. Helena to make a catalogue of southern stars. Bad weather rendered his expedition far less successful than he hoped, but, nevertheless, a beginning was made, and the foundations of our knowledge of the southern hemisphere were laid. He gracefully acknowledged the help and patronage of the King by naming a small constellation "Robur Caroli II.," but the name was afterwards omitted by a German editor. His name for a striking double star, Cor Caroli, has survived. In later years his studies of the positions of the stars convinced him that they were not really fixed in their places, but that some of them must have moved since the observations of Ptolemy. From this beginning, due to Halley, springs our knowledge of the proper motions of the stars and all that has come from it.

Another of Halley's great enterprises was the attempt to determine longitude at sea. It is quite easy for a sailor to determine his latitude (how far, that is, he is north or south of the equator), but his longitude is a different matter, and the uncertainty often led to grave difficulties and often disasters. Here, again, Halley saw that a great effort must be made to remove this disability. He obtained the loan of a ship from the King (not Charles II. by this time, but William of Orange), and was instructed to make a long voyage, especially in the southern hemisphere, to observe the magnetic variation, that is to say, the amount by which the compass points east or west of due north in various localities. In spite of the mutiny of his lieutenant (which caused his return home after first setting out), he completed his voyage. He made a chart of the variations, and thus solved, for the first time, this problem of determining the longitude. His solution was very soon superseded by a better, in the invention of the chronometer by John Harrison; but this does not alter the fact that Halley was the first to give a solution at all. Even his own defects seem to have inspired him to a method of compensating them. He was himself not a very accurate observer, nor skilled in the use of the instruments of a fixed observatory. Possibly his experience with rough and ready methods at sea may have contributed to this end. Be that as it may, he was so far out of personal sympathy with accuracy in observation that he used to say, "Take care of the minutes of arc and the seconds will take care of themselves." It is, therefore, not to be wondered at that his observations as Astronomer Royal were not of any value; and it might have happened that he would look for a successor equally indifferent to accuracy, but he was too great a man to make such a mistake. He set his heart upon being succeeded by Bradley, the most painstaking and accurate observer of the time (possibly of all past time), and Bradley's skill soon made up for any deficiencies of the previous twenty years.

But Halley showed his greatest insight in connection with the discovery of the great law of gravitation. He shared with others the suspicion (for in 1684 it amounted to little more) that a law of attraction, varying as the inverse square of the distance, would explain the movements of the planets round the sun; but while others were content to let the matter rest there, or to claim, falsely, that they had satisfactorily proved the proposition, Halley saw the vital necessity of sifting the matter to the bottom. When other inquiries had failed, he determined to visit Newton, at Cambridge, with the idea of enlisting his help in solving this great problem. To his great delight he found that it was already solved. Newton had already

¹ From the Aldred Lecture delivered before the Royal Society of Arts on May 4 by Prof. H. H. Turner, F.R.S.

proved that an object attracted by the sun in this way would move round it in an ellipse, and, since Kepler had already shown that the planets did move in ellipses, the existence of gravitation was established. Halley saw, further, how important it was to publish this discovery, and paid for the publication from his own pocket when other means failed. It might also be said that in this one particular of recognising the thing to be done and doing it Halley compared favourably with his great friend Newton, for Newton, after proving the proposition, had tossed it aside, shrinking from publication, which had sometimes engaged him in disagreeable controversy. Had it not been for Halley we might have lost this discovery, at any rate for a number of years; but Newton, though he was diffident as to publication, and failed perhaps to realise the importance of his discovery to the world, proved his own remarkable insight in a different manner. He, and he alone, saw that, even after the proof about the ellipse had been formulated, there was yet a grave difficulty in accounting completely for a universal gravitation as the cause, not only of the planetary movements, but of the falling of objects towards the earth. He realised that there was need of a further proposition, which he ultimately succeeded in proving, viz. that a sphere, however large, would attract another sphere, however close to it, as though it were concentrated at the centre. This completed the great law which was given to the world in 1686; but without this great proposition the law of gravitation would have remained a mere rough approximation instead of taking its place at once, and thereafter, as the most accurate law known to science.

Not only were the movements of the planets explained, but it became possible to calculate the orbits of comets, and Halley took the earliest opportunity of calculating as many as he could. This opportunity did not, however, come to him for nearly twenty years, since he was full of other projects. It was in the interval that he made his great voyage for determining the longitude; and it was not until 1704, when he had been elected Savilian professor of geometry at Oxford, that he found the leisure to make the cometary calculations required. The result was a list of twenty-four orbits, representing all the comets which had been sufficiently observed. He had the insight to see that this was a thoroughly important thing to do, though neither he nor anyone else suspected what was to be the most important outcome. Three of the twenty-four orbits were found to be nearly the same, those of the comets of 1531, 1607, and 1682. The figures were so closely the same that he felt sure they must relate to the same comet, though there was one difficulty, in that the interval between the two returns was not the same. This discrepancy, however, he rightly ascribed to the influence of the planets, especially Jupiter and Saturn. He pointed out that these planets disturbed one another, and therefore would disturb a comet too. He put very clearly also the point that the disturbance would be much greater in the case of a comet. We have said that a comet travels away to a great distance from the sun, and comes almost to a resting point; indeed, as Halley remarked, a very slight change in its velocity would send it away altogether from the sun's influence, that is to say, would make all the difference between a finite and an infinite time for its return. Hence a smaller disturbance might easily affect the time of its return seriously. There was no difficulty that he could see in identifying the three comets as the same, and in predicting a subsequent return in 1758. Halley did not live to see the return, but died in 1742, at the age of eighty-five, but he left on record his conviction that the comet would appear again, and his hope that posterity would remember to credit an Englishman with the prediction.

It was first seen on Christmas Day, 1758. It returned again in 1835, and now it is with us once more. The interval between the returns varies a few years, from about seventy-five to nearly eighty, the variation being due, as Halley surmised, to the interference of the planets with the comet's movements. It is one thing to realise, as Halley did, the general nature of this interference, and quite another matter, involving much laborious calculation, to determine it accurately. Halley, with his national pride, would have been delighted at the skill with which this problem has recently been attacked by two of his

countrymen, Mr. Cowell and Mr. Crommelin, of the Royal Observatory at Greenwich. Mr. Cowell, after trying old methods with more or less success, found it advisable to employ a totally new method. It has been the custom, hitherto, in such calculations to consider the path of the comet as an ellipse, according to Newton's great discovery, but an ellipse which is continually changing in detail owing to the disturbances of the planets. Mr. Cowell, however, has found it desirable to abandon the idea of the ellipse altogether, and to follow the comet, step by step, along its orbit, first forecasting a little ahead, then calculating the consequent attractions of the planets, verifying his forecast or modifying it, if required, and so, by making each step secure before proceeding to the next, obtaining, ultimately, the complete and accurate history of the comet between two returns. It will readily be understood that a process of this kind involves much labour. During seventy-four years the comet was followed by calculation alone, for it was hopeless to attempt to observe it. As a result of the calculations, it was predicted that it would be seen in a certain place in the sky in August and September, 1909, and on taking a photograph of this region the comet was found close to the predicted place. The honour of first identifying it in this way falls to Dr. Max Wolf, of Heidelberg, but it is some compensation to Englishmen that, with the help of Dr. Wolf's information, they were able to identify earlier images of the comet on photographs taken at the Royal Observatory, Greenwich, and earlier still at the new Observatory of Helwan, in Egypt. The generosity of Mr. Reynolds, of Birmingham, has furnished this last observatory with a fine reflecting telescope, the mirror of which, 30 inches in diameter, was, like that at Greenwich, made by the late Dr. Common, of Ealing; and with this fine instrument, in the splendid climate of Egypt, the first picture of Halley's comet at its present return was secured.

Messrs. Cowell and Crommelin have not only calculated the recent history of the comet, they have carried it back through the centuries as far as 240 B.C. We have seen that Halley collected all the observations of comets sufficiently good and numerous to enable him to calculate orbits, and these did not include any comet earlier than 1337, nor any appearance of his own particular comet before 1531. But more observations have come to light since then, especially in Chinese annals, and on further search being made, in the first instance by Mr. Hind some half a century ago, it was found that bright comets had appeared in 1456, in 1378, in 1301, and so on, which could with great probability be identified with Halley's. This probability Messrs. Cowell and Crommelin have now converted into a certainty. It was not possible, or even necessary, to carry back the computations into the past with the same accuracy as was adopted for the last return, for the observations available for identification were, in many instances, very rough, specifying, for instance, the position of the comet by the constellation in which it was seen; but they adopted something of the same principle of proceeding step by step, making the appearance at one return secure before working back from it to the preceding, and thus they were able to correct several mistakes in Hind's original list.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Council recommends that a grant of 100l. from the Worts Fund be made to Mr. E. A. Wilson, of Gonville and Caius College, who has been entrusted with the organisation of the scientific department of the British Antarctic Expedition, 1910, towards defraying the expense of the equipment.

The scientific staff of the expedition includes Messrs. D. G. Lillie, of St. John's College; E. W. Nelson, of Christ's College; T. G. Taylor, of Emmanuel College; E. A. Wilson, of Gonville and Caius College; and C. S. Wright, of Gonville and Caius College.

Grants of 50l. to Mr. C. E. Moss, curator of the University Herbarium, towards defraying the expense of botanical investigations which he proposes to make on the Continent of Europe; and of 25l. to Mr. R. H. Rastall, towards defraying the expense of a visit which he proposes

to make to South Africa for the purpose of carrying on geological investigations, are also recommended.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting Messrs. P. H. Cowell and A. C. de la C. Crommelin for the degree of D.Sc. *honoris causa* on May 21:—

"Ducentos fere abhinc annos Edmundus Halley, qui tum apud nos Professor erat Savilianus, a Newtono doctus vi quadam certa planetas suos intra circulos contineri, cum cometam magnum ipse observasset, hunc annorum quinque fere et septuaginta intervallis quasi legitimo tempore semper reditum esse praedixit. Vates erat verus, et nos hoc anno tertium ex illo tempore cometae reditum videmus. Cum quidem omnes astronomi ineunte statim anno eius adventum specularerent, simul atque visus est id egerunt ut cursum quo circa solem volveretur certissime constituerent. Ad hanc rem acceperunt duo viri, Philippus Herbertus Cowell, Andreas Claudius de la Cherois Crommelin, scientia et peritia singulari praediti, qui hunc nodum nova prorsus ratione solverunt. Qua in re distinguere vix possumus quid huic vel illi acceptum referendum sit: illud constat, nisi alter mathematicorum, alter astronomorum peritissimus fuisset, rem non potuisse navari.

"Duo igitur ad vos Philippum Herbertum Cowell, qui, cum plures annos astronomiae rationibus cognoscendis se dedidisset, multas palmas iam adeptus, id tandem consecutus est ut cometae Halleiani iter nova ratione statueret, et omnes calculos laboriose subduceret.

"Duo etiam Andream Claudium de la Cherois Crommelin, qui cum multos annos cometarum naturam investigasset, doctrina maxima instructus ad hoc munus accessit, et re latissime perspecta cometae redeuntis, iter non solum hoc anno definire potuit, sed quoties per duo millia ducentos quinquaginta annos hae caelestis hospes terram revisit."

The Vice-Chancellor (Dr. T. H. Warren), in admitting Messrs. Cowell and Crommelin to the degree, spoke as follows:—

"Salve fratrum par nobile, nec laboribus nec laude divisum, quos dum veluti Geminos illos, vel stellam quamdam duplicem, pari gloria, togis paribus fulgentes intueor, venit mihi in mentem aliquid versu dicere Vergiliano, licet paullum mutato,

'In medio duo signa, Conon et quis fuit alter,
Praedixit flammae reducis qui gentibus orbem?'"

"Ego auctoritate mea et totius Universitatis libenter addito utrumque, te Cononem, te Aratum novum, ad gradum Doctoris in Scientia, honoris causa."

THE honorary degree of Doctor of Laws was conferred upon Commander Peary by the University of Edinburgh on May 24, in recognition of his north polar work.

A REUTER message from Salem, Mass., U.S.A., states that the will of the late Mr. Isaac C. Wyman bequeaths practically his entire estate, valued at 2,000,000l., to Princeton University Graduate School for such use "as the trustees may decide."

A REUTER message from Cape Town states that the late Sir Donald Currie's daughters, Mrs. Mirrielees, Mrs. Molteno, and Mrs. Wisely, have given a sum of 25,000l. to the University of Cape Town for the construction of a hall as a permanent memorial to Sir Donald Currie. The University has gratefully accepted the gift, and has reserved a portion of the fund, producing 150l. per annum, for the foundation of a Currie Scholarship.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, May 17.—M. Armand Gautier in the chair.—The president announced the death of Stanislas Canizzaro, correspondant of the academy, and gave a short account of his work.—Gaston Darboux: The use of new methods of recurrence in the theory of orthogonal systems.—M. Bigourdan presented photographs of the Halley comet by M. Inígne, taken at the Observatory of Madrid.—A. Lacroix: The mineralogical constitution of the French phosphorites. The optical and physical properties are described in detail, and complete

¹ Cf. Verg. Ecl. iii., v. 40.

chemical analyses are given.—Paul Sabatier and A. Mailhe: A general method of direct preparation of the thiols by catalysis, starting with the alcohols. The general method proposed consists in passing a mixture of the vapour of the alcohol with sulphuretted hydrogen over thoria at a temperature between 300° C. and 360° C. The mercaptans from the first five primary alcohols were prepared with excellent yields. The substitution of sulphur for oxygen was also successful with allyl alcohol, benzyl alcohol, and various secondary alcohols, but the yields in these cases were not so good as with the primary alcohols. Thiophenols can also be prepared in the same way.—M. Blaserna was elected a correspondant for the section of physics in the place of Lord Rayleigh, elected a foreign associate.—E. Esclançon: Observations of Halley's comet. These results were obtained at the Observatory of Bordeaux, and diagrams are given showing the appearance of the comet on various dates.—J. Comas Solà: The flattening of Io, first satellite of Jupiter. Observations with the 38-cm. equatorial at the Fabra Observatory, continued since 1905, have confirmed the view that Io is flattened, in proportion, greater than any other body known in the solar system. The maximum flattening has been determined at one-fourth.—M. Borrelly: Observations of Halley's comet made at the Observatory of Marseilles with the comet finder. Data are given for observations for fifteen nights between April 21 and May 10, together with the positions of the comparison stars.—E. Tzitzéica: A new class of surfaces.—E. Ouyvet: The differential equation of the motion of a heavy spherical projectile in air.—Maurice Fréchet: Continued functionals.—M. Herrgott: The electric thermophile. An account of a woven material containing fine nickel wire, which is supple and can be heated electrically.—A. de Gramont and M. Drecq: Certain conditions of appearance of the band spectrum attributed to cyanogen. The band spectrum usually considered to be characteristic of cyanogen appears to be due to the simultaneous presence of carbon (in sodium carbonate) and nitrogen. The bearing of this on comet spectra is mentioned.—M. Houllé-vigue: The dimensions of the material elements projected by the kathodes in vacuum tubes. The metal projected (silver) is deposited on a glass plate, and the minimum thickness determined at which the layer conducts electricity. The conductivity appears suddenly, and is only established starting from a certain thickness of the metallic layer. The diameter of the particles calculated from the results of these experiments is of the order of 22 to 26 μ .—A. Besson and L. Fournier: The action of the silent discharge upon acetaldehyde in the presence of hydrogen. The product of the reaction was a very complicated mixture containing acetic acid and its homologues and several ketones.—F. Bodroux and F. Taboury: Synthesis of aromatic nitriles. Benzyl cyanide is treated with sodium amide and alkyl iodide or bromide. One or both of the hydrogen atoms of the methylene group can thus be replaced by alkyl groups, and several applications of this general reaction are cited.—Georges Darzens: The action of the hydracids upon the glycidic esters.—A. Arnaud and S. Posternak: Two new isomers of stearolic acid.—Marcel Godchot and Jules Frezouls: Hexahydrophenylglycolic acid.—C. Beys: The estimation of tartaric acid in crude natural materials.—J. Bertheaume: A new method of estimating the three methylamines in admixture with ammonia. The hydrochlorides are dried and extracted with pure chloroform, in which the hydrochlorides of dimethylamine and trimethylamine are soluble. These are further separated by means of their periodides, and the ammonia and methylamine separated by François's method with yellow oxide of mercury.—G. Boyer: Studies on the biology of the truffle (*Tuber melanosporum*).—Paul Dop: The Strychnos of eastern Asia.—J. Strohl: The relative weight of the heart and the effect of high altitudes.—Maurice Nicloux: The decomposition of chloroform in the organism. A method is described permitting the estimation of small quantities of chloroform mixed with large quantities of air. The author applies this to determine the amount of chloroform destroyed in the blood, and concludes that about one-half the total amount of chloroform fixed at the moment of anaesthesia is decomposed in the organism.—

H. **Coutière**: Cray-fish of the genus *Saron* with male dimorphs.—L. **Nègre** and J. **Bridé**: The nature of the parasite of epizootic lymphangitis.—G. **Seliber**: The determination of the volatile acids in the products of fermentation of some micro-organisms according to the method of Duclaux.—L. **De Launay**: The mean atomic weight of the silicated earth's crust.—Jean **Bousseac**: The distribution of the levels and *facies* in the so-called autochthone (Mummulitic) of eastern Switzerland.—Maurice **Filliozat**: The chalk of Blois.—Louis **Gentil**: The ancient orogenic movements in the Haut-Atlas of Morocco.

THURSDAY, JUNE 2, 1910.

THE MAMMALS OF SOMALILAND.

The Mammals of Somaliland. By R. E. Drake-Brockman. Pp. xvii+201. (London: Hurst and Blackett, Ltd., 1910.) Price 12s. 6d. net.

SOMALILAND, it is hardly necessary to point out, for its mammalian fauna, its flora, and to a certain extent its birds, almost constitutes a separate sub-region of the African domain, together with the adjoining districts of Galaland, Abyssinia, and the northern parts of British East Africa. The fullest description of its interesting mammalian fauna was written some years ago by Captain (now Colonel) H. G. C. Swayne, R.E., the discoverer of Swayne's hartebeest, one of the peculiar Somali forms. Since then, alas! through the unending attacks on the Somali fauna by British sportsmen and sportswomen and some of their foreign friends, not a few of the beasts common in the northern or British part of Somaliland in Colonel Swayne's day (beginning in 1885) have now disappeared from that territory or have become extremely scarce, and are not found in the list supplied by Dr. Drake-Brockman. It is curious, nevertheless (since the title of the book under review is "Somaliland"), that its author makes no allusion to some of the most peculiar and characteristic of "Somali" mammals—at least in theory—such as the Somaliland giraffe, an independent species (*G. reticulata*); a subspecies of "Cape" buffalo (probably *Bos caffer aequinoctialis*), which is certainly met with in the western, northern and southern parts of geographical Somaliland; besides other types referred to later in this review.

It may be that the author has preferred to restrict himself to such mammals as have been seen or obtained by himself. Yet he has been on the Juba River and in southern Somaliland, and fails to include in his list another most characteristic mammal of restricted distribution. Hunter's topi (*Damaliscus hunteri*), which from several points of view is like the vanished connecting-link which must have existed between the Bubaline group of antelopes and that of the Gazelline pallas (*Epyceros*), just as Swayne's hartebeest suggests a resemblance to the intermediate types between the hartebeests and the gnus. Also, it is probable that among the mammals of Somaliland should be included the Gelada baboon (*Theropithecus*). The present writer has himself seen live specimens of *Theropithecus* (probably *T. obscurus*) in French Somaliland, pets of the engineers working on the Harrar railway, which were said to have been captured close by and brought in for sale by the Somalis. Also in this book no allusion is made to the almost certain existence of a *Limnotragus* tragelaph in the Webbe and other big rivers of Somaliland (*vide* Colonel Swayne's book, "Seventeen Trips through Somaliland").

But though there may be these omissions from a full and complete record of the mammalian fauna of the Somali country, Dr. Drake-Brockman gives excellent descriptions of nine-tenths of the known

beasts of this still mysterious and insufficiently explored region (one of those portions of Africa with great discoveries in store for us concerning the past and present faunas of Africa). Also, he emphasises two points worthy of the attention of the League for the Preservation of the Fauna of the Empire (a league which fights despairingly against official apathy and the utter indifference of the overwhelmingly large majority of the British public, a public caring nothing about the fate of the dodo, of the Somaliland giraffe, of the English marten, or the Honduras ocellated turkey); and these two points are: (1) that the Somalis (for example), Midgans, and most other native tribes do not seriously ravage the big or small game of their country; and (2) that in spite of the meticulous game regulations (this qualification is the present writer's) there is a steady destruction of Grevy's zebras, oryxes, and numerous antelopes going on at the hands of European shooting-parties throughout Somaliland. We deduce from what this author says that the wild animals of British Somaliland of any notability must in some portions of the country be extinct. Probably officialdom does what it can. It is the nation from highest to humblest which wants converting to a right interest in biology.

Dr. Drake-Brockman has much of interest to say about the cheetah. He remarks on the much greater growth of mane in the cubs, their grey-white ground colour, and different black markings from those in the adult (a tendency to horizontal stripes instead of spots). He also adds to our knowledge of the life-history of the aard-wolf (*Proteles*), which he describes as secreting a foul-smelling liquid in glands near the base of the tail, and expressing this fluid secretion when attacked by dogs. According to his observations of the long-eared *Otocyon* "fox" (which, he says, is an easy animal to tame, and makes a delightful pet), this Eocene canine goes about in small packs rather than in pairs or singly. It seems to live a good deal on insect food. The Somali wild hunting dog (*Lycan*) is smaller than the Lycans of central and southern Africa, and has much shorter fur, is, indeed, inclined towards hairlessness—an interesting trait in view of a similar tendency in some varieties of *Canis familiaris*.

Of the Baira antelope (Beira is the accepted name, but is a misspelling of the Somali pronunciation) it is said that the females are slightly larger than the males. The author's excellent photograph of this peculiar Somali antelope emphasises its kinship with the klipspringer (*Oreotragus*).

As to the Somali waterbuck, is it really (as stated by Dr. Drake-Brockman) *Cobus defassa*, like that of equatorial East Africa, or an independent Somali species or subspecies? Colonel Swayne classed it as the *ellipsiprymnus* of South Africa, because of its grey-brown colour and the elliptical white mark on the rump. This is somewhat the description given by the present author; but *defassa* is, on the contrary, without a white mark on the rump, and is remarkable for its brilliant bay colour.

The Beisa oryx, the various gazelles of Somaliland—and if this is not *par excellence* "Gazelleland," what is?—the greater and lesser kudus, are all effectively

illustrated and described by Dr. Drake-Brockman. He tells us some new things about the long-necked, long-tailed dibatag (*Ammodorcas*) and gerenuk (*Lithocranius*), and about the oryx. In this last type (of which the book gives an excellent photograph) the reader is recalled to one of the problems of faunistic geography as yet unsolved, *i.e.* why is there such a strong affinity in mammalian and bird fauna, and to a lesser extent in flora, between south-west and north-east Africa, between Somaliland (in its largest geographical extent) and Trans-Zambezia? The Beisa oryx of north-east Africa and the Cape gemsbok are more nearly allied than either is to the fringe-eared oryx (*O. callotis*) of East Africa. In both north-east and south-west Africa we have ostriches, aard-wolves, otocorys, gazelles, foxes, black-backed jackals, secretary birds, striped hyenas, caracal lynxes, and cheetahs. North of the Zambezi and the Zambezi-Kunene line they do not exist, nor south of the Tana River and the Anglo-German frontier in Masailand.

There is even a slight correspondence (in these geographical extremes of Africa) in the affinities of the lowest human types. Linguistically, the only allies of the south-west African Hottentots are in equatorial German East Africa, and physically the only resemblances to the Bushman are to be met with in some of the Andorobo, Suk, and Doko helot tribes of north-east Africa, north and east of Unyamwezi and the Kilimanjaro district. Why should the connecting links of so many mammal and bird types have died out in between? The intervening regions were almost certainly covered down to quite recent times by dense forest, a forest only abated by the Neolithic negro. How did the "desert" types referred to of Somaliland and south-west Africa work their way through this forest-land across many degrees of latitude, and yet retain their peculiar adaptability (in colour as well as peculiarities of hoof and habit) for arid countries? A similar problem remains unsolved in regard to South America, in the south-western parts and southernmost extremity of which continent there are mammals related to North American types (such as Andean bear, the Antarctic wolf, and the Auchenia camelids) the nearest affinities of which are with North American forms, yet which to reach their present habitat must have traversed a greater or less breadth of densely forested, steamingly hot equatorial America.

H. H. JOHNSTON.

SOME BRITISH FRESH-WATER PROTOZOA.

British Fresh-water Rhizopoda and Heliozoa. Vol. II.

Rhizopoda. Part II. By the late James Cash, assisted by John Hopkinson. Pp. xviii + 166 + 32 plates. (London: Ray Society, 1909.) Price 12s. 6d. net.

THE appearance of the second volume of this useful monograph of the British Rhizopoda was heralded some few months ago by the sad announcement of the death of the author, Mr. James Cash. The descriptions of the species and the beautiful plates which illustrate them were from the hand of the devoted and enthusiastic Manchester microscopist, and it will always be a matter for sincere regret that his life was not spared to see the completion of his work.

NO. 2118. VOL. 83]

To Mr. John Hopkinson we are indebted for the notes on synonymy, for the bibliography, and for the responsibility of seeing the volume through the press after the death of Mr. Cash.

The genera dealt with in the present volume are those included in the divisions of the Conchulina called by the authors the Diffflugina and Nebelina. This leaves the treatment of the testaceous forms with filamentous pseudopodia and the Heliozoa to a third volume.

As pointed out in our review of the first volume (May 17, 1906), this monograph is one that is essentially systematic in its treatment. It includes the description of a number of forms which are considered by those who have made a special study of them to be specifically distinct or to be racial varieties of distinct species, but it does not attempt to deal with the more difficult problems of life-history, and the influence of the environment. To the working microscopist who is anxious to find names for the varieties he discovers in the fresh-waters that he visits it will doubtless be of some value, for it gives him, in a convenient form and with excellent illustrations, a statement of the names that have been given to the varieties of Diffflugia, Lesquereusia, Quadrula, and other well-known genera. But a purely systematic work of this kind cannot fail to raise in the mind of an inquirer many interesting questions that it altogether fails to satisfy. For example, of the genus Diffflugia alone no fewer than twenty-three species are described, varying in length from 15μ to 250μ . Is there really any satisfactory evidence to prove that the smaller forms, such as *D. penardi* and *D. globulosa*, are not the younger stages in the growth of the larger forms? In the closely allied genus Centropyxis, Schaudinn has proved that the zygote formed by the fusion of a megagamete and a microgamete forms a small shell, but no one has, at present, described in detail the characters of the shells of the different stages of growth from the zygote until the full size of the adult is attained. Until this has been carefully done by the culture method, with two or three examples, the real value of the specific characters used in systematic treatises must be accepted with very great hesitation. In the meantime, it might be of some assistance to zoologists if a naturalist endowed with the skill and patience of the late Mr. Cash would give us a census of the Diffflugia varieties or forms that are found in a particular pond or Sphagnum bog once for every month during a year or two. Such a census might, at any rate, suggest certain coincidences of occurrence which would be worthy of further investigation.

A few figures are given of two individuals "in conjugation" (*e.g.* *Diffflugia oblonga*, p. 13, *Cryptodiffflugia oviformis*, p. 79, *Nebela collaris*, p. 96), but the recent researches of protozoologists render it extremely improbable that a true process of conjugation occurs at all under such conditions as the figures indicate. It may be plastogamy or it may be a late stage of fission that has been observed, the absence of any indication of the nuclear structures in the figures rendering it impossible to form an opinion on this point, but there is really no reason to suppose that it is conjugation.

The volume is, as usual with the Ray Society's publications, well printed, copiously illustrated, and, thanks to the labours of Mr. Hopkinson, provided with very complete lists of reference to literature, and an index.

TECHNICAL CHEMISTRY OF SUGAR AND STARCH.

Traité complet d'Analyse chimique, appliquée aux Essais industriels. By Prof. J. Post and Prof. B. Neumann. Deuxième Édition Française entièrement refondue. Tome seconde, deuxième fascicule. (Paris: A Hermann et Fils, 1910.) Price 8 francs.

THIS edition of Post and Neumann's work is translated by MM. Pellet and Chenu from the third German edition. The particular fascicule now under notice deals with the chemical control of the manufacture of sugars and starches.

Beetroot sugar naturally claims the lion's share of attention in a Continental book dealing with sugar, and, by following the text in the case of this product, a good idea of the work as a whole will be obtained.

An outline of the process by which the sugar is extracted gives the reader in a page or two a general introduction to his subject. This leads to an exhaustive account of the various methods which are available for determining the quantity of sugar present in any solution of saccharine substances. Naturally, they are well-known processes—areometric, gravimetric, polarimetric, and volumetric; but they are well explained, both as regards theory and practice, and illustrated with figures of the requisite apparatus.

Coming next to the more specialised part of the work, we find, to begin with, detailed instructions for the testing of beetroot seed, and also specifications (German, Austrian, and French) of the conditions which the seeds are required to fulfil. Next follows a scheme for the analysis of the roots themselves, including full directions for those most important preliminary operations the sampling and pulping of the materials.

Having the pulp, what, precisely, is the best method of extracting the sugar from it? Much depends on this, and a full discussion of the *pros* and *cons.* of the various processes is entered into; namely, as to whether water or alcohol is the best solvent, whether it should be used hot or cold, and whether this or that *modus operandi* is to be given the palm for merit. Eventually the conclusion is arrived at, and supported by Dr. Herzfeld "*après de longues études*," that extraction with cold water is in every way preferable to the use of alcohol for the purpose. It is simpler, easier, quicker, more economical, and more exact.

The samples of roots being analysed *secundum artem*, and the proportion of sugar duly determined, we pass to the *jus de diffusion* obtained in the actual manufacture. This is a weak aqueous solution of sugar and other soluble matter extracted from the roots by diffusion in water, and full directions are given for its examination. Next the syrups and massecuites are dealt with, modified processes of analysis being used, to suit their more highly saccharine nature; and eventually the finished products—

the dry sugars and molasses—come under review. This, however, is not all; there is the question of by-products to be considered, including the best methods of utilising the residues from the pulp and molasses; and also there is the examination of the various materials, namely, water, chalk, carbonic acid, sulphuric acid, strontianite, and so on, that are used in the various stages of the manufacture.

These matters are all dealt with at length. Many figures of the necessary apparatus are given, and also several tables of numerical values which will much facilitate the analyst's work.

The remaining sections of the book, treating of cane-sugar, starch, dextrine, and glucose, are written in a similar practically useful manner. If in these industries, or in the future British beet-sugar production to which some hopeful eyes are turning, any chemist requires a laboratory handbook, he might do worse than study the one under notice. C. S.

PETROLEUM MINING AND OIL-FIELDS.

Petroleum Mining and Oil-field Development. A Guide to the Exploration of Petroleum Lands, and a Study of the Engineering Problems connected with the winning of Petroleum. By A. Beeby Thompson. Pp. xx+362. (London: Crosby Lockwood and Son, 1910.) Price 15s. net.

THE engineering part of the book contains a large amount of instructive information, especially in regard to customary procedure in Russian oil-fields, but the author betrays a lack of knowledge of recent practice in some of the American oil-fields. Thus, his remarks on steel wire cable drilling on p. 193 are misleading, for it is common knowledge that at the present time this system is certainly in favour in the United States, and may, in fact, be said to be generally used for deep wells in that country, often after a depth of 600 to 800 feet has been reached. Similarly, the statement made on p. 218, as to the method adopted when a dropped tool cannot be recovered by "fishing," ignores the usual practice of "side-tracking" by raising the casing and drilling off with a wedge. Again, on p. 238, the diameter of the last string of casing is understated, for American wells, started with a diameter of 12 inches or 14 inches, are frequently completed at a depth of 3000 feet, or even 4000 feet, with a diameter of 6 inches, and it is incorrect to state that in the United States the casing is always manufactured from mild steel, for wrought-iron casing is manufactured in that country and is readily obtainable. In the description of the process of cementing wells, on pp. 266-8, there is no mention of the latest and most effective system, which consists in pumping the fluid cement, without any admixture of sand, through tubing packed inside the casing, so that it circulates below the shoe and passes up on the outside of the casing, which is afterwards lowered and the packer withdrawn.

The description of fishing tools is a good and comprehensive account of these appliances, but generally the treatment of the engineering branch of the subject is unequal, and there is a predominance of the Russian practice, to which the author unconsciously

supplies the key-note by comparing some oil-sands with "fresh caviare" (p. 286).

In the chapter devoted to the geology, chemical composition and treatment of petroleum, the author is evidently less at home, and there are many statements to which exception might be taken. Thus the description of the structure of the Peruvian oil-fields (p. 53) is inaccurate, a series of anticlinals with intervening synclines being represented as a persistent monoclinical. The expression "concentration" (p. 59) for the flowing of oil to replace that which has been ejected with much solid matter in suspension is a novel one in this connection, and the same may be said of the terms "low density," "low resistance," and "high absorption," applied to the spaces vacated.

As the author fails to distinguish between benzene and benzine (pp. 132, 138), it is not surprising that he should assert that the frequency of association of petroleum with coal and lignite is "a source of speculation." Taking the Stock Exchange meaning of speculation this may be true, but the frequency, even of adventitious proximity, still less of any causal relationship, is an obsolescent fallacy which it is not worth while to controvert afresh.

As this purports to be a practical work on petroleum mining and oil-field development, it is regrettable that greater judgment has not been displayed in the selection of the illustrations. Many of the plates add, no doubt, to the attractiveness of the volume, but convey no instruction. Amongst these are the photographic illustrations of groups of specimens of oil-rocks, bitumens, &c., a "mud-volcano" showing a level surface on which walking is being cautiously attempted, and a cart laden with Trinidad pitch.

More care should have been exercised in proof-reading. Thus in the last line but one of p. 223 the word "for" should be "by," and, judging by the context, the word "not" has been omitted in the first line of the following page, the author being thus made to state the reverse of what he intended.

ESSAYS ON ANGLING.

Minor Tactics of the Chalk Stream, and Kindred Studies. By G. E. M. Skues. Pp. xii+133. (London: Adam and Charles Black, 1910.) Price 3s. 6d. net.

IT is long since we have read any book, written by an angler for anglers, with so much pleasure as Mr. Skues's "Minor Tactics of the Chalk Stream." The polemics of ardent advocates of the dry fly or the wet fly may instruct, and possibly convert, but they weary the reader; the object of the present book is to advance no theory, but to make the angler approach his subject (and his trout) with an open mind, and think out for himself the problems with which he is confronted. Herein, we conceive, lies the true value of the book. The scene is laid upon the banks of a chalk stream, or of some carrier in the water-meadows that holds dark, hog-backed trout; for setting we have the willows and lush herbage of a southern valley, while the reed warbler, the dabchick, and the corn-crake, are cast for minor parts; yet there is

counsel which we would commend to those whose waters run through heather and bog-myrtle, where the trout are small, with fair golden bellies and ring-spotted sides, and the angler's music is the sweet spring cry of the curlew or the drumming of the snipe.

It is of the essence of Mr. Skues's teaching that the angler should cast aside the dogmas of his predecessors, and should study nature for himself; nature as seen in the trout, and on the banks of the stream, and, above all, in the life-histories of the insects eaten by the trout. There is no dogmatism here, but a pleasant didactic manner, instructing while it amuses, and amusing when it does not instruct; the moral is pointed by tales of full baskets or of bad days (our author's methods seem to have eliminated blanks), and there are constant reminders that bring the reader from his theories straight back to the river's bank. We may learn how to tie flies in imitation of the nymphs of Ephemerids, and how to fish with them, of an effort to reproduce the alder-fly lava and its results, and of the sad fate of the artificial freshwater shrimp; we may further read of the undoing of trout that bulge or tail, of trout that live in strange and unapproachable holes, and of those gourmet trout whose tastes need humouring.

The temptation to quote from Mr. Skues is irresistible, the difficulty is to select; whether to reproduce his tale of the day on which there was no rise of fly but a strong rise of water-rats, or his comments on flies, or on human nature and its reluctance to jeopardise a shilling cast and twopenny fly for the sake of getting a fish out of some weedy or bushy hole. Here, for instance, is one comment with which we cordially agree:—"Indeed, why a trout should take any artificial fly is a puzzle to me. The very best are not really very like the real things. One thing is clear: It is not form which appeals to the trout, but colour and size." In the light of this passage, the flies shown on the frontispiece should be studied and compared with the actual flies and nymphs.

Throughout the book the same ruling idea is found; the preaching of no system, the upholding of no tradition, but a plea for "unfettered judgment, independence of tradition, and, above all, the inquiring mind." We wish Mr. Skues success in his campaign; incidentally we wish him many readers, and we wish his readers many more such books as this. But when these books come let them be indexed; good advice is elusive, and captions alone are not always sufficient guides.

L. W. B.

ZOOLOGICAL STUDIES.

Studies from the Zoological Department, University of Birmingham. Vol. ii. Edited by Prof. F. W. Gamble, F.R.S. (1910.)

THIS volume consists of reprints of sixteen papers from various journals, the outcome of work done in the years 1905-9 by the staff and students of the zoological department of the University of Birmingham. It is appropriate that the first paper in the volume should be one by the late head of the depart-

ment—Prof. T. W. Bridge—and that it should deal with a subject which he had made peculiarly his own, namely, the air-bladder of fishes. The main purpose of this interesting paper is to consider this remarkable organ, not from the points of view of morphology and function, though these aspects are not neglected, but as the source of isinglass. The author pointed out that, although there are 7000 or 8000 species of fishes with air-bladders, few are utilised for the supply of isinglass, and he suggested that the air-bladders of some of our larger British food-fishes, such as the cod, hake, gurnard, &c., might be of value for this purpose. Isinglass is apparently the only product of the animal body which can be used as a clarifying agent in brewing operations, and its mode of action does not seem to be at all clearly understood, but it is believed that it depends on the fibrous nature of the substance. The fibres swell out in the liquid, particles become entangled in their meshes, and are carried, with the settling of the isinglass, to the bottom of the barrel.

There is one other contribution from the pen of the late Prof. Bridge, probably his last published work, on the presence of a false acetabulum in a Bandicoot. Dislocation of the head of the right femur resulted in the formation of a false socket on that side of the pelvic girdle, dorsal to and closely resembling the normal acetabulum, which latter had undergone retrogressive modification as the result of the loss of function.

Half the remaining papers in this volume are concerned with fishes—Mrs. Merritt Hawkes records the presence of a vestigial sixth branchial arch in the Heterodontidae, describes the cranial and spinal nerves, the abdominal viscera, and a vestigial seventh branchial arch of *Chlamydoselachus*, and gives a useful account of the theory of nerve components; Mr. A. D. Imms describes the gill-rakers of the spoonbill, and the oral and pharyngeal denticles of Elasmobranchs; and Mr. R. H. Whitehouse discusses the morphology of caudal fins, directing attention to the effects of specialisation, especially abbreviation, of the axis and restriction of the caudal fin in homocercal tails, and concluding that the present homocercal caudal fin is really a posterior anal which owes its present position to the great abbreviation of the axis coupled with excessive upturning of the end of the chorda.

There are further contributions from Mr. Imms on *Anurida* (being his L.M.B.C. memoir on this Collembolan), and on the occurrence at Port Erin of a pseudo-scorpion (*Obisium muscorum*) in the fissures of rocks in such positions that the specimens had to endure submersion twice daily. The studies also include papers on sex-inheritance in the moth *Abraxas grossulariata* and its variety *lacticolor*, and on animal parthenogenesis, by Mr. L. Doncaster; on the anatomy of the "green fly" of rose trees by Mr. A. J. Grove, and on the gonadial grooves of *Aurelia* by Mr. T. Goodey.

The studies bear testimony to the range of view of the late professor and to his stimulating influence on his pupils.

OUR BOOK SHELF.

Physiology of the Special Senses. By M. Greenwood, Jun. Pp. vii+239. (London: Edward Arnold, 1910.) Price 8s. 6d. net.

In trite phraseology, this book supplies a long-felt want, and supplies it in a manner which is altogether commendable. It is elementary, but not so elementary as merely to traverse the same ground as that covered inefficiently in so many text-books. In reading the chapters devoted to the special senses in many text-books of physiology, one feels irresistibly that the author is out of sympathy with the subject. In this book the physiology of the special senses is introduced to the reader with illuminating clearness born of thorough knowledge and judicial discrimination. The requirements of the student are catered for by a teacher who knows how to interest his audience, but at the same time demands an attentive application of intelligence. Thought is stimulated, and the desire for further knowledge evoked. Each chapter concludes with a short but well-selected bibliography, pointing out the path for further study.

After an introduction dealing with the laws of Müller, Weber and Fechner, cutaneous sensation, taste and smell, the sense of position and movement, hearing, vision, and the physiology of space come successively under review. The work of Head and his collaborators, Rivers, Sherren, Ham and Thompson, upon protopathic and epicritic sensibility is clearly described, whilst the subsequent researches of Trotter and Davies are discussed and criticised. Taste and smell, the sense of position and movement, and hearing are adequately treated, but, as was to be expected, the physiology of vision in its manifold and complex manifestations demands the major part of the book, more than half the pages being devoted to its consideration.

After a chapter on the comparative physiology of vision, retinal processes, electrical, phototropic and chemical responses are dealt with. The student is led on in logical sequence to visual adaptation, entailing a discussion of peripheral vision and total colour-blindness. The chapter on recurrent vision theories of adaptation gives the reader ample food for reflection, and in entering upon the thorny subject of trichromatic vision the author wisely quotes the warning words of Helmholtz:—"The confession of actual doubt is better than the delusion of dogmatic certainty."

The treatment of colour-vision and colour-blindness is admirable. Expanded and treated more exhaustively in the same judicial spirit it might form a valuable corrective to the obsessions which the subject seems almost inevitably to induce. Further chapters are devoted to after images, historical theories of vision, the Young-Helmholtz theory, Hering's theory, and simultaneous contrast.

Reminiscences of a Strenuous Life. By Prof. Edward Hull, F.R.S. Pp. iv+119. (London: Hugh Rees, Ltd., 1910.) Price 4s. 6d. net.

THOUGH nothing appears in this simple record to justify the adjective in the title, it will afford to many a pleasant reminder of a life still keen and active, yet bridging the years between Thomas Oldham's lectures in Dublin and the Darwin celebration of 1909. Dr. Hull originally studied at Trinity College, Dublin, with the view of becoming a clergyman of the Church of Ireland, and it is interesting to note that a course in the Irish language then formed a part of the recognised curriculum. Having, however, been attracted by engineering, he came under Oldham's influence, and, with his aid, began work on

the staff of the Geological Survey of Great Britain. His chief was Sir Henry de la Beche; his first instructor in the field was J. Beete Jukes; and during the next fifty years he became acquainted with all the prominent geologists in our islands. His principal official work was in connection with the Irish branch of the Survey, of which he became director in 1869. Some of the controversies of the next twenty years may have been "strenuous"; but Dr. Hull gives only a bare hint of this. In a kindly spirit he dwells on the many friends he made, a large number of whom are fortunately still amongst us. There is an engaging *naïveté* about some of his anecdotes, as when he confesses (p. 27) that he was shocked to find that one of these friends was a Liberal; or when he mentions that he lectured on a biblical subject with an archbishop in the chair. But his reminiscences of scientific societies in Dublin will come home to all those who remember the old friendly gatherings, which have already grown a shade more formal, partly through the spread of suburban homes, and partly through the development of more "strenuous" and specialised activities.

Dr. Hull's geological expedition to Arabia Petrea and Palestine has been described elsewhere, and is here only lightly touched on. An abstract is given of his work on the submerged valleys of the European plateau (p. 105); but we miss a mention of the fact that, under his direction, the geological survey of Ireland was completed on the one-inch scale before his retirement in 1890, every sheet being accompanied, as Jukes had planned, by a descriptive memoir. These geological memoirs may vary a good deal in their degree of completeness, but their publication was very systematically carried on. We probably owe to Dr. Hull the delicate and artistic colouring of the northern sheets of the Irish Survey, which made them absolutely without rivals, until stronger tints were used in recent years. In spite of the evidence of the present reminiscences, it is hard to realise that Dr. Hull's official career ended, after full years of service, close on twenty years ago. A good portrait and a bibliography accompany the volume.

Catalogue of Bronzes, &c., in Field Museum of Natural History. Reproduced from Originals in the National Museum of Naples. By Prof. F. B. Tarbell. (Chicago: Field Museum of Natural History, 1909.)

This publication constitutes a fascicle of the seventh volume of the anthropological series of the Field Museum of Natural History, Chicago. The objects described in this "Catalogue" are reproductions in bronze of originals in the National Museum of Naples from the Campanian cities buried by the eruption of Vesuvius in 79 A.D. With a few exceptions "these objects constitute a fairly representative selection from among the bronze utensils, instruments, and articles of furniture in the great Neapolitan collection; and, while not exact in every particular, they do, nevertheless, give a fairly correct idea of the originals." As no complete and scientific account of the Naples bronzes "has ever been issued, it has seemed worth while to prepare a somewhat detailed catalogue, with illustrations, of these reproductions." The catalogue enumerates and describes with considerable detail some 300 different objects, of which seventeen are designated "pre-Roman," and illustrates almost the entire series in 117 excellent plates. To archaeological students and such other Americans as may have no opportunity of visiting Naples, these reproductions will be almost as valuable as the originals, and from them the museum will receive grateful acknowledgment, both for having had the

reproductions made and for this excellent account of them, of which European students will not fail to appreciate the value when in face of the original collection in Naples.

The Building and Care of the Body. An Elementary Text-book in Practical Physiology and Hygiene. By Columbus N. Millard. Pp. x+235. (New York: The Macmillan Company, 1910.) Price 2s. 6d.

As Mr. Millard says in his preface, teaching pupils how to develop strong, healthy bodies should be one of the chief aims of our schools. One of the objects of his book is to convince children that certain practices are likely to make them happier and more comfortable, abler in play and work, and so lead them to regard the study of the laws of health as worth while. The author has already made a favourable impression among teachers in this country by his earlier book, "The Wonderful House that Jack Has," and the present volume is likely to prove useful, since it provides brightly written and well-illustrated lessons on the simple facts of human physiology and hygiene.

The English Lakes. Described by A. G. Bradley. *Canterbury.* Described by Canon Danks. *Oxford.* Described by F. D. How. All pictured by E. W. Haslehurst. Each pp. 56. (London: Blackie and Son, Ltd., 1910.) Price 2s. net each.

The first three volumes of a series designed to bring before readers the beauties of England are certainly very attractive books. The text is interesting, touching lightly history, geography, archaeology, and any other subject able to contribute facts or fancies likely to arrest the attention. We imagine the volumes are not intended to serve any serious purpose; but though unsuitable for guide-books, they will certainly become favourites with lovers of the districts they severally describe.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Temperature Conditions within Clouds.

At the meeting of the British Association for the Advancement of Science held in Winnipeg last August, a paper was read before the Physics Section by Prof. A. Lawrence Rotch, director of the Blue Hill Observatory, in which a rise of temperature was described as having been recorded by a *ballon-sonde* meteorograph in passing through a cloud. In the discussion which followed considerable doubt was expressed as to the possibility of such a condition existing. That there was an increase in temperature recorded by the meteorograph as it passed upward through the cloud there can be no doubt (see diagram in *Meteorologische Zeitschrift*, December, 1909, p. 554). Dr. John Aitken, in NATURE of November 18, 1909, says that he sees no reason to question the truth of the record, for he has on numerous occasions observed similar increases of temperature while enveloped in a cloud upon the summit of a mountain. He directs attention to the fact that great caution must be exercised in obtaining temperatures under these conditions, for, on account of the excessive radiation that occurs within the cloud, unless the instrument is sufficiently insulated from the heat rays, the thermogram will be vitiated. In the case of the ascent referred to, the increase of temperature was not unreal, for due precaution, in the form of an especially prepared insulator, had been taken to eliminate the effects of radiation, and the ventilation was sufficient.

In order to determine the temperature conditions within and about clouds for a large number of cases, an examination was made of the records obtained in the kite-flights

made at Blue Hill Observatory. These data are particularly valuable for such a study, since in each flight continuous records of temperature, pressure, humidity, wind-velocity and direction were obtained for all heights reached by the uppermost kite, below which the meteorograph is attached to the wire. In the kite meteorograph used, the thermometer and the hair-hygrometer are screened as much as is possible, thus rendering the heat received from radiation a negligible amount.

A total of sixty-four kite flights were found in which the meteorograph penetrated a cloud, and, since in six of these flights two cloud-sheets were encountered, the temperature conditions in seventy cloud-strata were obtained as a basis for the investigation. Of these, 63 per cent. showed a rise in temperature of 3.0° F. or more in the upper part of the cloud or immediately above it, 23 per cent. showed no apparent effect of the cloud on the temperature conditions, 7 per cent. showed an inversion below the base of the cloud, while the remaining 7 per cent. showed an isothermal condition prevailing from the base to the summit of the cloud. The flights in which the records

heights above it, where a decrease again began. In every one of these cases there were the characteristic cyclonic conditions of a shallow easterly wind at the ground overlaid by a warm south-west wind, with precipitation following. It is thus evident that the increase in temperature was caused by the importation of relatively warm air, and hence began at a height independent of the cloud, the latter only reinforcing the larger warming. In the smallest group, that including the five cases in which there was a practically isothermal condition throughout the cloud, the distinguishing characteristic was really that of the largest group, for, since the usual condition in the lower free air is that of a fairly uniform decrease of temperature approaching the adiabatic rate for dry air, an isothermal state is theoretically equivalent to an increase of temperature with increasing height, such as characterise the cases of the first group. If this be granted, 70 per cent. of the instances show an increase of temperature in the upper part of the cloud and beyond for a short distance.

This phenomenon of an increase of temperature is entirely independent of the difference in the adiabatic rates of dry and of saturated air, that for the latter being about one-half that of the former. The marked decrease in

FIG. 1.—Curve of November 3, 1904, showing increase of temperature occurring within and above cloud.

were obtained were distributed with fair uniformity throughout the year, and the clouds encountered represent all kinds except cirrus and cirro-stratus, these having rarely been penetrated. Moreover, although by far the greater number of flights were made in the daytime, many flights at night are included.

In the largest of the four groups, namely, the one including the flights which showed a rise in temperature in the upper part of the cloud or immediately above it, the increase usually began about half-way between the base and the summit, and persisted until the maximum temperature for the inversion was reached a short distance above the uppermost part of the cloud. Beyond that point the usual rate of decrease, approximately the adiabatic rate for dry air, prevailed as high as the kite ascended. In the next largest group, that including flights in which the cloud had no apparent effect on the temperature conditions recorded, a fairly regular rate of decrease, somewhat similar to the adiabatic rate for saturated air, was found. In the next group, that including cases in each of which there was an inversion below the cloud, the increase in temperature persisted throughout the cloud and to various

FIG. 2.—Curve of April 4, 1905, showing increase of temperature beginning below cloud.

relative humidity almost always occurring just above a cloud is probably simply the result of the increased temperature. Dr. Shaw, the director of the English Meteorological Office, in discussing the thermal relations of floating clouds, says:—"A floating cloud, a finite mass of air carrying water particles, is losing by radiation into space (at night) through the clear air above it more heat than it receives from the earth beneath; the water globules will, in consequence of this loss of heat, evaporate, and the cloud will vanish" (Quarterly Journal of the Royal Meteorological Society, vol. xxviii., 122, p. 95). It is also worthy of note that in a balloon voyage made in Germany recently, not only was there noted a "warming above the cloud, or at least above the lowest plane of formation," but an increased temperature was recorded in a stratum of ordinary haze (Elias and Field, Quarterly Journal of the Royal Meteorological Society, vol. xxxi., 134, p. 125).

Eddy Formation—A Correction.

IN Prof. Bryan's solution of the problems in eddy formation (NATURE, February 3, p. 408) no mention is made of the fact that a vortex in one plane at rest, when the method of conformal representation is used, does not in general lead to a solution in which the corresponding vortex is at rest.

Taking a single vortex at $z=z_0$ at rest, let

$$w = im \log (z - z_0).$$

Transform by putting $z=f(t)$, and let $z_0=f(t_0)$,

$$w = im \log \{f(t) - f(t_0)\} \\ = im \log (t - t_0) + im \log \left\{ \frac{f'(t_0) + f''(t_0) \frac{t - t_0}{2} \dots}{2} \right\}$$

expanding in the neighbourhood of $t=t_0$, and at the vortex

$$\frac{dw}{dt} = im \frac{d}{dt} \log (t - t_0) + \frac{im f''(t_0)}{2 f'(t_0)},$$

the first part giving the velocity due to the vortex itself and the second the motion of the vortex. The vortex will not be at rest unless $f''(t_0)=0$.

Employing Prof. Bryan's method to obtain a solution giving a vortex at rest in the t plane in the cases considered by him, with the vortex in the z plane not necessarily at rest, we have

$$w = Uz + im \log \frac{z - a - ib}{z - a + ib}$$

$$z = f(t)$$

$$a + ib = f(t_0).$$

Then the velocity at any point is given by

$$\frac{dw}{dt} = \left\{ U + \frac{im}{z - a - ib} - \frac{im}{z - a + ib} \right\} f'(t).$$

At the vortex the motion is given by

$$\frac{dw}{dt} = \left\{ U - \frac{im}{z - a + ib} + \frac{im f''(t_0)}{[f'(t_0)]^2} \right\} f'(t_0),$$

omitting the infinite term due to the vortex itself. If the vortex is at rest,

$$U - \frac{m}{zb} + \frac{im f''(t_0)}{z [f'(t_0)]^2} = 0 \quad (1)$$

and if the velocity at $z=0$ in the z plane vanishes,

$$U - \frac{zmb}{a^2 + b^2} = 0 \quad (2)$$

Prof. Bryan's first transformation is $z=t^n$, so the condition (1) becomes, since $t_0^n = a + ib$,

$$U - \frac{m}{zb} + \frac{im}{z} \frac{n-1}{n(a+ib)} = 0 \quad (1)$$

If n is not unity, (1) and (2) give

$$n = \frac{1}{2},$$

which lies outside the prescribed limits of n . Consequently no solution of this type can be obtained giving a vortex at rest.

Prof. Bryan's second transformation is

$$Z = \sqrt{c^2 + t^2}.$$

Condition (1) becomes in this case, since

$$c^2 + t_0^2 = (a + ib)^2,$$

$$U - \frac{m}{zb} + \frac{im}{z} \frac{c^2}{(a + ib)((a + ib)^2 - c^2)} = 0 \quad (1)$$

which gives

$$a(a^2 - 3b^2 - c^2) = 0 \quad (3)$$

$$U - \frac{m}{zb} + \frac{mc^2}{2b(3a^2 - b^2 - c^2)} = 0 \quad (4)$$

Equations (3), (4), and (2) cannot be satisfied by any values of a , b , and m . A solution of the two-dimensional problem of liquid impinging at right angles on a plate of finite breadth with two stationary vortices at the back of the plate and finite velocities at the edges is impossible.

E. H. HARPER.

MR. HARPER is quite right. It would appear from his investigation that it is impossible to apply the transformations in question to fluid motions with stationary vortices, notwithstanding that a vortex transforms into a vortex, and a fluid particle other than a vortex which is at rest transforms into a particle also at rest. It is a pity that this fact was overlooked, and that results were consequently published which are of less interest than was supposed at the time.

G. H. B.

The Nutritive Value of Black Bread.

It appears to me that the contributor of the article on this subject in NATURE of May 5 has overlooked one all-important question, viz. how much of the nitrogen present in each form of bread is actually digested.

I had occasion to look up this question last year, as I happen to be a politician who is "particular about his facts," and I agree with your contributor in detesting "allegations," political or otherwise, that are "wanting in scientific accuracy." I referred, accordingly, to Wynter Blyth's "Foods: their Composition and Analysis," and found on p. 173 a table showing "the amount of dry substance, &c., absorbed in percentages of" (a) North German black bread (*Pumpernickel*) made of whole rye meal with leaven; (b) Munich rye bread, which is a mixture of rye and coarse wheat meal, with leaven; (c) white wheaten bread.

The percentages absorbed were:—

	Dry substance	Nitrogen
(a)	80.7	57.7
(b)	89.9	77.8
(c)	94.4	80.1

"It is thus shown," says Wynter Blyth, "that of the black bread a person would have to eat very much more than of white bread." I worked out the corollary of these facts in a letter published in the *Western Daily Mercury* of February 18, 1909, and showed that, on the basis of these analytical results, it would be necessary to eat 8 lb. of *Pumpernickel* to obtain the nitrogenous nutriment afforded by 5½ lb. of wheaten bread.

My copy of Wynter Blyth's book was published in 1888, and his results are quoted from G. Meyer's experiments. It is, of course, possible that during the last twenty years Meyer's results may have been proved wrong, and that pure rye bread has been proved to yield as much digestible nitrogen as wheaten bread yields. Should this be the case, I shall be much obliged by information as to the latest and most trustworthy experiments.

FRANK H. PERRY-COSTE.

Polperro, Cornwall, May 16.

THE criticism is quite to the point, but is not the last word to be said on the subject. It is well known that in the digestion of whole-meal breads there is larger waste; but, on the other hand, if in the initial material there is a greater amount of certain constituents, then, in spite of a larger percentage waste, the actual quantity of these ingredients utilised in the body may be greater. In Rubner's experiments, cited in "Standardisation of Bread. Bread and Food Reform League," this was found to be the case. The percentage of nitrogen absorbed from white flour being 79.93, and that from whole meal being only 69.53, nevertheless the actual amount absorbed from equal weights of the two materials was larger in the case of the whole meal, and this was even more marked with the fat and the inorganic constituents; but at the moment I am unable to find similar analyses relating to black bread itself.

THE WRITER OF THE ARTICLE.

Native Tantalum.

SINCE the communication by Mr. P. Walther regarding native tantalum from the Ural Mountains was published in NATURE of September 16, 1909 (p. 335), another small quantity of a few dekagrams of native tantalum has been recognised in the collection of the deceased mining director, having been collected from the Altai Mountains. It was found in very similar circumstances, and at about the same time, as the tantalum from the Ural Mountains. The difference is in the impurities; the Altai tantalum contains gold from a slight trace to 0.0095 per cent., but no trace of manganese, tin, and niobium could be detected; the latter three have been found in the Ural tantalum. The average percentage of tantalum is 98.99 per cent. The average measurement of the crystals is about 0.1 mm., and the crystals are of the regular system, as in the Ural tantalum. The hardness (between 6 and 7) and the specific gravity (11.2) are the same. The specific gravity mentioned in NATURE of September 16, 1909, has been found too low, the error being due to air bubbles.

Newcastle-on-Tyne.

W. VON JOHN.

THE RECENT ERUPTION OF MOUNT ETNA.

EVERY eruption of Mount Etna since 1883 has taken place on its southern slope. The eruption of 1883, which was preceded and accompanied by very severe earthquakes, caused a radial fracture, running roughly from north to south, from the central crater to an altitude of 950 metres on the aforesaid slope; but that eruption was abortive, only lasting three days, and forming very small craters and insignificant flows of lava.

The eruption of 1886 took place on the same fracture of 1883, without any severe earthquakes. A large crater was formed, a great mass of lava was expelled, and the eruption lasted twenty days.

The eruption of 1892, on the same fracture of 1883, was preceded and accompanied by a few slight earthquakes; it formed four large craters and other

figures approximately giving the altitudes of the middle of the eruptive areas:—

Eruption of 1883: altitude 1050 m.

„ 1886: „ 1450 m.; difference 400 m.

„ 1892: „ 1850 m.; „ 400 m.

„ 1910: „ 2175 m.; „ 325 m.

This suggests, therefore, that successive eruptions break out on the same fracture, but each higher than the last. This is easily explained by the fact that the lava of an eruption, tending to flow down, within and upon the fracture, closes it in the lower part, and leaves it more or less open in the higher, where, consequently, another eruption may be produced more easily.

We now come to the recent eruption. From the early hours of March 23 until 8h. 15m. a.m., the

FIG. 1.—Eruption of Etna seen from the heights N.-N.E., April 4, 1910. Photograph by Assistant L. Taffara.

small craters, emitted still more lava than the eruption of 1886, and lasted six months. Thus during these two eruptions it appeared that the lava found a passage prepared, whence its emission was easy.

During the month of April, 1908, there was an eruption on the eastern slope of the Valle del Bove; it was accompanied by a few slight earthquakes, but no raised craters were formed, little lava was expelled, and the disturbance lasted less than twenty-four hours. Evidently this also was an abortive eruption, probably because (as it did not take place on the fracture of 1883) it found no free opening for the emission of the lava, and met instead the unyielding rocks of the higher parts of the Valle del Bove. If we consider only the eccentric eruptions, those which have taken place since 1883 (including the recent eruption, which, as will be seen, is on the same radial fracture as the others), we find the following

seismographs of the Observatory of Catania registered many slight shocks, which followed one another almost continually. Of those which in the large seismograph had an amplitude ($2a$) greater than 1 mm., there were twelve, the severest of which ($2a=13$ mm.) took place at 2h. 55m. a.m. But even this last shock was not felt by the inhabitants of the villages nearest the place of the eruption, so that it did not raise any alarm. These circumstances, together with the fact of its being night and everyone asleep, prevented anything abnormal being observed on the volcano until 8h. 15m. a.m. At this hour, rising above the mist and above the Piano del Lago, a thin column of steam was seen, widening at the top and taking the characteristic form of a pine (*Pinus italicus*). In fact, a large fracture had been formed, having a length of almost 2 kilometers, from Monte Castello to the western base of the Montagnola, in the direc-

tion of N.N.W., between the height of 1950 metres and 2400 metres, and on the old fracture of 1883.

In the new fracture were a great number of craters, which emitted lava, bombs, incandescent lapilli, and clouds of steam and dust (Fig. 1). At first the lava issued from the highest point, and formed a small

tioned its width reaches half a kilometre; below the gorge the width even reaches one kilometre.

The depth of the lava varies from a few metres to a hundred metres in some places. The lava reached the lowest point near the Cisterna della Regina, ten kilometres from the new craters, on April 6.

FIG. 2.—Lava flowing from lower craters on Etna. Photograph by Mr. W. Schlatter.

stream going towards the south, which had the length of nearly two kilometres, but afterwards the principal emission was from the lower craters, from which a perfect river of molten rock, fifty metres wide, rapidly descended towards the south (Fig. 2). When it reached the east side of Monte Faggi, at a distance of two kilometres from these craters, having found a narrow passage between the above-mentioned mountain and the first lava of 1892, it formed a magnificent fiery cascade, ten metres wide and twenty metres in height (Fig. 3). Then it flowed on towards S.S.W., passing Mount Sona on the east, then towards the south, going through a gorge between Mount San Leo and Mount Rinazzi. Beyond the obstacle formed

The higher streams continued to flow and extend until April 20, when the flow of lava ceased, and the eruption was at an end. It had, therefore, lasted twenty-nine days.

A. Riccò.

THE ETHNOGRAPHY OF SOUTHERN INDIA.¹

COCHIN has now followed the good example of the neighbouring South Indian States, Mysore and Travancore, in carrying out a survey of its population. The account of the survey, conducted by Mr. L. K. Anantha Krishna Iyer, will ultimately consist of three volumes. The first, devoted to an account of the forest and other low-caste tribes, has now appeared, to be followed by a second describing the higher castes, and a third dealing with physical anthropology. The work is, on the whole, a creditable performance, and it is illustrated by a good series of photographs. More precision in the matter of quotations and references is to be desired. With the last census report of the State the student will now possess ample information regarding the people.

The work is introduced by Dr. J. Beddoe, who discusses recent contributions to Indian ethnology. His note is followed by an essay from Dr. A. H. Keane, in which he propounds his views on the origin of the races of India. Criticising the conclusions of Sir H. Risley, he lays down four principles. First, that there is no fundamental unity in the people, "the superficial uniformity of physical characters being far less than is commonly supposed, and due not to a fanciful primordial unity, but to secular interminglings of several originally distinct ethnical groups superinducing surface resemblances." Secondly, that the assertions of

FIG. 3.—Eruption of Etna on March 29, 1910. Lava fall from S.E. Photograph by A. Riccò.

by this gorge, the rate of movement of the lava-stream diminished, owing in part to the fact that the slope of the ground is less, but the lava spread out considerably; in fact, from the lower craters to the cascade the lava-stream is no more than 100 metres wide, but from the cascade to the gorge above men-

classical Hindu writers, claiming racial unity, are worthless, being mainly in the interest of the "twice-born" and priestly class. Thirdly, that there are five primary stocks out of which the present population has been formed—Negrito, probably derived from Malaysia; Kolarian, Dravidian, and Aryan, who arrived in the order named from beyond the northern mountain ranges; lastly, the Mongol, now mainly confined to the Himalayan slopes. Fourthly, that three groups, Kolarian, Dravidian, and Aryan, are represented by distinct linguistic stocks, and that hence compound terms, like the Indo-Aryan, Dravido-Munda, and Scytho-Dravidian of Sir H. Risley, are meaningless, if not actually misleading. It is needless to say that, perhaps with the exception of the second, these principles will be disputed by various Indian ethnologists. The fact is that the collections of physical measurements in India itself, and still more from border lands, are at present insufficient for a settlement of these tangled problems.

Among the many interesting topics discussed by Mr. Iyer, perhaps the most valuable is his account of the Oti black magic of the Parayans, by which the adept believes that he can acquire the power of trans-

castes may avoid him; a Nayadi pollutes a Brahman by approaching within a distance of three hundred paces, and a priest can purify himself only by renewing his sacred thread, bathing, and consuming the five products of the sacred cow. Mr. Iyer, with some regret, admits that this policy is naturally driving the outcasts into the arms of the Christian missionary, conversion immediately elevating them in the social scale, and placing them on a level with their new brethren. It is clear that if Hindus desire to secure Anglo-Indian sympathy, and retain these people within their religious organisation, they must set their own house in order, and must lose no time in joining the new association, which has received the patronage of the Guicowar of Baroda, and aims at more considerate treatment of the depressed races, of which the present book gives a comprehensive description.

SHEFFIELD MEETING OF THE BRITISH ASSOCIATION.

AS announced already, the British Association will meet this year in Sheffield under the presidency of Dr. T. G. Bonney, F.R.S. Members of the association who have not seen the city since the last meeting there thirty-one years ago will find themselves now quite at sea, so great have been the changes in streets, buildings, growth, and, it may be added, public spirit during that time. It has now been found possible not only to provide ample accommodation for the sectional work, but to do so compactly, all the sections except one being within a few minutes' walk from the reception room. The reception, smoking, writing, and general committee rooms will be housed in the suite of assembly rooms belonging to the Cutlers' Company, which were used in 1879 for the evening soirées. The reception room of that date is now allotted to Section E. The Cutlers' Hall is also close to the tramway centre, and so is easily accessible from all parts of the city.

The evening discourses are to be given in the Victoria Hall, a place easy to speak in and easy to hear

in. The Lord Mayor (Lord Fitzwilliam) will give a soirée at the Town Hall, and the Chancellor of the University (the Duke of Norfolk) one at the University. The latter is to be associated with an evening garden-party in the Weston Park, which surrounds the University, to be given by the local committee. A series of garden-parties is being arranged, of which one will be given by Lord and Countess Fitzwilliam at Wentworth. Among others, excursions are already arranged to Chatsworth and Haddon, The Dukeries and Birchinlee, in the heart of the wild Peak country, where huge reservoirs are being constructed for the water supply of Sheffield, Derby, Nottingham, and Leicester. The latter are a portion of the development which is rapidly transforming the district round the Peak into a lake country, the valleys running down from the high moors being dammed to form, in many cases, extremely picturesque sheets of water.

The various committees engaged in making the arrangements are determined to make the meeting a success so far as they are concerned. The scientific success will depend on the association itself. A large attendance of members is expected, not only because

The Kanizans' Prayers before Prediction. From "The Cochin Tribes and Castes."

formation into an animal, of causing and curing disease, and so on. It is, however, unlikely that the sorcerer, being here both priest and intercessor, settles the relation of magic to religion.

Much information is provided on the subject of the social relations of these outcast tribes. Probably owing to their protection from the inroads of foreign invaders, the Hindus of South India, whose example has been followed by the outcasts, surround themselves with a number of tabus in regard to the pollution by touch, the use of common food, and the like, much more stringent than those which are in force among the northern races. For instance, the Kadars, primitive dwellers in the forests, are contaminated by the touch of a Malayan, a cognate tribe. The educated Madrasi is prone to accuse the Anglo-Indian of race insolence in restricting social intercourse with him, while he himself, in his dealings with the lower tribes, is much more restrictive. Thus even the presence of a Pulayan in a town or market is considered a source of defilement, and "they are shunned as if infected with plague"; the Valan, when on a public road, has continually to call out so that the higher

of the local attractions, but because a meeting in the colonies has generally been followed by a large meeting at home. Few places have industries the operations of which afford such interest to visitors. To see an armour-plate rolled or the forging of some huge mass of red-hot metal is a sight for a lifetime, whilst the variety of the industries engaged in some form of steel-making or silver-plating is very great. Arrangements are being made whereby a large number of the more important works will be open for inspection by members.

It is generally supposed that Sheffield is a sort of city of dreadful night, and that it and smoke are convertible terms. This is, however, a complete delusion. Few cities of its size have more delightful suburbs or such picturesque scenery in the neighbourhood. The city stands at the confluence of five valleys, with contributory streams to the Don. The ridges between rise sharply to 900 feet above it, and then run up to the grouse moors, the valleys being each distinctive and well wooded. The near neighbourhood is full of historic and archæological interest. Sherwood Forest is on one side and Little John's grave on the other. The Peak caverns, the beautiful Derwent valley, with Chatsworth and Haddon and the gorge of Matlock, are close at hand, and the whole district is a pedestrian's paradise. It is hoped no member of the association will be deterred from coming by what he has seen from the railways, which in many cases actually pass through some of the large works.

PROF. ROBERT KOCH, *For. Mem. R.S.*

BY the death of Prof. Robert Koch there goes from amongst us one of the most remarkable men of his time, a man of tremendous determination, great capacity, and indefatigable energy, who has left an impress on the science and practice of medicine such as is made by a few exceptional men only. It would be affectation to say that all his work is of equal value, for although under his hand and mind no subject could remain unaltered, his pioneer work on the isolation and cultivation of bacteria in solid media, his studies in anthrax, and his work on tuberculosis and cholera, must always stand out above any other that he did. The controversial methods of his earlier years, as exemplified by his controversy with Pasteur in 1883, were succeeded by methods of a less pungent, but equally vigorous, character, but his arguments were always respected, even by those who did not agree with him, as those of a man thoroughly in earnest, whilst his utterances could always be accepted as those of a man who had every right, by reason both of experiment and experience, to give full and free expression to his opinions, opinions that must be carefully weighed and considered, especially by those who differ most widely from him.

Born in Klausthal, Hanover, on December 11, 1843, Robert Koch was a member of a large family. His father held some official position in the Department of Mines and Forests. At nineteen Koch commenced his medical studies in the University of Göttingen, at which he worked for five years. After passing his State examination and taking his degree, he became assistant medical officer in the General Hospital in Hamburg. He then engaged in private practice, first at Langenhagen, near Hanover, moving thence to Rackwitz, where he remained until he went as a volunteer surgeon with the army in the Franco-Prussian war. In 1872 he again started private practice, this time in Wollstein, in Posen, where he commenced his investigations and studies on the isolation of pure cultures of bacilli, studies which led

to the method of cultivation of bacteria on solidifying media, a method to the use of which we owe many of the most important advances made in the bacteriology of disease.

Up to Koch's time, Salomonsen's and Cohn's methods of isolating single bacteria were the only methods available. Salomonsen mixed a very small number of organisms with a large quantity of blood, and drew the mixture into a series of long, fine glass tubes; then as the organisms grew and used up the oxygen in the blood, little black points made their appearance along the course of the tube. Blood taken from the tube broken at one of these black points was often found to contain a pure culture of a single organism only. This method, of course, could not receive very general application, but as the blood might coagulate in the tube, the organisms could not move about at all readily until the clot was broken down or decomposed by the organisms themselves. Cohn's method consisted in diluting the culture containing the organisms with very large quantities of broth, and then taking a single drop and transferring it to a flask or tube containing broth; in this case the observer trusted to the dilution being so great that a single drop would contain only a single organism. These methods, imperfect as they were, were used by Pasteur and Lister in their investigations, and were brought by them to considerable efficiency.

Koch's method of isolation was exceedingly ingenious but very simple. Taking a nutrient medium containing meat juice or sugar along with certain saline constituents to which had been added from 5 per cent. to 10 per cent. of gelatin, he boiled or heated the mixture several times to 70° C. or 80° C. in order to destroy any germs that might already be present. The material to be investigated was then added to this sterilised nutrient medium whilst still in a fluid condition. The mixture was then well shaken, so as to distribute any organisms that might be present, and poured over a glass plate sterilised by heat contained within glass vessels similarly sterilised. When this nutrient medium cooled down it became a solid jelly, and the organisms were fixed in position, each organism giving rise to a colony, so that each organism with its progeny was isolated and could be studied separately. At this date we are apt to lose sight of how much bacteriologists owe to Robert Koch for this simple method, which was devised by him in order that he might study more thoroughly than had yet been done the anthrax bacillus, the bacillus that gives rise to splenic apoplexy in cattle, and to one form of malignant pustule in the human being. By means of this method, too, he was able to isolate and study various organisms found in wound infection and in septicæmias of certain animals, the results of which are given in a paper translated and published in 1880 in the Transactions of the New Sydenham Society. His studies on the production of immunity against anthrax in cattle and sheep were, however, anticipated by Pasteur, who, in 1881, gave his marvellous and striking demonstration at Chartres.

In 1880 Koch was appointed Government adviser to the Imperial Board of Health, and in the laboratories in the Luisenstrasse carried out that series of investigations which ended in the demonstration of the presence of the tubercle bacillus in the diseased tissues of tuberculous animals and in the sputum and tissues of human beings suffering from tuberculosis. Here again his ingenuity and mastery of methods enabled him to do what so many others had failed to accomplish—to stain the tubercle bacillus in the tissues and to isolate and study this organism on artificial media outside the body. As the tubercle

bacillus would grow luxuriantly only at the body temperature, Koch found it necessary to obtain some solid medium that would not melt at that temperature, and, going on the principle that the fluids of the body would probably afford the best nutrient medium for an organism that grows so readily in the tissues, he took the blood serum of sheep, calves, &c., which not only contained the necessary nutrient elements for the bacillus, but was consolidated by heat, and he found that if the consolidation were effected at a sufficiently low temperature, the medium retained most of its nutrient properties. Here again was a tremendous advance, and his paper, read on March 24, 1882, before the Berlin Physiological Society, and published in the report of the Imperial Board of Health, was received with acclamation on every hand, and although criticism of all kinds was directed against his findings, Koch maintained his thesis against all comers. After this work on tuberculosis, Koch was naturally looked to, not only by his own countrymen, but by scientific men of all countries, as the man most likely to solve the questions bound up in the causation of cholera. In 1883 he went out to Egypt on a quest for the *causa causans* of cholera, and in 1884 acted as chairman of the German Cholera Commission, which carried out much of its work in India. His works on cholera, one volume published in 1884 and a second in 1894, must be looked upon as classical monographs, and from 1884 onwards the cholera vibrio, or comma bacillus, became indissolubly associated with cholera as its prime etiological factor.

In 1885 Koch was appointed professor of hygiene in the faculty of medicine in Berlin University, and his classroom and laboratory became the resort of students from all parts of the world, as they had already been at the Gesundheitsamte, though on a smaller scale. His pupils there trained took up many of the problems for the consideration of which he had neither time nor energy. In 1890, at the tenth International Medical Congress, he announced the discovery of tuberculin, and, in a series of admirable experiments, demonstrated the action of tuberculin as an immunising agent, an aid to diagnosis, and even as a curative when injected into animals already suffering from tuberculosis. The announcement of this treatment seemed to give hope of prolonged life to thousands of tuberculous patients, many of whom clamoured to be treated. The method, however, had not been sufficiently fully developed, and there can be little doubt that it fell into disrepute, not because it failed to accomplish what had been claimed for it by Koch, but because it failed to give such results as had taken form in the imagination, alike of patients and of medical men, who could not understand the limitations of such a method of treatment—a method still in its infancy. Those, however, who really studied the tuberculin treatment never lost heart, and in 1897 Koch reported a new tuberculin, with which much more satisfactory curative results have since been obtained. There can be little doubt that some modification of this method must form the basis of any specific curative treatment.

In 1891 Koch was appointed director of the magnificent new Institute for the Study and Treatment of Infective Diseases, and here, with his band of workers, in which were men whose reputation is now world-wide, continued to work out some of the problems in which he was now interested. In 1896 he was called to South Africa to study rinderpest, a disease which, with the assistance of Kolle and Turner, he traced to its cause and for which he devised a method of immunisation. As the result of these observations, on which were built up investigations by later workers, rinderpest has become a

manageable disease. At this time Koch first took up the question of sleeping sickness, but, like most other observers, he failed at the outset to find any organism that he could associate causally with the disease. From this he turned his attention to the bubonic plague, studying it in India and German East Africa. Following up the observations of Yersin and Lowson, and tracking down the bacillus of plague, he found that it was really conveyed by rats, and that, however, it was endemic in Mesopotamia, in Hunan in China, in Tibet and Mecca, and in Kissiba, Victoria Nyanza. As a result of his observations, he expressed the hope and assurance that in time these plague centres might be cleansed, and when the reservoirs and carriers of the disease could be localised, plague might gradually be exterminated. How far these prognostications may be realised it is still early to state, but the continuation of this line of research and the tracking down of the flea as a further carrier have undoubtedly brought this period nearer.

In 1901 Koch exploded his great bombshell at the International Congress on Tuberculosis in London when he said, "I feel justified in maintaining that human tuberculosis differs from bovine and cannot be transmitted to cattle." That he wished further evidence, however, is evident from the fact that to this statement succeeds the following:—"It seems to me very desirable, however, that these experiments should be repeated elsewhere in order that all doubts as to the correctness of my assertions may be removed." As regards infection of the human subject by the material from tuberculous cattle, he said:—"I should estimate the extent of infection by the milk and flesh of tuberculous cattle and the butter made of their milk as hardly greater than that of hereditary transmission, and I therefore do not deem it advisable to take any measures against it." It was this last statement to which special objection was made, as it involved such a complete alteration in our method of procedure in connection with milk and milk products from tuberculous cattle. It is not necessary here to repeat what has been now before the public for so long in the Interim Reports of the Royal Commission on Tuberculosis and of the German Commission on Tuberculosis, the Transactions of the International Congress on Tuberculosis at Washington, and many papers by individual workers. Moreover, there seems some reason to believe that latterly Koch had modified his views somewhat, in so far that in his interview with the *Times* correspondent in Berlin during the early part of last year he stated that the "Differences still unsolved between my critics in the Royal Commission and myself have been greatly reduced by further examination, and are now very slight." As shortly before his death Koch was making a very thorough search for the bacillus of bovine origin in cases of pulmonary tuberculosis, it is to be hoped that his colleagues and literary executors will give the world the results of his investigations.

In 1903, still in search of fresh fields to conquer, he returned to South Africa to study on the spot coast fever (allied to Texas fever), a condition due, apparently, to the presence of protozoal parasites in the blood. At this period his investigations were occupying so much of his time that in order to devote himself to them more thoroughly he retired from his position as director of the Institute for the Study and Treatment of Infectious Diseases. In 1905 he was awarded the Nobel prize in recognition of his great services to medicine, an award approved by all.

In 1906, returning to East Africa, he continued his studies on sleeping sickness, especially in relation to its treatment by atoxyl. At one time it appeared as though he had obtained a drug specific for this

disease. It was found, however, that although there was amelioration in the condition of the patient in the early stages of the treatment, the drug soon lost its effect, whilst certain sequelæ, e.g. blindness, the results of the action of the drug, led men to be exceedingly chary of using it. In connection with sleeping sickness, Koch, following up Bruce's theory of a living reservoir in which certain parasites might exist without giving rise to any definite and appreciable disease, instancing the wild buffalo, where the parasite is kept alive in its host without apparently doing any damage, but ready to attack non-immunised animals when carried to them by the tsetse fly (*Glossina morsitans*), Koch suggested that the crocodile might be the reservoir host of the trypanosome that gives rise, when carried to the human being by another tsetse fly (*Glossina palpalis*), to sleeping sickness, and he then made the suggestion, afterwards carried out, that the infective zone around certain waters should be cleared of its underwood, and the crocodiles lurking there, and in the neighbouring waters killed. Koch also worked at malaria in Java and in the Malay Peninsula. He studied black-water fever and tried to determine its relation to malaria, or, alternatively, to quinine poisoning contracted during the treatment of malaria.

Koch's last great public appearance was at the Washington Congress on Tuberculosis in 1908, when he announced that he intended to devote the remaining years of his life to the settling of the question that he had raised in London eight years earlier, and everyone hoped that he had some years of useful work before him. These years have been all too few, and we cannot expect that the work he then undertook is finished.

The record of a man's work is his best obituary notice—and in such a case as that now under consideration the writer is relieved of an enormous responsibility—but this notice would be very incomplete did it not contain some record of the honours accorded to him by his fellows, especially those who followed and appreciated his work. Robert Koch was an honorary member of a very large number of learned associations, amongst them of the Prussian Academy and of the Royal Society of London. He had been invested with the Prussian and French Orders of Merit, and with orders of various kinds awarded by the rulers of almost every State in Europe. In some cases these distinctions might mean but little to those who come after us, but, associated with Koch's name, they must ever retain their significance as associated with one of the names on the imperishable roll of the great in science. The death of Robert Koch involves a loss not to Germany only—all mankind is the poorer.

MAJOR PHILIP CARDEW, R.E.

MAJOR PHILIP CARDEW, whose death we record with deep regret, combined a fine mathematical mind with careful scientific training, and a remarkable natural ability in grasping the principles involved in any practical question. He passed through Woolwich Academy with every honour, and started a brilliant career in the Royal Engineers in 1871. He was appointed, in 1883, instructor in electricity at the Military School of Engineering at Chatham, and threw himself with great energy into those innumerable electrical problems which were being so rapidly developed in telegraphy, telephony, electric lighting and power. In 1888 he was selected as the first electrical adviser to the Board of Trade, and he inaugurated the rules and regulations for the use of electricity for public supply and for electric tramways and railways. These rules have formed a model for

all countries, and there is very little doubt that the freedom of water and gas pipes in England from electrolysis due to stray tramway currents is the result of the wise restrictions which Major Cardew initiated. The standardisation of electrical units was part of his work.

When Major Cardew retired from the Board of Trade his energies were diverted into the execution of various lighting, power, and traction schemes. Under his personal guidance, every Government dockyard in the British Empire has been equipped with electric power, and numerous electric railways, tramways, and lighting systems originated. He was a prolific inventor, and his vibrator is largely in use in connection with military telegraphs, while the hot-wire voltmeter which bears his name was for years one of the few trustworthy electrical instruments. The Cardew safety earthing device has also been of great value in connection with the public supply of electricity.

Major Cardew contributed a number of papers on electrical subjects to the Royal Society and the Institution of Electrical Engineers.

His death, at the early age of fifty-eight, is greatly to be regretted. He was intimately associated with all the modern developments of electricity, and his experience and advice were much in demand.

NOTES.

IN consequence of the death of King Edward VII., the usual ladies' conversazione of the Royal Society will not be held this year.

At a meeting of the council of the Royal Society, held on Thursday, May 26, at Burlington House, an address of condolence and homage to His Majesty King George V. was adopted, and the society's seal affixed. At the ordinary meeting of the society, which followed, the address was communicated to the fellows present by the president, Sir Archibald Geikie, who spoke as follows:—"Since the last meeting of the society a great calamity has unexpectedly befallen the country, and under the shadow of that mournful event we now resume our duties. The death of King Edward is a national loss, the full effect and meaning of which cannot yet be appreciated. We, fellows of the Royal Society, share in the universal sorrow that a life so revered, so full of achievement, and with the promise of still many fruitful years, should have been cut short in its prime. But we have also a more personal ground for regret. The late King had been for nearly half a century one of our fellows, and on his accession to the throne had become our patron. Among the many claims which His Majesty had to our regard, not the least was the interest which he always took in the furtherance of that natural knowledge which the Royal Society was founded by Charles II. to promote. In our annals the name of King Edward VII. will always hold an honoured place. The council has approved and sealed an address to His Majesty King George V. in which, while expressing our condolence in the deep grief of the Royal Family, we offer our respectful congratulations on his accession to the throne of his ancestors, and our confident hope that his reign may be long and prosperous." The address was then read from the chair, and was adopted in silence, the fellows present all standing.

As we go to press, the *Terra Nova* is starting on her journey with the British Antarctic Expedition, and, after calling at a number of places, is expected to arrive at Lyttelton, New Zealand, about October 13. Hitherto Antarctic expeditions have sailed to the south in the latter

part of December, but with the *Terra Nova* it is hoped to penetrate the pack ice at an earlier date than it has been possible for previous expeditions to do, and accordingly the ship will leave New Zealand towards the end of November, and probably reach McMurdo Sound about the end of December. On arrival in McMurdo Sound the western party will be landed, and as soon as the winter station has been established the greater number of the party will proceed to the south to lay depôts. It may be possible to start this party off not later than the third week in January. At the same time, the ship will leave McMurdo Sound and proceed to the eastward to explore King Edward's Land. A small eastern party will probably be left with full supplies and some transport facilities. After landing the eastern party the ship will return to McMurdo Sound, and then proceed to the northward. At the latest this will probably be in the third week of February. If there is coal enough the *Terra Nova* will be directed to investigate the pack in the region of the Balleny Islands, and to proceed to the westward or to the south of these islands. These objects will occupy the ship during the month of March, after which she will be directed to return to New Zealand. The western party, it is hoped, will by the month of April be safely established in the hut, with suitable depôts laid well south of the barrier. During the winter, preparations will be made for an effort to reach the South Pole in the following season. Captain Scott states that he does not propose to start upon the southern journey until the month of October. That month and the following will be spent traversing the Barrier and ascending the glacier. He hopes to reach the upper plateau fairly early in December, and an ideal day for reaching the South Pole would be December 22. Captain Scott will be accompanied by, among others, Lieut. E. R. G. R. Evans, R.N., second in command; Dr. E. A. Wilson, chief of scientific staff; Lieut. H. L. L. Pennell, R.N., magnetic and meteorological work in *Terra Nova*; Surgeon G. M. Levick, R.N., doctor and zoologist; Surgeon E. L. Atkinson, R.N., doctor, bacteriologist, parasitologist; Dr. G. L. Simpson, physicist; Mr. T. Griffith Taylor, geologist; Mr. E. W. Nelson, biologist; Mr. D. G. Lillie, biologist; Mr. W. G. Thompson, geologist; and Mr. C. S. Wright, chemist.

SIR DAVID GILL, K.C.B., F.R.S., has been appointed a Knight of the Prussian Order of Merit. The honour was conferred on Tuesday through the German Ambassador in London, by order of the German Emperor.

DR. W. THOMAS, assistant lecturer in the Liverpool School of Tropical Medicine, has been appointed director of the new laboratories at Manaus, in the State of Amazonas.

THE death is announced, in his sixty-third year, of Prof. W. Rose, emeritus professor of surgery at King's College, London, and author of a number of works on various surgical subjects, including the standard text-book "A Manual of Surgery," of which he was joint author with Mr. A. Carless.

THE Harben lectures will be delivered by Sir W. B. Leishman, F.R.S., professor of pathology in the Royal Army Medical College, London, in the Royal Institute of Public Health, on June 8, 15, and 22, the subject being "Anti-typhoid Inoculation."

THE *Pourquoi Pas?* having on board Dr. Charcot and other members of his expedition to south polar regions, arrived at Guernsey on Tuesday. Dr. Charcot expressed

satisfaction with the journey, and said that he had accomplished all that he had expected, and had brought back valuable scientific results, including a large collection of animal remains. Among the geographical results is the charting of land south of the Adelaide Islands.

THE council of the Royal Society of Arts has elected the Hon. Theodore Roosevelt a life member of the society under the terms of the by-law which empowers it to elect annually not more than five persons who have distinguished themselves by the promotion of the society's objects. The first American member of the society was Benjamin Franklin, who was elected in 1755.

THE annual general meeting of the Research Defence Society will be held on Friday, June 3, at 5 o'clock, in the library of the Royal College of Physicians, Pall Mall East, S.W. The chair will be taken by the Earl of Cromer, president of the society. The other speakers will be Sir Richard Douglas Powell, Bart., K.C.V.O., Sir David Bruce, K.C.B., F.R.S., Mr. Anthony Hope Hawkins, and Mrs. Scharlieb.

THE *Times* Geneva correspondent reported that on May 26, at 7.12 a.m., a violent earthquake shock traversed the whole of Switzerland from north to south, touching Bâle, Zürich, Berne, and Geneva. Messages from Paris and Berlin showed that the shock was felt at Belfort, Mülhausen, Upper Alsace, and parts of Baden. At Freiburg the shock lasted for some seconds. During the previous evening violent thunderstorms visited some parts where the earthquake was recorded.

THE annual meeting of the Selborne Society will be held in the theatre of the Civil Service Commission, Burlington Gardens, on Friday, June 17. After business has been transacted an address will be delivered by Mr. J. Buckland on the traffic in feathers and the need for legislation. The Selborne Society, of which the late Lord Tennyson was, and Lord Avebury now is, president, has recently been developing its work and increasing its activities. During last year it acquired new offices at 42 Bloomsbury Square, in order to form a home for its library and to provide reading and committee rooms.

THE council of the Institute of Metals has appointed a committee to investigate the causes of the corrosion of non-ferrous metals by sea-water, acids, &c., and by other chemical and electrolytic reactions. The members of the committee are:—Sir Gerard Muntz, Bart. (chairman), Prof. H. C. H. Carpenter (secretary), Captain G. G. Goodwin, R.N., Prof. A. K. Huntington, Mr. J. T. Milton, Mr. A. Philip, Mr. L. Sumner, Prof. T. Turner, and Sir William H. White, K.C.B., F.R.S. The committee has decided, in the first instance, to confine its attention to the question of the corrosion of condenser tubes in marine engines and in stationary engines using foul water, or being subject to violent electrolytic action, such as often occur in electric power stations.

MANY members of the British Association will learn with regret of the death of Mr. Alfred Colson, who was chairman of the executive committee and local honorary secretary for the meeting of the association at Leicester in 1907. Mr. Colson was a past-president of the Institution of Gas Engineers, and also of the Leicester Literary and Philosophical Society. His work as the gas and electric light engineer of the Leicester Corporation will remain a permanent memorial to his adaptability and technical knowledge, and his great organising powers will be remembered by all who were present at the Leicester meeting of the British Association.

THE Board of Education has been informed through the Foreign Office that the second session of the seventeenth International Congress of Americanists will be held at Mexico City on September 8-14. The sessions will be held in the lecture hall of the National Museum in Mexico City. An organising committee has been formed, the president of which is Sr. Lic. D. Justo Sierra, Secretary of Public Instruction and Fine Arts for the Government of Mexico. Communications to the congress, which may be either oral or written, may be made in English, French, German, Italian, Portuguese, or Spanish. The congress will deal with questions relating to the ethnology, archæology, and history of the New World. For further information application should be made to the general secretary of the organising committee, Sr. Lic. D. Genaro Garcia, Museo Nacional, Mexico, D.F.

WE regret to see the announcement that Prof. Emil Zuckerkandl died on May 28, in his sixty-first year, at Vienna, where he had occupied the chair of anatomy for nearly thirty years. He was well known to anatomists for his many and varied contributions to human and mammalian morphology. He was trained under Hyrtl and Carl Langer, and acted as prosector in the University of Vienna until he was called to fill the chair of anatomy at Gatz in 1887. His best known work, on the anatomy and diseases of the nasal cavities (1882-92), is one which will remain an authoritative memoir for many years to come. His numerous monographs on the arterial system and on the morphology of the brain, especially of the ape and marsupial, are based on elaborate and patient observation, but somewhat prolix, and unrelieved by wide and happy generalisations. It is rather his contributions to the more medical and practical side of human anatomy that will prove of permanent value. He was successful in maintaining the world-wide reputation which Hyrtl and Langer and other previous occupants of his chair had won for the Anatomical School of Vienna.

MR. MICHAEL CARTEIGHE, whose death occurred at Goring-on-Thames on May 30, was for fourteen years president of the Pharmaceutical Society of Great Britain. He received his pharmaceutical education at the School of Pharmacy, and also studied at University College, London, where he became demonstrator in chemistry under Prof. Williamson. While at University College he took part in some important chemical and physical researches, one of the most notable being an investigation of the electrical conductivity of alloys, wherein he was associated with Drs. Matthiessen and Holzmänn; the results of the work were embodied in a paper which was read before the Royal Society. Circumstances decided him not to pursue a scientific career, and he joined his brother, who was a partner in the pharmaceutical business of Messrs. Dinneford and Co., and on the death of his brother he became sole proprietor. He first became a member of the council of the Pharmaceutical Society in 1866, and assisted in the drafting of the Pharmacy Act of 1868, by which the sale of poisons was restricted to registered chemists and druggists, and the practice of pharmacy placed on a more or less regular basis. For many years he was a member of the society's board of examiners. From 1882 to 1896 he held the office of president, and his endeavour throughout that period was to place the educational standard of pharmacists on a higher plane, for he realised the force and wisdom of the policy of the founders of the society, namely, that the foundation of effective organisation was education in its widest sense; his efforts were largely devoted to securing for the society a position among the

recognised technical and scientific institutions of the country. With his period of office are associated radical improvements in the society's school, the development of the library and museum, and the foundation of the research laboratory. Notwithstanding the amount of time he devoted to the Pharmaceutical Society, Mr. Carteighe found opportunities for work in other directions; he was one of the founders of the Institute of Chemistry, of which he was for many years a vice-president. He was also a vice-president of the Society of Arts during several years, was one of the most prominent members of the British Pharmaceutical Conference, and was for forty years a member of the Royal Institution. Mr. Carteighe was in his sixty-ninth year.

A DESCRIPTION of the Mitsu-Bishi Dockyard and Engine Works appears in *Engineering* for May 20. These works are among the oldest and largest in Japan, and are situated at Nagasaki and at Kobe. The completeness of the equipment will be understood from the fact that the company is capable of producing, without subcontracting, not only every type of ship, machinery, and boilers for land and marine use, but also of steel girders, steel buildings, electrical machinery, Parsons marine steam turbines and turbo-generators, Stone's manganese-bronze castings, and Morison's "Contraflo" condensers. The company is one of the most important exhibitors at the Japan-British Exhibition at Shepherd's Bush. It is of interest to note that, both in the Nagasaki and Kobe works, the specification and wording in drawings, books, forms, orders, &c., in fact, every writing in the establishment, are in English, besides a greater portion of the correspondence. It is curious to notice a workman carrying out the work to the letter with a drawing worded entirely in English, although he is not able to quote a simple intelligible sentence.

IN a paper on steel testing read at the Institution of Mechanical Engineers on Friday, May 27, by Mr. B. Blount, Mr. W. G. Kirkaldy, and Captain H. Riall Sankey, comparisons are made of the tensile, impact-tensile, and repeated bending methods of testing. In the impact-tensile method the specimens were not notched, as is more usual in other impact tests, and were attached to a tup arranged to fall freely through a height of 30 to 40 feet. The tup was of adjustable weight, and was attached to the lower end of the specimen, a cross-head being fixed to its upper end. After falling a measured height the cross-head is arrested by coming into contact with the top faces of a split anvil; the specimen is broken, and the tup continues its fall between the two parts of the anvil. The breaking of electrical contacts during the fall enables the energies at impact and after impact to be deduced, and hence the energy utilised in breaking the specimen. In this method the whole of the material in the cross-section under observation is brought simultaneously under the influence of the impact stress. Three test-pieces of each type of steel were broken by this method, and the readings agree fairly well as regards the energy absorbed by the rupture. The average disparity from the mean is about 6 per cent. The readings of elongation and contraction of area are also in good agreement.

THE old myth of the occurrence of live frogs and toads enclosed in blocks of stone or of coal is not yet dead, but ever and again shows signs of life in the way of vigorous assertion of supposed cases of the phenomenon. We have received a communication from a resident in Leicestershire in which the writer states that, while recently breaking a lump of coal, "from the centre a live half-grown toad fell

out on its back. I called the attention of my neighbours to it, and I thought it was dead; but in a few minutes it began to move about, so I took care of it, and have it now as well as the piece of coal. There is the cavity in the coal where it laid. I can vouch for its genuineness. Is it of any value as a curio to naturalists or geologists? I have had several amateurs to see it." It matters little to tell the reporters of such occurrences that the thing is absolutely impossible, and that our believing it would involve the conclusion that the whole science of geology (not to speak of biology also) is a mass of nonsense. Why that is so it would be difficult to make them understand, for at present, with the exception of the comparatively few professional and amateur geologists, the general public, even some of the most educated, are as ignorant of the most elementary facts of geology as they are of the Chinese language. All popular beliefs, however, rest upon some basis of fact, though the facts may be imperfectly observed and erroneously interpreted. The true interpretation of these alleged occurrences appears to be simply this—a frog or toad is hopping about while a stone is being broken, and the non-scientific observer immediately rushes to the conclusion that he has seen the creature dropping out of the stone itself. One thing is certainly remarkable, that although numbers of field geologists and collectors of specimens of rocks, fossils, and minerals are hammering away all over the world, not one of these investigators has ever come upon a specimen of a live frog or toad imbedded in stone or in coal. Why are these alleged occurrences testified to only by those having no knowledge of geology, and, indeed, for the most part by uneducated workmen? It would indeed be an epoch-making event in the history of science if, for instance, a member of the Geological Survey should lay before us a genuine case of a live frog enclosed in stone!

To the May number of the *Psychological Review* Miss June E. Downey contributes a paper on the determination of sex from handwriting. She concludes from her investigations "that it is possible to determine sex from handwriting in perhaps eighty cases out of a hundred." She finds that "the presence or absence of the so-called sex-signs is . . . influenced largely (1) by the amount of writing done; (2) by age and consequently, to a certain extent, by practice; (3) by professional requirements such as shown by the conventional writing of grade teachers and the rapid hand of bookkeepers." The writing of two hundred persons was examined in this investigation, being submitted to "two professional graphologists and to fifteen persons ignorant of the art of graphology. . . ." A considerable number of the two hundred persons whose writing appears in the series are known to have been educated wholly in co-educational schools in America.

MR. G. W. LAMPLUGH, F.R.S., sends us an interesting article (reprinted from the *Naturalist*) entitled "Man as an Instrument of Research," which formed his recent presidential address to the Hertfordshire Natural History Society. We quote the following paragraphs:—" . . . first, to learn rightly to understand the evidence of the senses; and next, to learn to convey what has been gathered from them in unmistakable terms, are the indispensable qualities in the equipment of man as an instrument of research. . . . Unless . . . we qualify not only as observing, but also as recording instruments, the new knowledge we may have acquired remains merely personal. . . . I suppose that one of the chief difficulties experienced by everyone using language for the description of phenomena is that the observed facts form, as it were, an entangled mass, with innumerable threads, interlacing, converging, diverging

around their common centre in all directions; whereas their expression in language necessitates that the corresponding ideas shall be spun off in linear sequence on a single plane."

IN a paper recently read before the Royal Philosophical Society of Glasgow, Prof. G. Elliot Smith discusses the evolution of the practice of mummification in Egypt. It originated from the experience gained of the desiccation of the corpse in hot dry sand. The activity of the grave-plunderer even in pre-dynastic times necessitated adoption of precautions to secure the safety of the remains, and the discovery of the use of copper led to the invention of the coffin, the sarcophagus, and the rock-cut tomb. The abundance of salt and soda, and the use of resin by women for cosmetics, suggested the custom of embalming. The difficulty of accepting this explanation has hitherto lain in the late date assigned to most existing mummies, none of those in the Cairo Museum being older than the last king of the seventeenth dynasty (*circa* B.C. 1580); but much older mummies have recently been traced. One of the time of Snefru was found by Prof. Flinders Petrie near the Medum Pyramid in 1891, and was examined by Prof. Keith (*NATURE*, 1908, p. 342). The date of this specimen has now been fixed by Dr. G. A. Reisner about 2700 B.C. (*NATURE*, March 31, p. 136). It is thus more than eleven centuries older than the other examples, and justifies the belief in the early adoption of the practice of mummification in Egypt.

THE *Zoologist* for May is largely devoted to the habits of animals, Mr. B. F. Cummings contributing the first portion of an article on the formation of useless habits in British newts, as observed in specimens in captivity, and Mr. E. Selous continuing his observations on the nuptial habits of the blackcock.

DR. W. E. HOYLE has sent us a copy of a list of the generic names of the dibranchiate cephalopods, with their typical species, published in vol. xxxii. of the *Abhandlungen der Senckenbergischen Naturforschenden Gesellschaft*, forming the "Festschrift zum Siebenzigsten Geburtstag von Wilhelm Kobelt."

To vol. xxxii., Nos. 2 and 3, of *Notes from the Leyden Museum*, Dr. E. D. Van Oort contributes a long list of birds from western Java and Krakatau, among which a *Gerygone* is described as new. Later on Dr. E. Hartert expresses the opinion that *Passerina*, in place of *Plectrophenax*, should be used as the generic title of the snow-buntings, while Dr. Van Oort maintains precisely the opposite. This scarcely looks like the attainment of that uniformity in nomenclature of which so much is from time to time heard.

ACCORDING to the *Field* of May 21, a correspondent of the *Baltische Waidmannsblad* states that before the Russians came to the province of Ussuri the tiger was literally king of the forest in that district. The natives, Chinese and others, as well as the immigrant Coreans, looked upon the animal as a god. If any of them met a tiger there was no question of resistance or fighting; the man threw himself on his knees and allowed himself to be killed if the animal attacked him. When domestic animals were seized, the owner looked quietly on. Generally it was the Chinese who risked their lives when they went to the forest to collect shed deer antlers or roots of the ginseng plant for medicinal purposes. They fell easy victims to the tigers, which at that time frequented the immediate neighbourhood of Vladivostok, where the primeval forest remained dense and almost impenetrable. Gradually the Russians settled in these tracts, and the first thing they

d'd was to clear away the trees in order to cultivate the land. This checked the tigers, and not only did the white man defend himself with courage when attacked, but became the aggressor. The tigers came to distinguish between Chinese and Koreans on the one hand and white men on the other, and, unless circumstances prevented, avoided the latter.

A USEFUL "Catalogue of Nearctic Spiders," by Mr. Nathan Banks, has lately been issued as Bulletin 72 of the United States National Museum. It includes more than 1300 species, and the author anticipates that at least 2000 will be recognised "when the west and south are explored as thoroughly as New England now is." The arrangement followed is on the whole that of Simon's "*Histoire naturelle des Araignées*." It is of interest to note that a large proportion of genera and a small proportion of species are common to the European and North American faunas. The inclusion of the southern States in the "Nearctic Region" leads to the appearance of some characteristically tropical spiders, such as the large Theraphosidae, but there is no information as to the distribution of northern species in Canada.

Of the various agricultural students' publications, few are more interesting than the Proceedings of Armstrong College Agricultural Students' Association. The current issue (part ii., vol. ii.) contains a paper by Dr. Stevenson on Aberdeen Angus cattle, their breeding and management, and a very readable essay by Mr. Walling on a typical north Devonshire farm. The association encourages its members by the offer of prizes to prepare papers on agricultural subjects, and to carry out agricultural experiments. The membership during the past year is stated to have been 130.

THE prospects of vanilla-growing in the West Indies are discussed in a recent issue (No. 204) of the *Agricultural News*, the problem having arisen because of the recent rise in price of vanilla. Hitherto there has been some fear, not altogether unfounded, that the synthetically prepared vanillin would drive the natural product out of cultivation, but since the passage of the American pure-food law has necessitated a declaration of the materials used, it has been found that people prefer the natural vanilla, the sale of which is said to have increased in consequence. It appears that the general production and consumption are both increasing, but only in the French colonies is there any immediate likelihood of over-production. The reports from various markets which are summarised in the article seem to be favourable on the whole.

MR. J. W. SMALL has recorded in the *Ceylon Observer* the occurrence of a cocoa-nut palm at Jaffna, Ceylon, with sixteen branches arising near the base of the plant. A similar instance, but with only five branches, is described by Dr. S. Pulney Andy in the Transactions of the Linnean Society, Botany, xxvi., 661. A list of branched specimens of *Cocos* is given by Morris in the Journ. Linn. Soc., xxiv., 1892, 294, in a paper on the occurrence of branching and forking in palms. Ridley, in the *Annals of Botany*, xxi., 45, and xxiii., 338, enumerates nineteen genera of palms in which branching of the stem takes place, and states that this occurs most commonly in *Cocos nucifera*, although the percentage of branched trees is not large. In most cases the branching appears to be due to the development of lateral buds, and the rapidly growing shoots so produced soon equal in size that from which they originated. It has been stated, though not clearly proved,

that the destruction of the terminal bud by insect or other agency may be followed by the production of lateral buds. No instance of branching in monocarpic palms has been recorded.

A PAMPHLET on the origin of typhoons has been prepared by Mr. J. I. Plummer, chief assistant, Hong Kong Observatory. The author points out that although his paper has not received the imprimatur of scientific opinion, it is at least the outcome of twenty years' experience of typhoons, with exceptional means for their examination. Much still requires to be known about the tracks followed by such storms, the cause of their re-curvature, rate of translation, and frequency. They have been under special observation in the vicinities of Mauritius, Bay of Bengal, Eastern Archipelago, south-east of China, and West Indies. Their frequency varies considerably in these localities; in the Bay of Bengal and the West Indies the storms, the author states, appear to be more noted for their severity than for their number, while the northern part of the China Sea appears to be more troubled by them than any other portion of the globe. Among the main conclusions drawn are, (1) that although the open sea is the point where they become appreciable, the earliest beginnings of typhoons must be sought for on land; (2) that one typhoon is never the cause of another; if several proceed from a limited area within a few days, they are caused by separate impulses; (3) that a typhoon, once formed, does not tend to coalesce with another, but rather repels it, with the result that one becomes intensified at the expense of the other.

IN the second number of the Bulletin of the Calcutta Mathematical Society (1909), recently received, Prof. C. E. Cullis continues his discussion of Möbius's cubic surface, the nature of which was explained fully in the first number. In addition to several other original papers, a translation is given of the late Prof. H. Minkowski's address on space and time, and the notes, abstracts, and lists of current literature render this second number as valuable a book of reference to the mathematician as its predecessor.

AN interesting new "record" in connection with the possibilities of microscopic vision is mentioned in the Journal of the Royal Microscopical Society (April) by Mr. Edward M. Nelson. In 1898 Mr. Nelson observed, for the first time, tertiary markings on the diatom *Coscinodiscus asteromphalus* mounted in realgar in a slide of "Nottingham" deposit. Although he has tested hundreds of objectives with a balsam mount of the same diatom, it has been found impossible to resolve the tertiaries in this medium until a month or two ago, when a new Zeiss's long tube $\frac{1}{2}$ apochromatic of numerical aperture 1.4 rendered them conspicuous. A comparison of this test with the previous ones leads the author to assert that the new lens marks a distinct advance on its predecessors.

UNDER the title "The Most Curious Craft Afloat," Dr. L. A. Bauer gives in the March number of the *National Geographic Magazine* (Washington) an interesting popular account of the work of the non-magnetic yacht *Carnegie*. The article is well illustrated from photographs taken by various expeditions sent out by the Carnegie Institution of Washington, and some of the illustrations enable one to appreciate very thoroughly the difficulties of magnetic survey work in the remote parts of Canada, India, and China.

SEPARATE copies have reached us of several papers which the staff of the Reichsanstalt at Charlottenburg have communicated to the "*Annalen der Physik*" during the last six

months. Amongst them are two which deal with the saturation pressure of water vapour at temperatures outside the range 50°C. to 200°C. , covered by the experiments of Drs. Holborn and Henning in 1908. The first paper, by Drs. Scheel and Heuse, deals with temperatures between 0°C. and 50°C. They use the static method, measuring the temperature by a platinum thermometer and the pressure by the modified mercury manometer we noticed in these columns some time ago. The second paper, by Drs. Holborn and Baumann, deals with the range from 200°C. to 376°C. Temperatures were measured by the platinum thermometer, pressures by a weighted piston moving in a brass cylinder. Except at the highest temperature the three sets of measurements can be represented by formulæ of the type suggested by Thiesen,

$$\text{i.e. } (t+273) \log \frac{p}{760} = a(t-100) - b\{(365-t)^4 - 265^4\},$$

where a and b are constants.

MR. W. P. SEXTON informs us that the value of the specific heat of the first four molecules of water of crystallisation in copper sulphate given by him in his note to the Faraday Society, referred to in NATURE of May 5 (p. 292), should have been 0.449, and not 0.499, as stated in our report.

THE issue of *The Central* for April is a memorial number dealing with the life and work of the late Prof. W. E. Ayrton, F.R.S. The number contains two memoirs by Mr. Maurice Solomon and Prof. T. Mather, F.R.S., respectively, and is illustrated by four portraits of Prof. Ayrton at various ages. A list of Prof. Ayrton's scientific publications completes the number.

THE first parts of two new works dealing, respectively, with "Our Canaries" and "Cage-bird Hybrids," have been received from the office of *Cage Birds*. The works will be published in monthly parts, price sixpence each, and will provide keepers of canaries and breeders of canary mules and British bird hybrids with full details relating to the selection, breeding, and general management of these cage birds, either for pleasure or profit. Coloured plates and other illustrations add to the attractiveness of each work.

THE Sleeping Sickness Bureau, under the direction of its honorary managing committee, has issued a revised edition of its brochure entitled "Sleeping Sickness: How to avoid Infection." The pamphlet is for the use of travellers and residents in tropical Africa, and gives an account of *Glossina palpalis* and illustrations of this and other biting flies. Much useful information is provided as to places where persons are liable to be bitten, and the steps to be taken to abolish and to prevent the spread of the fly.

A COPY of the report of the Indian Association for the Cultivation of Science for the year 1908, which was published in Calcutta last year, has just been received. One of the chief activities of the association is the arrangement of lectures on scientific subjects, and we notice that 286 were given under the auspices of the association during 1908. The association also conducts a chemical laboratory, where students are encouraged to follow systematic courses of work, and arranges for regular meteorological observations to be taken at its observatory and for their publication. The finances of the association appear to be in a flourishing condition. In fact, the officers may be congratulated upon the useful work which is being accomplished under their guidance.

OUR ASTRONOMICAL COLUMN.

THE SOLAR CONSTANT.—In No. 4, vol. xxxix., of the *Memorie della Società degli Spettroscopisti Italiani* Dr. Gorczynski discusses the pyrheliometric observations of the solar constant made at Źrsynova (Polonia) during 1909. The value obtained was 2.05 gr. cal./cm.² min., and, from a discussion of the values obtained at various observatories by different methods, Dr. Gorczynski concludes that this value is very near the truth.

ORIGIN OF BINARY STARS.—In No. 3, vol. xxxi., of the *Astrophysical Journal* Prof. H. N. Russell discusses the origin of binary stars from the point of view that they are produced by the fission of rotating masses. He deduces the conditions of such a mass which would precede and follow the process of fission, and also shows that the available data derivable from existing systems are in accordance with the theory. Finally, Dr. Russell concludes that whilst the development of nuclei in the original nebula must be invoked to account for the formation of star clusters, it is more reasonable to suppose that binary systems have been produced by fission.

THE ASTRONOMICAL SOCIETY OF ANTWERP.—The annual report, for 1909, of the Société d'Astronomie d'Anvers contains a record of much, extremely useful, service performed in the popularisation of astronomy. Popular lectures in French and Flemish were given by various members of the society, and were free to all; further, they were well attended. There is a project on foot to obtain facilities from the town authorities for the erection of a larger observatory, and it is expected that the object will be attained during the present year; the society could then do more than ever to spread the study of the heavens.

The interest in, and general ignorance concerning, Halley's comet displayed by English crowds during the past few weeks engender the wish that more could be done for popular astronomy in England, and the present moment seems favourable; but it could probably only be done by the private munificence of some friend of science. There can be no two opinions as to the urgent need for popular instruction in the oldest of the sciences.

OBSERVATIONS OF HALLEY'S COMET.

THERE is little more to record of Halley's comet yet; as a popular spectacle, in England, its appearance has been somewhat of a failure, and we shall have to wait some little time before the results obtained by astronomers in different countries are available. Some amount of resentment has been expressed in the popular Press at the feeble appearance of the famous comet, but it should be clearly understood that it is our hazy summer skies and the brightness of our northern twilight that are to blame. In a letter to Prof. Turner Mr. Knox Shaw, of the Helwan Observatory, describes it as really a glorious sight, about May 11, far exceeding in its glory comet 1910a; it then had a straight tail 38° long. Yet at Helwan there were only three fine nights during the first fortnight in May.

With his note in No. 20 of the *Comptes rendus* (May 17) M. Esclançon gives four diagrams showing the progressive development of the nucleus and its appendages between February 13 and May 11. On the former date the nebulous head was nearly circular, but the ill-defined nucleus had already two embryo extensions, which gave it a triangular appearance. On April 27 the head was parabolic, with the nucleus a little behind the focus, and two jets forming a broad ∇ streaming behind; there was also a bunch of rays issuing in the shape of a fan towards the sun. On May 10 this aigrette was larger and better defined, having an angle of 70° and a length of about $30'$, but the two rear streamers were not so definite. Up to this time the aigrette had appeared to be symmetrical with regard to the axis of the comet, but on May 11 it was appreciably displaced, the angle between the axes of the aigrette and of the comet being some 20° or 30° . M. Esclançon suggests that this observation might indicate an oscillation of the aigrettes such as was noted during the apparition of 1835. He also remarks upon the great length of tail, which on May 16 was about 65° , corresponding to an actual length of 0.20 astronomical unit.

The observations of M. Borrelly, recorded in the same number of the *Comptes rendus*, indicate what a splendid object the comet has appeared to those situated in a favourable atmosphere. "Very beautiful," "superb," and "magnificent" are the descriptions applied to it as seen at the Marseilles Observatory. The observations extended from April 16 to May 13, and many changes were noted; on April 23 it was seen that the nucleus had a very pronounced red tint. On May 4 the comet was as bright as Markab, and the tail was 15° long. A sudden transformation took place on May 13, when, for the first time, a bright, straight streamer was seen to issue from the rear of the nucleus, dividing, medially, the rectilinear tail, which then had a length of 43°; the extremity of this tail was about as bright as a sixth-magnitude star, and was situated, approximately, in the position R.A. 22h. 6m., dec. +6°; the comet was still visible in daylight.

In order to escape the disadvantageous conditions obtaining in Britain, Prof. George Forbes took a sea trip from Swansea to Savona, and was rewarded by some splendid views of the comet, which he describes in the *Times* for May 31. The observations commenced on May 15, and the head of the comet was never seen, but on May 18 a tail extending for 100° was watched from 2 a.m. until 5 a.m.; this was in long. 9° 38' W., lat. 38° 54' N. On May 15 the 30° tail was about as bright as the Milky Way, but the next morning it was fainter; at times, however, it appeared to brighten. The morning (3 a.m.) of May 17 found it again much brighter for fully 50°, and it could be distinctly traced for a distance of 70°. The tail was perfectly straight, and narrowed down towards the extremity furthest from the sun; across its width its brightness appeared to be quite homogeneous, there being no dark shade along the axis and no rifts. As compared with the tails of Donati's and Coggia's comets it was, so far as Prof. Forbes's memory goes, much brighter and of a much greater length. On May 18 the tail was much widened at the root, where the brightness appeared to be concentrated; the narrowing from root to tip appeared to be more accentuated, and the position of the axis among the stars had not altered from the previous day.

According to Prof. Forbes, the earth was in the tail of the comet on May 19; and, from 2.30 to 3 a.m., a brightening near the horizon and an illumination of the dark edges of dense, black, cumulus clouds were seen by him and by the ship's officers. This was long before any trace of dawn could appear, and all the observers agreed that these peculiar phenomena must be due to light from the comet's tail; the ship was then in long. 7° 54' W., lat. 36° 36' N. The same phenomena were repeated on the following morning. It should be noted that at the time of writing his notes (May 24) Prof. Forbes had not seen any reports, concerning the cometary observations, since the S.S. *Kinsale* left Swansea on May 13.

In a letter received from Mr. G. W. Grabham, dated Khartoum, May 19, the writer remarks how feeble the accounts of British observations of the comet appear to one who has observed it in lat. 15° 36' N. He first saw it on April 19, when it was a conspicuous object, with a tail broad in proportion to its length. With field-glasses he could make out some 2½° or 3° of tail, and beyond that there was a faint glow extending about 2° further. A letter sent by Mr. Grabham to the *Sudan Times* caused a number of people to wait up for the comet, and it was easily seen by many on subsequent mornings, until it became more difficult owing to bright moonlight. After the moon waned it was quite a striking object, and, on the mornings of May 12 and 13, its tail stretched half-way to the zenith. An article on the comet, written by Mr. Grabham, appears in the *Sudan Times* in both English and Arabic.

Mr. Leach also sends us a further report and a drawing of the comet as seen with field-glasses on May 20, at 7.45 p.m., at Malta. On May 17 and 18 the comet was well seen, except the head, which was eclipsed by a search-light beam from the forts; but the tail was seen, and, on the latter date, extended to a distance of about 95°. The sketch made on May 20 shows the nucleus surrounded by a misty halo which has the shape of a pair of horns, with the nucleus on the forehead. On May 21 about 20° of tail was seen, but this faded as the moon got brighter, and

on May 22, 23, and 24 the comet was seen without any signs of a tail.

A number of notes on the comet appear in No. 21 (May 25) of the *Comptes rendus*. M. Eginitis records the observations made at Athens on May 18 and subsequent days. On the morning of May 20 the tail was seen in exactly the same position as the previous night, and in the evening was seen, in the telescope, as turned towards the sun. On account of its curvature it was not seen in the east on Saturday morning (May 21), but in the evening was seen turned towards the east. M. Eginitis is of the opinion that the earth's passage through the tail was either greatly retarded or did not take place; nor were any signs of the head apparent as it transited the sun's disc.

M. André reports that the preparations for astronomical observations of the passage were rendered nugatory by clouds, and that the electrometers and magnetometers recorded no abnormal action.

Acting upon M. Guillaume's suggestion, M. Georges Claude attempted to trace cometary matter among the residual inert gases left from the liquefaction of air. With his apparatus at Boulogne-sur-Seine he is able to treat 350,000 litres of air per hour, and to detect the presence of one-millionth part of any extraordinary gas. Experiments carried out on May 17 (4 hours), 19 (9h. to 12h., Paris M.T.), 20, and 23 failed to reveal any difference of density in the residue greater than the probable error of observation.

MM. Angot, Lebel, and Limb and Nanty, all report

Apparent path of Halley's Comet, May 29-July 16.

slight electric and magnetic disturbances registered at their observatories during the computed time of the earth's passage through the tail of the comet; but in no case was the disturbance extraordinary, nor could it be attributed to any abnormal condition produced by the comet.

The following is a further extract from the daily ephemeris published by Dr. Ebell in No. 4411 of the *Astronomische Nachrichten*:-

Ephemeris for 12h. Berlin M.T.

Date	α (true) h. m.	δ (true)	Date	α (true) h. m.	δ (true)
June 2 ...	10 04 ...	+1 34.2	June 26 ...	10 43.0 ...	-2 20.1
" 6 ...	10 13.7 ...	+0 23.1	" 30 ...	10 46.7 ...	-2 41.8
" 10 ...	10 22.6 ...	-0 25.4	July 4 ...	10 50.1 ...	-3 2.6
" 14 ...	10 29.2 ...	-1 1.8	" 8 ...	10 53.3 ...	-3 22.8
" 18 ...	10 34.5 ...	-1 31.5	" 12 ...	10 56.4 ...	-3 42.8
" 22 ...	10 39.0 ...	-1 57.0	" 16 ...	10 59.5 ...	-4 2.9

The estimated magnitudes decrease from 1.0 on June 2 to 4.6 on July 16, while the distance from the earth increases from 52 to 197 millions of miles.

The apparent path among the stars is shown on the accompanying chart, but owing to its increasing apparent proximity to the sun and its decreasing magnitude the comet will be observed with difficulty during the later part of the ephemeris. The planets Mars and Jupiter are also shown, but Mars will set at about 10 p.m. on June 25 and about 2½ minutes earlier each succeeding day, whilst Jupiter sets at about midnight at the end of June.

A NUTRITION LABORATORY.

ATWATER'S development of apparatus for the exact measurement of the heat given off by the human body under varied conditions of food-supply and activity is well known. Prof. F. G. Benedict, who cooperated with Atwater, has continued similar observations as director of the Nutrition Laboratory in Boston, which is devoted exclusively to work of this type, and is well endowed by the Carnegie Institute for that purpose. The calorimeter equipment of this new laboratory, as described by Benedict and Carpenter in a recent publication,¹ affords remarkable evidence of the value that may be secured by giving a mature investigator a free hand in the organisation of means for furthering standard research of the type in which he is most interested.

Two "respiration calorimeters," shown in the accom-

panying photograph, have been constructed, and are in use for observations upon subjects of different physiques and different conditions of health continued over periods of several hours. Others are being constructed for more prolonged observations, occupying days, under varied conditions of rest and work. In their construction a rare amount of successful attention to minute detail has secured perfect instruments showing at every point substantial improvements upon the original pattern. As tested by the combustion of known quantities of ethyl alcohol within these chambers, the errors in estimating the amount of oxygen consumed, the carbonic acid and water vapour given off, and the output of heat, have been reduced to less than 0.5 per cent. The tests were made with the apparatus arranged as for an actual experiment, and the difficulties surmounted may be gathered from the fact that, through the "closed circuit" formed by the calorimeter chamber and a series of water and carbonic acid absorbers,

75 litres of air are driven per minute over periods of hours without leakage of material or of heat. The heat issuing from the subject is carried out of the chamber along one definite channel by a stream of water traversing a "radiator system" within the chamber, and is accurately measured by weighing the escaping water and observing its temperature increment. The ingenuity displayed in modifying known thermometric methods in the interests of these observations, and in obtaining continuous records of temperature differences, is in itself remarkable.

In the accompanying illustration are shown some of the internal fittings of the large constant temperature room in which the calorimeters are housed, the "oven-like" structure on the right being the "bed-calorimeter" into which a recumbent patient is inserted upon a stretcher. In the background is the "chair calorimeter," into which the subject enters by the roof, and in the foreground are

General View of the Calorimeter Room in the Nutrition Laboratory in Boston.

placed the absorber systems and large balances used in measuring their increments of weight.

SEWAGE DISINFECTION.¹

IN view of the prominence at present given to the question of the disinfection of sewage and sewage effluents, the publication of the results of Prof. Phelps's latest investigations on the subject is undoubtedly of great interest to those engaged in public-health work.

It is stated in the introduction that the investigations on which the report is based were conducted by the author at the Sanitary Research Laboratory and Sewage Experimental Station at Boston, Mass., and in collaboration with the author by Mr. Francis E. Daniels at the sewage disposal works at Red Bank, N.J., and by Mr. Ezra B. Whitman at

¹ "Respiration Calorimeters for Studying the Respiratory Exchange and Energy Transformations of Man." By F. G. Benedict and T. M. Carpenter. Pp. viii+102. (Washington: Carnegie Institution, 1910.)

¹ "The Disinfection of Sewage and Sewage Filter Effluents, with a Chapter on the Putrescibility and Stability of Sewage Effluents." By E. B. Phelps. Pp. 91; 39 tables, 1 plate. (Washington: Government Printing Office, 1909.)

the Walbrook testing plant at Baltimore, Md., under co-operative agreement with the Massachusetts Institute of Technology, the State Sewerage Commission of New Jersey, and the City Sewerage Commission of Baltimore.

After considering the various possible methods of disinfection, and referring to numerous investigations made in America, England, and on the Continent, the author concludes that, in the absence of further information in regard to the possibilities of heat (with consequent recovery of ammonia) and of organic compounds, chlorine compounds are most applicable in the case of the disinfection of sewage and sewage effluents. The authors' large-scale experiments were therefore confined to the disinfection, by means of chloride of lime, of sewage, septic sewage, and effluents from trickling filters.

In common with other workers, Prof. Phelps finds that whereas treatment with comparatively small quantities of chlorine fairly readily eliminates 95 per cent. or more of the total organisms present, complete sterilisation can only be obtained with difficulty and at relatively very much greater cost, which he concludes would render it impracticable for regular adoption. Pages 39 to 46 and 56 to 60 deal with the disinfection, by means of chloride of lime, of effluents from trickling filters at Boston and Baltimore respectively.

The experiments at Boston refer to the disinfection of the total effluent (5000 gallons in twenty-four hours) from two trickling filters 50 feet square and 8 feet deep. The work extended over a period of seven months, including both winter and summer months, so that the results obtained may be taken as average results under working conditions.

It was found that with two hours' storage the addition of 3.5 parts per million of available chlorine (in the form of bleaching powder) was sufficient to effect a reduction, on the average, of 96.8 per cent. and of 99.2 per cent. of the total organisms at 20° C. and of *coli* organisms respectively present.

In consequence of the greater purity of the Baltimore filter effluent, similar results to the above were obtained with the addition of less chlorine, viz. 2.2 parts of available chlorine per million.

As a result of the experiments on the disinfection of Boston sewage and of septic sewage at Red Bank, N.J., the author concludes that an average of 7 or 8 parts per million of available chlorine is sufficient to disinfect the sewage, whereas the septic sewage requires from 10 to 15 parts per million, this increased amount being mainly due to the presence of sulphuretted hydrogen.

On this account it is stated in the conclusions that where no purification is required beyond that given by septic action and by disinfection, it is advantageous to reverse the process by disinfecting the crude sewage before it enters the tank.

In this connection it is interesting to note the author's remarks on p. 56:—"There would be a great multiplication of bacteria in the tank, so that the number in the final effluent would probably be as great as in the raw sewage, and perhaps even greater. Nevertheless, the disinfection could be as effective on the pathogens as if it were applied as a final process. The subsequent development of saprophytes would have no sanitary significance, and would doubtless be of real value in the subsequent self-purification of the organic matter after it had been discharged into the stream."

The available evidence is favourable to this assumption, but further information is required in regard especially to the significance of the further development of organisms.

It is also interesting to observe that the investigations of the author have led him to revise his earlier views in regard to the use of electrolytic hypochlorites, and to conclude that, taking all things into consideration, it is preferable to use bleaching powder as a source of chlorine rather than to instal an electrolytic plant at the works. For many reasons this conclusion will meet with general approval on the part of those in charge of sewage works.

A table of carefully considered costs is given, on the basis of disinfecting 5,000,000 gallons per day by means of bleaching powder, from which it will be seen that the author estimates the total cost of treatment at from 2s. 2d. per million gallons (1s. 3d. cost of bleaching powder) for

the addition of 1 part of available chlorine per million, to 21s. per million gallons (18s. 9d. cost of bleaching powder) for 15 parts of available chlorine per million.

These costs include the cost of chloride of lime, storage tanks, labour, &c., and are much lower than those given for treatment with electrolytic hypochlorites produced at the sewage works by Digby (the *Surveyor*, vol. xxx., No. 778, p. 687) and Shenton in 1906, and recently repeated by Shenton (the *Sanitary Record*, vol. xliii., No. 1013, 1909, p. 392), which vary from 3s. 9½d. per million gallons for the addition of 1 part available chlorine per million to 19s. for 5 parts available chlorine per million, exclusive of charges for plant, storage tanks, and labour.

This difference in cost is accounted for by the fact that the latter investigators estimate the cost of available chlorine produced electrolytically at the works at 10d. per kilogram, whereas, using bleaching powder, it should not exceed 3½d. per kilogram.

While Prof. Phelps's investigations afford very valuable information and add considerably to the literature on the subject of sterilisation of sewage and sewage effluents, his suggestions in regard to the degree of disinfection are open to objection, especially when applied to English conditions.

In considering this matter, the difference between American and English conditions must be borne in mind, not only in regard to the chemical composition and bacterial content of the sewage or effluent, but also to the probably more important point of the conditions of discharge.

Speaking generally, from both points of view American conditions are the more favourable, as not only is the sewage more dilute, but also, as a rule, the relative volume of the river into which the effluent is discharged is much greater than in the majority of English cases.

In the case of the Boston sewage experimented upon, the bacterial content was only 5,000,000 per c.c. as compared with from 20,000,000 to 30,000,000 per c.c. in the case of an average English domestic sewage.

Further, it has been found that English effluents of satisfactory chemical composition may contain as many as 100,000 *coli* organisms per c.c.

It is therefore doubtful whether such a degree of disinfection as proposed by the author might not in certain cases give rise to an undue sense of security, especially as no reference is made to the treatment of the large volumes of storm-water which are discharged direct to the rivers, from numerous storm-water overflows, a question which is intimately connected with the subject of the disinfection of sewage effluents.

In the final chapter is described some very interesting work carried out in connection with the methylene blue test proposed by Spitta. With preliminary standardisation for any particular effluent, this test would appear to afford, in a very simple manner, valuable information in regard to the stability of sewage effluents. As carried out by the author, the test allows finer distinctions to be drawn between stable and unstable effluents than is the case with the ordinary incubation test, which classes an effluent either as non-putrefactive or putrefactive, without reference to the degree of putrefaction. It would be interesting to know how far such a colour test is applicable to the effluents from trade sewage.

EDWARD ARDERN.

OCEANOGRAPHICAL INVESTIGATIONS IN THE ATLANTIC AND MEDITERRANEAN.

WE are informed that a Danish expedition has just set out from Copenhagen with the intention of carrying out renewed investigations along the Atlantic Slope and in the Mediterranean. The leader of the new expedition, as of the earlier Danish expeditions, will be Dr. Johs. Schmidt, who is well known for his previous Atlantic work, especially on the eel, and he will be accompanied by the following men of science:—J. W. Nielsen, hydrographer; C. H. Ostenfeld and O. Paulsen, plankton specialists; Sven Palitsch, specialist in chemistry from the Carlsberg Laboratory in Copenhagen; and a biological assistant. The vessel is the research steamer *Thor*, of the Danish Government. During the first part of the cruise,

in the waters of Iceland and the Færøes, the investigations will have a more official character, being carried out at the expense of the Danish Government and as part of the international scheme of work. The second part of the cruise will set out in the beginning of July from some English port. The expenses of this portion of the expedition will be defrayed partly by the Carlsberg Institution of Copenhagen, which does so much for the promotion of science in Denmark, partly from private sources.

Both in the Atlantic and Mediterranean the expedition will work over waters which have been already, for a great part, investigated by the *Thor*. It is not proposed to devote much time to the Atlantic region south of Ireland, and there is the less reason for doing so as previous workers, especially the Prince of Monaco, Schmidt, and the Irish investigators, have already done so much there. Nevertheless, a series of deep-sea hydrographical observations from the south of Ireland to the coast of Morocco, continuous with similar series from Iceland to Ireland and through the Mediterranean, will be of extreme interest, both in biological matters and as a further contribution towards understanding the circulation of the waters of the Atlantic and the adjacent seas.

In the Mediterranean, on the other hand, the hydrographical and biological conditions are only imperfectly understood. As is well known, the Mediterranean is an almost completely land-locked and independent ocean, with an average depth of more than 1000 fathoms, descending at places to 2000 fathoms. This huge basin is connected with the Atlantic at the Straits of Gibraltar by a narrow sill or threshold, which is only 200 fathoms deep. Any mixing of the Atlantic water with the Mediterranean water can therefore only proceed on the surface, and the renewal of the deeper layers, which is necessary for the development of an abyssal life, and which actually does take place, can only be due to the conditions, evaporation, convection currents, but mostly wind influence, prevailing in the Mediterranean itself. On the other hand, it seems certain from earlier investigations that the deep water of the Mediterranean, which is much more saline than the Atlantic, occasionally or normally wells up over the threshold at the Straits and flows out into the Atlantic as a deep-water current with a northerly direction. A further interesting topographical feature of the Mediterranean is that it is divided into two deep-water basins by a submarine ridge, which stretches across between Sicily and Tunis, and is only about 150 fathoms deep. The circulation of the waters within the two deep basins west and east of this ridge must therefore be for the most part independent. The determination of the character of the water in the two basins, in all layers from the surface to the bottom, promises results of more than usual interest.

The hydrographical observations will be of two kinds, physical and chemical. The temperature and salinity will be determined, as also the direction and strength of the currents, in all depths from surface to bottom, in accordance with the most modern methods employed by the international investigations. Entirely new methods have also been recently worked out by Danish men of science at the Carlsberg Laboratory in Copenhagen for the determination of the chemical composition of sea water, for example, the dissolved gases (O, N, CO₂) and the alkalinity (concentration of H-ions). It is probable that these new methods will throw fresh light upon the factors determining the differences in the occurrence and appearance of the organic life at different depths and in different waters, differences which the salinity and temperature by themselves cannot explain. It is obvious that the waters mentioned in the Atlantic and Mediterranean offer exceptional opportunities for such an investigation.

On the biological side, the investigations will be on the lines followed by the International Council for the Study of the Sea, and will be directed, in the first place, to the elucidation of the life-histories and biological conditions of the principal fishes. The advantage of making investigations over a wide area, as from Iceland to Morocco and the Mediterranean, is just that the differences in the physical conditions are marked on a large scale, and can be connected directly as cause to effect with the very distinct differences in the occurrences and biological phenomena of all organisms, from the floating plankton to the

fishes. One of the most interesting problems here will thus be to determine the relation between the Atlantic and Mediterranean faunas, how far the latter is dependent, if at all, on the former, and the differences in the abyssal life of the two regions, all in connection with the physical and chemical differences.

A NEW AMPEREMETER.

A NEW aperiodic millivolt and amperemeter for continuous and alternating currents has been brought to our notice by Messrs. Isenthal and Co. The operation of the instrument is based on methods already described by Drude and Klemenčič, in which the current to be measured is caused to heat up thermojunctions, thus setting up indirectly a current which actuates the movement of the instrument. The novelty in the present instrument consists in the arrangement adopted for combining the action of a number of thermojunctions in such a manner that thermocurrents are produced of sufficient magnitude to deflect an ordinary pivoted moving-coil instrument.

The thermocouples are placed in the four arms of a Wheatstone's bridge, the movement being connected to two opposite corners of the bridge, and the leads carrying the current that is to be measured to the remaining corners. The polarities of the thermocouples are so chosen that when the bridge is warmed up by the passage of a current the electromotive forces set up in the four arms conspire so as to send a current through the movement. The arms of the bridge are adjusted so that the thermoelectric current passes through the movement without entering the external circuit, and the current from the external source passes through the thermocouples without affecting the galvanometer.

As the deflections of the instrument depend on the heating effect of the current to be measured, it should give correct readings for direct current or alternating current of any wave-shape or frequency. It seems that sources of error might be introduced by Peltier effects and changes of temperature of the surroundings, and it would be interesting to learn to what extent such errors are appreciable, and in what manner they have been compensated for.

The sensitiveness of the meter is 225 millivolts with a current of 1 ampere, and its range as an amperemeter can be increased to any extent by the use of shunts.

GEOLOGY OF THE LONDON DISTRICT.

THE Geological Survey cannot well be charged with neglect of London, except in the matter of six-inch maps, a want that will probably be soon seen to. From 1864 to 1906 various memoirs were issued which deal, though sometimes only partially, with the geology of London and the neighbourhood. Two of these, however, treat of the whole district and the whole of its geology, and now we have a third, in which the results reached by many workers are given up to date.

This memoir may be said to have been done by Mr. Woodward to celebrate his retirement from office, more than a year ago, and a remarkably good celebration it is. From its very low price it is within the reach of all students, and we may hope that its author may live to edit many editions.

The area described is that covered by the lately published four sheets of the new geological map of London, some errors in which are duly noted on p. v. After a general account of the area, five pages are given to an account of the various beds beneath the Chalk, which do not come to the surface here, their presence underground having been proved only by borings. These consist of Devonian rocks, at the base, Red Rocks of doubtful age,

¹ Memoirs of the Geological Survey. The Geology of the London District. By H. B. Woodward, F.R.S. Pp. viii + 142 + plate. (London: His Majesty's Stationery Office: E. Stanford; Edinburgh: W. and A. K. Johnston, Ltd. Dublin: Hodges, Figgis and Co., 1909. Price 1s.

Great Oolite beds, possibly some Lower Greensand, and in every boring Gault and Upper Greensand. The omissions in the series are notable; we have no certain Carboniferous rocks, only a possibility of Trias, no Lias, only one division of the great Jurassic series, and no Wealden beds, a perfect succession being reached only with the Gault.

To the description of the Chalk nine pages are given, and as the Middle and Lower divisions are found only underground, in borings, these are concerned chiefly with the Upper Chalk. The zones of the whole formation, with the distinctive fossils, are noted.

The Eocene Tertiaries, which form so large a part of the district, take twenty-five pages for their description, which are followed by four pages on faults and disturbances, after which the various members of the great Drift series, so greatly in evidence in the district, are described at some length, the Older Drifts with eleven pages to their credit, the Glacial (and allied) Drift with thirteen, whilst the description of the Valley Drifts, with their flint implements, extends to twenty-three pages.

The stratigraphic series ends with Recent beds, the Alluvium of the rivers being described in eight pages, after which the remaining ten pages of the chapter treat of some other matters, namely, a description of the Thames, its tributaries and its buried rivers, floods, fords, old trackways, a short account of the growth of London, and a summary of the physical changes in the district from the time of the deposit of the Chalk to the formation of the Alluvium.

The question of water-supply from the various beds is discussed in nine pages, and various other economic questions in other ten, which conclude the work, except for the lengthy index.

The plate is a contour-map of the district, with a geologic section from the valley of the Gade, on the north-west, to beyond that of the Darent, on the south-east.

At the end of the various subjects a list of the chief works relating to each is given, and this will be of much use to those who want further detail. But with this memoir in hand nearly everyone may know as much about the geology of London, using that name in a wide sense, as he needs to know.

ECONOMIC ENTOMOLOGY.

IN the last number of the *Journal of Economic Biology* (vol. v., pp. 9-17) Mr. W. E. Collinge gives some interesting notes on the form of the egg of the horse bot-fly (*Gastrophilus equi*), its attachment to the horse's hair, and the method of its hatching. The narrow end of the subconical egg is not simply glued to the hair; it clasps the hair by means of a pair of ridges or lips, so that the area of attachment is like that of the ox warble-fly (*Hypoderma bovis*), only less specialised. With regard to the mode of hatching, Mr. Collinge's observations and experiments confirm, in the main, the statements of Bracy Clark and Osborn. He found that the eggs were most readily induced to hatch by the application of moisture, from sixteen to twenty days after hatching; none could be induced to hatch after thirty-six days.

Mr. R. Newstead describes in the same part (pp. 18-22) a couple of new species of Coccidæ from the Congo, which live as guests of ants (*Cremastogaster* and *Sima*) in their nests in the hollow shoots of plants. It is very rarely that insects of this family are found in the hollow stems of their food-plants. One specimen contained a minute lepidopterous larva which had partly destroyed its host.

It is well known that economic entomologists in North America are much troubled by the ravages of insects purposely or accidentally imported into their country from Europe; one of the most famous of these is the gipsy moth (*Porthetria dispar*). Dr. L. O. Howard has lately (U.S. Dept. Agric. Bur. Entom., Tech. Ser., 19) described some parasites reared from the eggs of this insect. It is remarkable that the parasites—various species of minute Hymenoptera—all come from Hungary, Russia, and Japan. From Gipsy-moth eggs imported from western Europe no parasites could be reared, and, though the moth has been in the

United States for more than forty years, no American species is known to attack its eggs. "Non-parasitism of *P. dispar* by native species," writes Dr. Howard, "is probably due to the character of its egg-mass, which is so compact and so thoroughly protected by the scales of its parent as possibly to disguise its character from species unacquainted with it." G. H. C.

ALTERATIONS OF THE DEVELOPMENT AND FORMS OF PLANTS AS A RESULT OF ENVIRONMENT.

THE fungus *Saprolegnia* is chosen as an example among the lower plants. This fungus lives on dead insects, and shows three distinct stages of its development:—(1) vegetative growth of the mycelium; (2) asexual reproduction by motile zoospores; (3) sexual reproduction by male and female organs. Under ordinary conditions these three stages follow one another quite regularly until, after the ripening of the resting spores, the fungus dies; but, according to the special conditions of every stage, it is possible to produce them as we desire, and also to alter their succession. Under very favourable conditions of nutrition the fungus must continuously grow, without being propagating and without dying. Numerous other lower plants, as fungi and algæ, show the same relations to environment.

Flowering plants present far more difficulties, in consequence of their very complicated structure. *Sempervivum Funkii* is taken to show how far the development of such a plant depends on environment. *Sempervivum* appears as a short stem covered with thick sappy leaves; we call this form a *rosette*. The rosettes produce in an asexual way new daughter-rosettes, of which each comes to flower under suitable conditions, and dies after the ripening of seeds. The state of a plant, destined to flower but without recognisable rudiments, is called *ripe to flower*. The formation of the inflorescence consists of three essential stages:—(1) the lengthening of the stem; (2) the production of several branches at the top; (3) the birth of flowers.

Under very favourable conditions of nutrition, a rosette ripe to flower can be transformed again into a vegetative one, which must always grow without sexual reproduction. In blue light, during March and April, a lengthening of the rosette ripe to flower takes place, but without flowering. Such a lengthening of the stem is wholly independent of flowering, because all rosettes, also the youngest ones, are able to lengthen in red light. On the other hand, the flowers can result without lengthening when the rosettes are exposed to a high temperature. The production of flowering branches can be prevented, the inflorescence at the end having but a single flower. In other conditions numerous branches are to be found on the whole stem, even in the axils of the old leaves, particularly as the result of injuries.

We come to a new series of forms by replacing flowers by leaf-rosettes, which can be produced on all parts of the inflorescence, even on the flowering branches, alone or mingled with flowers. The plants, of which the inflorescence bears rosettes, do not die at the end of summer as is normal, but live another two or more years, appearing in peculiar forms. It can be shown that flowers vary in an exceedingly high degree under certain conditions. The number and arrangement of all members as sepals, petals, stamens, and carpels can be altered. Further striking variations of the normal forms appear in such artificially modified flowers by the transformation of sepals into petals, of petals into stamens, of stamens into petals and into carpels. Experiments were made to answer the question whether alterations of flowers can be transmitted. For such researches *Sempervivum acuminatum*, which produces easily ripe seeds, was used. The seeds of flowers artificially altered and self-fertilised gave rise to twenty-one seedlings, among which four showed surprising deviations in their flowers. With two seedlings all the flowers were greatly altered, and presented some of the alterations of the mother plant, especially the transformation of stamens into petals. The experiments are being continued.

¹ Abstract of the Croonian Lecture delivered at the Royal Society on May 26 by Prof. G. Klebs.

PLANTS OF SCOTTISH LOCHS.¹

AN interesting account of the lochs of Kirkcudbrightshire, Wigtownshire, Fife, and Kinross, and the plants that grow in them and on their shores, is given by Mr. G. West in a paper recently published by the Royal

Dortmanna, &c., which are usually associated with peaty water, are absent.

Wigtownshire, which is remarkable for its great tracts of treeless peat-moor, affords examples of both kinds of lochs. Those sheets of water that are situated on the open moors resemble highland lochs in their general features.

Those lakes that are within the zone of active agriculture are decidedly of the lowland type.

In Fife and Kinross a few lochs of a semi-highland character may be found on the higher hills. The greater number of the lochs in this district, however, are distinctly of a lowland type, and many of them have a very rich flora, comparatively rare plants often occurring in great abundance; the greater number, however, have had their natural features considerably altered by the hand of man. In some parts new lochs have been created by the construction of dams, &c. In other places shallow sheets of water that could be put to no useful purpose have been drained, and the sites utilised for agriculture, whilst in a few cases lochs are used as receptacles for sewage. The only lochs of this area that retain their natural conditions are the smaller ones on the Cleish Hills.

On account of the comparative lack of knowledge respecting the ecology of aquatic and semi-aquatic plants, the author considers that it is premature to attempt at present the grouping and generalising of sets of observed phenomena relating to their distribution.

In the seven areas investigated, about 175 lochs have been visited; these vary in size from what are practically inland seas, such as Loch Ness, to mere ponds, like Lochan Diota. These lochs have to a considerable extent their individual floristic peculiarities, and this fact inhibits

FIG. 1.—An example of a wind-exposed highland loch—Loch Grennoch (by Cairnmore of Fleet). View from the north-west end, looking south. The sandy bays are not well shown as the scale is so small. This loch has scarcely any littoral vegetation.

Society of Edinburgh. This is the author's second paper on the botanical aspects of Scottish lochs, and includes many valuable details relating to the districts investigated. The systematic list of plants shows the distribution of each plant in all the areas studied, and other particulars. Details are given respecting the physical characteristics of each loch and its surroundings, and everything of interest is described from a botanical point of view, especially the plant associations.

The lochs of north-west Kirkcudbrightshire are chiefly of the highland type, i.e. having considerable elevation above sea-level, water more or less peaty, barren sandy or stony shores, scarcity of those plants having leaves that float on the surface, and having such marsh vegetation as may exist chiefly on the western side, because, owing to the prevailing westerly winds, the erosive power of the waves on the eastern shores prevents the development of a littoral flora there, besides which many plants associated with the richer food supply of the lowland lochs are absent.

In south-east Kirkcudbrightshire there are comparatively few lochs, and these are mostly of the lowland type, i.e. having a relatively small elevation above sea-level, non-peaty water, muddy or marshy shores which are frequently covered with marsh plants, an abundance of plants with floating leaves, and, although large lowland lochs usually have their marsh vegetation chiefly on the western shores, such is not the case with small lowland lochs, besides which certain plants such as *Isoetes lacustris*, *Lobelia*

FIG. 2.—An example of a large loch the wind-heltered western margin of which has an abundant vegetation—Loch Ken. View near New Galloway from the west shore looking north, showing a large association of *Nymphaea lutea* extending along the loch for about a quarter of a mile outside a zone of *Scirpus lacustris*. The water over the *Nymphaea* area is from 2 to 7 feet deep.

the process of condensation of such features into a short summary. The lochs may, of course, be grouped in accordance with their striking physical characteristics, such as elevation above sea-level, exposure to wind, nature of shore, depth of water, condition of the bottom, whether rocky, stony, sandy, clayey, muddy, &c., kind of water,

¹ "A Further Contribution to a Comparative Study of the Dominant Phanerogamic and Higher Cryptogamic Flora of Aquatic Habit in Scottish Lakes." By George West. With 62 plates. Proc. Roy. Soc. Edin., sess-ion 1909-10, vol. xxx., part ii., No. 6. Pp. 65-181. Price 14s. 3d.

whether peaty or non-peaty, rich or poor in plant food-salts, &c.; and these characters very largely depend upon the physiographical features of the surrounding country. When the combination of such factors respecting any loch is known, the plants likely to be found there may be

flora, but between the flora and fauna as well; and it is at present impossible to set down a complete satisfactory statement of the ecology of any single group of aquatic plants. We must, therefore, for the moment leave the final generalisation of the causes which govern the distribution of plants, and content ourselves with the routine work of taking evidence of that which occurs, not being too eager to surround ourselves with metaphysical hypotheses which seek to explain the observed phenomenon by a noumenon, nor to cloak our ignorance and delude our senses with vague concepts that transcend actual demonstration, and, when analysed, explain to our intelligence nothing whatever.

Again, the restriction of certain plants to particular localities may be accounted for by observing that they are ill adapted for any mode of dispersal to which they are likely to be subjected; it is then difficult to understand their introduction to their present situation. It is not easily explained why *Equisetum limosum*, *Carex rostrata*, *Phragmites communis*, and others, should be so widely distributed about the margins of all kinds of lochs, whereas *Cladium Mariscus*, an equally dominant species, should be restricted, in the areas under discussion, to a few places in Wigtownshire. When the subsistence of plant-ecology has taught us the full facts regarding the relationship existing between organism and environment, then shall we be able to generalise sets of phenomena regarding the geographical distribution of water plants to some useful purpose.

FIG. 3.—An example of a small, somewhat wind-sheltered semi-highland loch the western margin of which has a zone of marsh vegetation—Loch Dow, Cleish Hills. View of the west side from the south end, looking north-west, showing *Carex rostrata* bordering the west side of the loch. The darker patch standing out of the water on the right is an association of *Equisetum limosum*.

roughly indicated, but this apparent simplicity is frequently modified by other agencies.

The laws which govern the geographical distribution of aquatic plants cannot be fully understood until science has revealed more facts regarding the ecology of the plants than it at present possesses; it is therefore futile to attempt the deduction of general laws, with only an inadequate knowledge of the phenomena to be generalised. During the last great Glacial epoch it is certain that all forms of the higher plants were banished from the greater portion of Scotland. Towards the end of that era, as the mantle of ice and snow began to retreat, so would plants encroach again over the country from the region to the south, where its influence had been less severe. What precise causes influenced most this gradual northward march of aquatic and terrestrial plants cannot now be determined, but probably they were such as affect the distribution of plants at the present day. The plants no doubt followed the lines of least resistance and greatest traction, not only in their geographical advance, but also in their adaptations of structure and function to the varying environments. These lines must necessarily be ramified and involved, perhaps to an insoluble degree; yet on them are the secrets of plant geography to be discovered, on the basis of physiological anatomy and plant psychology.

By such methods a most interesting inquiry would be, What is the equilibrium that has been attained between the forces of resistance and traction that has caused certain species to arrive at, and remain in, restricted areas? This is a subject bristling with difficult chemical and physical complications, combined with the various influences resulting from the never-ceasing action and reaction, not only between the different members and associations of the

The study of the plants of the lochs suggests that aquatic plants have not always had their origin from terrestrial forms that had been forced into the water by more robust competitors on the land, as is sometimes stated, but, more probably, because certain mutable forms

FIG. 4.—An example of a small and shallow lowland loch having an abundant vegetation—Otterston Loch, showing a portion of a large association of *Polygonum amphibium* on the water in the foreground, and the bank below the trees covered with marsh plants, such as *Carex rostrata*, *C. paniculata*, *Phalaris arundinacea*, &c.

have exhibited a tendency, as some do even now, to take on the aquatic habit, that mode of living being more agreeable to their requirements. Some plants form themselves into dense associations consisting of one species only, which spread over considerable areas, and not only prevent others from growing amongst them, but year by

year extend their borders at the expense of neighbouring plants. In the vanguard of such colonies there is doubtless very keen competition for the space, and the weaker or less suitably adapted species will be slowly driven before the stronger. This, however, is unlikely to go on continuously, because the stronger species will sooner or later meet with physical or chemical barriers which it is ill adapted to overcome, but to which the weaker species may be better adapted. Quite commonly, it is not that competition for available space is so great, but that the local conditions favour the dominant growth of a few individual species. One frequently finds normal terrestrial or marsh species taking on the aquatic habit: instance *Ranunculus Flammula*, *Juncus supinus*, *J. acutiflorus*, *Peplis Portula*, &c., but always of their own free will, so to speak, i.e. by the exercise of the subtle power of adaptability, which is more or less the common possession of all plants.

From another aspect of this interesting subject it appears that other causes for variation, with the consequent production of new forms, lie in the fact that although the conditions for plant life are so often remote from the ideal, yet the plastic power possessed by plants, enabling them to adapt themselves to the various combinations of edaphic and climatic conditions, is so great that there are comparatively few spots, where existence is possible, in which some plant or other is not able to thrive and carry on its metabolic activities. Now in order to maintain a proper tone of health, a plant has of necessity to respond in suitable ways to all the varying external impressions. A plant is therefore in a constant and continual state of change, owing to the never-ceasing mechanical, physical, and chemical changes of its unstable environment. The plastic nature of many plants enables them to modify their organs in reciprocation to any fairly constant set of environmental conditions, and it is in this endeavour to accommodate themselves for the maintenance of healthy existence in places that are either inhospitable or too luxurious that certain deviations, either fixed or transient, from the usual forms of more normal environments are to be accounted for, and such variations occur in almost every loch. That some of such variants may doubtless be concerned in the origin of new species and varieties is the impression received, but other causes also contribute towards that process.

The rapid increase of aquatic and marsh plants in reservoirs that are used for the public water supply is occasionally a matter of anxiety and expense to the owners. Enormous sums of money are frequently paid by public bodies for advice respecting the construction of reservoirs to persons wholly unacquainted with the local geological features, as well as with the flora and fauna of the district. Whilst it is very unwise to construct a reservoir over a geological fault and expect it to hold water (and this has been done), it is equally vain to make a shallow reservoir in the line of the constant migration of water-fowl (i.e. between their resorts) and expect it to maintain a freedom from water plants. The greatest depth at which aquatic plants will flourish in Scottish waters is about 40 feet. It is very unlikely, however, that the species capable of growing at such a depth will ever become a nuisance in a reservoir; but at a depth of 20 feet it will be found that, in suitable water, many species capable of giving trouble will flourish. Upon consideration of these facts, it seems advisable, as a prevention against the development of water plants, to construct reservoirs with sides so steep that a minimum depth of from 20 to 25 feet will be maintained within a few yards of the margin. Moreover, the sides, unless of natural rock, should be faced with stonework, which will further impede the growth of plants, as well as prevent discoloration of the water by wave-erosion.

The 124 figures contained in the present paper, together with the 110 which illustrate the author's previous publication on the same subject, form an interesting and instructive series of views of the vegetation of Scottish lochs from an ecological aspect.

In a comparative table the plants are arranged in seven ecological groups, in each of which the species found in peaty and non-peaty lochs are indicated with the depths at which they grow. The list of plants contains some new records for the districts.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Vice-Chancellor has published to the Senate a minute of the council of Trinity College supporting the plea for the establishment of a professorship of bio-chemistry, and stating that, with the view of making increased provision for higher teaching and research in that subject, pending the establishment of a professorship, the college has appointed Mr. F. G. Hopkins, at present reader in chemical physiology, to a prælectorship in bio-chemistry, and proposes to elect him to a fellowship.

The General Board of Studies will shortly proceed to appoint a university lecturer in mathematics in succession to Dr. Hobson. The appointment will be for five years from October 1, 1910. Candidates are requested to send their names, with testimonials if they think fit, to the Vice-Chancellor on or before Saturday, June 4.

Mr. R. H. Lock has been approved by the general board of studies for the degree of doctor in science.

Mr. A. J. N. Tremearne has been approved for the diploma in anthropology. This is the first time a diploma has been granted in this subject.

The board of agricultural studies, in consultation with the president of the Royal Agricultural Society, has nominated Mr. F. R. Salter to be the Gilbey lecturer on the history and economics of agriculture for one year from October 1, 1910.

At the closing ceremony of session 1910-11 of the University College of North Wales, Bangor, to be held on Friday, June 24, Dr. J. J. Dobbie, F.R.S., principal of the Government Laboratories, London, will deliver an address on "Museums: their Aims and Methods."

On Monday evening, May 23, on the invitation of the Rector of the University of Berne, Prof. Schäfer, of Edinburgh, gave a lecture on the functions of the pituitary body in the aula of the University before a large and appreciative audience. The lecture formed one of a series which was designed to commemorate the seventy-fifth anniversary of the re-founding of the University. In proposing a vote of thanks the Rector announced that the University had conferred the honorary degree of M.D. upon the lecturer, who was thereupon duly presented with the diploma.

STEPS are being taken by the Government of Queensland to invite applications in London for the professorial staff of the university shortly to be opened in that State. The chairs to be filled are classics, mathematics and physics, chemistry, and engineering. Applications will shortly be invited by Major T. B. Robinson, the Agent-General in London, from gentlemen competent to fill the positions. The salary of each professor is to be £900 a year. The Government of Queensland will contribute £10,000 a year for the next seven years to the University. Arts, science, and engineering will be the three great faculties, and the proposal in the first Bill that commerce was to be a faculty, with a lecturer and a degree of B.Com., has disappeared.

PROF. RUDOLF TOMBO, jun., of Columbia University, contributes to *Science* of May 6 some interesting statistics of certain Continental universities. During the winter of 1909-10 there were 58,342 students in attendance at German universities, 93.5 per cent. of these being men and 6.5 per cent. women. The matriculated students constituted 90.8 per cent. of the grand total, the remainder being auditors. The largest number of German students were to be found at Berlin, which had a total of 10,319; the next six out of the 21 German universities with their number of students were Munich, 7321; Leipzig, 5630; Bonn, 3880; Breslau, 2759; Halle, 2660; and Göttingen, 2342. Berlin attracted the largest number of matriculated women, and was followed by Munich, Göttingen, Heidelberg, and Bonn. Vienna is by far the largest of the Austrian universities, being surpassed in point of attendance (9580) only by Berlin among German institutions, while the University of Berne (2507) is the most largely attended of Swiss universities. If the attendance at the German universities during the winter of 1909-10 be compared with that of 1893-4, it is found that the number of matriculated

students has more than doubled during this period, the gain being one of 113 per cent., that is, from 27,424 to 58,342. There has been a marked change, too, in the relative position of the various German universities since 1893-4, when the largest universities were, in order, Berlin, Munich, Leipzig, Halle, Würzburg, Bonn, and Breslau. The only university that shows a decrease in the attendance of matriculated students as against 1894 is Würzburg, and there the loss is very slight.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 5.—Mr. A. B. Kempe, treasurer and vice-president, in the chair.—Colonel Sir David Bruce, Captains A. E. Hamerton and H. R. Bateman, and Captain F. P. Mackie: The development of trypanosomes in tsetse-flies. Until the end of 1908 it was believed that tsetse-flies acted merely as mechanical agents in the transference of trypanosome diseases. The parasite was supposed to be carried by the fly in the same way that vaccine lymph is carried—on the point of a lancet from one child's arm to another. The limit of time of infectivity of the fly was placed at forty-eight hours, and it was believed that if an infected area were emptied of its sleeping-sickness inhabitants for a couple of days, it would then be quite safe for healthy persons to enter it. At the end of 1908 Kleine made the discovery that a tsetse-fly could convey a trypanosome for some fifty days after the fly had fed on an infected animal. The experiments were carried out on these lines in Uganda. Both lake-shore and laboratory-bred flies (*Glossina palpalis*) were used, and various trypanosome diseases besides sleeping sickness were experimented with. Tsetse-flies are numerous on the lake-shore, 500 or more being caught every day by a few fly-boys. The flies brought up from the lake-shore were found to be naturally infected with at least two species of pathogenic trypanosomes, so that it was afterwards found necessary to use flies bred in the laboratory from pupæ gathered on the lake-shore. At first it was difficult to find these pupæ, but after some time the supply was more than sufficient, as many as 7000 being brought up in one day by a few natives. These experiments go to show that a late development of trypanosomes takes place in about 5 per cent. of the flies used. This development of trypanosomes in the inside of a fly renders the fly infective and capable of giving the disease to the animals it feeds on. The shortest time which elapsed before a fly became infective after feeding on an animal infected with sleeping sickness was eighteen days, the longest fifty-three days, and the average thirty-four days. An infected fly has been kept alive in the laboratory for seventy-five days, and remained infective during that time. It is not known how long the tsetse-fly may live under natural conditions on the lake-shore. Experiments made to test directly the duration of the infectivity of tsetse-flies show that they can retain their infectivity for at least two years after the native population has been removed from the fly area.—Dr. H. G. Chapman: The weight of precipitate obtainable in precipitin interactions.—Miss Ida F. Homfray: The absorption of gases by charcoal. The experimental portion of the work here summarised consisted in determining the volumes of gas absorbed by a known weight of charcoal, 3 grams, at definite temperatures, varying from that of liquid air to that of boiling aniline, and at pressures up to 80 cm. of mercury. The gases used were He, A, N., CO, CH₄, C₂H₄, CO₂, O₂, and mixtures of N₂ and CO. After making all necessary corrections, the isothermals were constructed, and from them points of equal absorption were read off, the family of curves so obtained being termed the isosteric diagram. The concentration for each isostere was calculated in the form

$$C = \frac{w \times 100}{W + w},$$

where w is the weight of gas absorbed and W that of the gas-free charcoal. The concentration of pure gas when $W=0$ thus becomes 100 per cent. Two relations have been obtained which hold, within experimental accuracy, for all

these gases:—(1) each isostere follows Ramsay and Young's rule for saturated vapours,

$$\frac{T_0}{T_1} - \frac{T'_0}{T'_1} = R(T_0 - T'_0),$$

and is expressible by Bertrand's vapour-pressure formula. (2) at constant pressure $dT/d \log C = K$. Also, in all cases at low pressures, and in some cases at all pressures, when these straight lines are produced to $\log C=2$, i.e. 100 per cent., the corresponding temperature is found to be the recognised boiling point of the liquefied gas at that pressure. By means of a simple formula the heats of absorption at various concentrations were calculated, and the thermodynamical relations are comparable to those of concentrated solutions. Calorimetric measurements were made in the case of CO₂, and found to agree well with the calculated values. The suggestion put forward, as a result of the experimental work, is that a homogeneous solution phase is formed in equilibrium with the gas phase, the presence of a large concentration of charcoal greatly raising the equilibrium temperature of the volatile component at a given pressure. This rise is not constant, as in the case of dilute solutions, but is itself inversely proportional to the gas concentration. If any other function of the quantity of charcoal, such as its surface area, were substituted for the mass in calculating the concentrations, the relations between the absorption results and the constants for the liquefied gases would be lost. For mixtures of two gases in charcoal the phase rule holds, and the relations can be deduced from those of the components.

Royal Meteorological Society, May 25.—Mr. H. Mellish, president, in the chair.—W. C. Nash: The daily rainfall at the Royal Observatory, Greenwich, 1841-1903. From the statistics given in this paper it was shown that the average annual rainfall for the sixty-three years was 24.19 inches with 157 rain days. The day with the maximum number of rain days to its credit is December 5, while the days with the least number of rain days are April 18, 19, June 27, and September 13. There were ninety-four occasions during the whole period on which the rainfall exceeded 1 inch in the day. The greatest fall was 3.67 inches, on July 26, 1867.—L. C. W. Bonacina: Low-temperature periods during the winters 1908-9 and 1909-10. It is often observed that if a given week, month, or other period in one year is marked by some very special meteorological character with respect to one or more elements of weather, the corresponding period the following year shows exactly the opposite character. Dealing with the last two winters, the author directed attention to four very remarkable frosts which stand out prominently, viz.:—(1) December, 1908, in the south of England; (2) March, 1909, in the south of England; (3) November, 1909, in Scotland and Ireland; and (4) January, 1910, in Scotland and the north of England.—R. Corless: The rate of rainfall at Kew in 1908. A method was described of obtaining information about the rate of fall of rain from the records of a self-recording rain-gauge, which yields a continuous trace showing, by the position of the pen, the amount of rain fallen.

PARIS.

Academy of Sciences, May 25.—M. Émile Picard in the chair.—Remarks by the president on the forthcoming meeting of the International Association of Academies at Rome.—H. Deslandres: The influence of comets on the terrestrial atmosphere according to the cathodic theory. The study of Morehouse's comet showed that the whole of the light emitted by the tail was of cathodic origin and it is highly probable that the tails of comets emit penetrating rays analogous to the γ rays of radium. These rays could ionise the atmosphere and cause the immediate condensation of supersaturated water vapour. Hence connection is at least possible on this theory between Halley's comet and the weather.—P. Villard and H. Abraham: The existence of two explosive potentials. For a given system of electrodes two explosive potential exist. The first is the potential of the brush discharge, the second appears to be the normal explosive potential and is more definite. Between these two limits there is a continuous silent discharge.—A. Haller and A. Comtesse

The action of the bromides of *ortho*- and *para*-anisyl-magnesium upon anthraquinone and β -methylantraquinone. In these reactions substitution derivatives are formed in all respects analogous with those obtained with phenylmagnesium bromide and quinones. The reduction products of the diols obtained are also described.—**Ch. André**: The passage of the earth through the tail of Halley's comet. Observations with both the electrometer and magnetometer gave negative results.—**M. de Kerillie**: The aurora borealis. Laws and heliodynamical theories. Observations are discussed tending to prove the accuracy of the heliodynamical theory of the aurora.—**A. Blondel**: Observation of Halley's comet made at the Toulouse Observatory with the Brunner Henry equatorial of 38-cm. aperture. The apparent position of the comet and the comparison star are given for May 8.—**Léopold Féjer**: The partial sums of Fourier's series.—**G. Sagnac**: The interference of two beams superposed in the inverse sense along an optical circuit of large dimensions. The arrangement figured resembles that of Michelson in using half-silvered plates, the path of the rays being 30 metres. Some of the inconveniences of silvered glass interferometers are discussed.—**A. Chassy**: The absorption of energy by the passage of an alternating current through a gas at atmospheric pressure. The energy has been measured by the amount of heat developed; above a certain potential the heat developed is proportional to the intensity of the current.—**Paul Jégou**: A very sensitive electrolytic detector working without an auxiliary electromotive force. One of the platinum electrodes is replaced by a mercury-tin amalgam. The detector has a sensibility of the same order as the ordinary form, is invariable with the time, and is unaffected by vibrations.—**Pierre Sève**: A new model balance for the determination of magnetic fields. The apparatus described and figured is an improved form of the instrument designed by Cotton and made by Weber.—**Georges Claude**: The composition of the atmosphere after the passage of Halley's comet. A determination of the proportion of (helium-neon) showed no variation.—**A. Lafay**: A modification of the resistance of the air produced by roughnesses suitably arranged on the surface of a body. The experimental results given have a bearing on the problem of aerodynamics.—**Georges Meslin**: The structure of the lines of the spectrum.—**C. Chénoveau**: The precision of the measurement of magnetic susceptibilities. A discussion of a method recently proposed by M. Pascal.—**Louis Maiciba**: The effect of penetration in dielectrics.—**M. Barre**: The solubility of silver sulphate in alkaline sulphates.—**E. Briner** and **A. Wroczyński**: The chemical action of high pressures: the compression of nitrous oxide and a mixture of nitrogen and hydrogen: the decomposition of carbon monoxide by pressure. No change was observed for nitrous oxide after compressing to 600 atmospheres at a temperature of 420° C. Negative results were also obtained with a mixture of hydrogen and nitrogen up to pressures of 900 atmospheres. Carbon monoxide showed clear evidence of chemical change after exposure to a temperature of 320° C. under a pressure of 400 atmospheres.—**Daniel Berthelot** and **Henri Gaudechon**: The chemical effects of the ultra-violet rays on gaseous bodies. On exposure to the ultra-violet rays a mixture of cyanogen and oxygen was nearly quantitatively converted into carbon dioxide and nitrogen. Ammonia mixed with oxygen gave as a final product water, nitrogen, and hydrogen. Hydrogen does not combine with oxygen under these conditions. Formic acid was identified amongst the products of the reaction with a mixture of acetylene and oxygen.—**Georges Denigès**: The presence of tartaric residues of wine in an ancient flask. The flask dated from the first century. Tartaric acid was detected in the deposit on the sides, proving that wine was originally placed in the flask.—**P. Clausmann**: The action of ozone upon carbon monoxide. The interaction of carbon monoxide with ozone produces carbon dioxide. The oxidation is increased by exposure to light and by the presence of moisture.—**H. Cousin** and **H. Hérissey**: Dehydrodicarvacrol.—**J. B. Senderens**: Ketones derived from benzoic and phenylacetic acids. The properties of a series of ketones prepared by the general catalytic method described in a previous paper.—**N. Cherchoffsky**: The determination of the place of origin of a naphtha or of

substances derived from it.—**H. Gault**: The condensation of ethyl oxalate with ethyl tricarballoylate.—**H. Pariselle**: A new synthesis of natural and racemic erythrite.—**W. Louguinine** and **G. Dupont**: The heat of fixation of some ethylenic compounds. The hydrobromic acid was used in xylene solution, as much more concordant results were obtained with this than with aqueous hydrobromic acid.—**Ernest F. L. Marchand**: *Plasmodiophora brassicae*, a parasite of the melon and of celery.—**J. Capus** and **J. Feytaud**: A method of treatment against *Cochylis* and *Eudemis*. FORTHCOMING CONGRESSES.

JUNE 19-23.—International Congress of Mining, Metallurgy, Applied Mechanics and Practical Geology. Düsseldorf. General Secretaries: Dr. Schröder and Mr. Löwenstein, Jacobi-strasse 3/5, Düsseldorf, Germany.

JULY 4-8.—International Congress in Naval Architecture and Marine Engineering. London. Secretary: 5 Adelphi Terrace, London, W.C.

JULY 10-25.—International American Scientific Congress. Buenos Aires. Address for inquiries: President of the Executive Committee, c/o Argentine Scientific Society, 269 Calle Cevallos, Buenos Aires.

JULY 27-31.—International Congress on the Administrative Sciences. Brussels. Secretary of British Committee: Mr. G. Montague Harris, Caxton House, Westminster.

AUGUST 1-6.—International Congress of Entomology. Brussels. Chairman of Local Committee for Great Britain: Dr. G. B. Longstaff, Highlands, Putney Heath, S.W.

AUGUST 1-7.—French Association for the Advancement of Science. Toulouse. President: Prof. Gariel. Address of Secretary: 28 rue Serpente, Paris.

AUGUST.—International Congress of Photography. Brussels. Correspondent for United Kingdom: Mr. Chapman Jones, 11 Eaton Rise, Ealing, W.

AUGUST 2-7.—International Congress on School Hygiene. Paris. General Secretary: Dr. Dufestel, 10 Boulevard Magenta. Paris. Hon. Secretaries for Great Britain: Royal Sanitary Institute, 90 Buckingham Palace Road, S.W.

AUGUST 15-20.—International Zoological Congress. Graz (Austria). President: Prof. Ludwig von Graff. Address for inquiries: Präsidium d. VIII. Internationalen Zoologen-Kongresses, Universitätsplatz 2, Graz (Österreich).

AUGUST 18-26.—International Geological Congress. Stockholm. General Secretary: Prof. J. G. Andersson, Stockholm 3.

AUGUST 29 TO SEPTEMBER 6.—International Union for Cooperation in Solar Research. Mount Wilson Solar Observatory. British Member of Executive Committee to whom inquiries should be addressed: Prof. A. Schuster, F.R.S., Victoria Park, Manchester.

AUGUST 31 TO SEPTEMBER 7.—British Association. Sheffield. President: Prof. T. G. Bonnev. F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

SEPTEMBER 6-8.—International Congress of Radiology and Electricity. Brussels. General Secretary: Dr. J. Daniel, 1 rue de la Prévôté, Brussels. Correspondents for United Kingdom: Prof. Rutherford and Dr. W. Makower, University of Manchester, and Dr. W. Deane Butcher, Holyrood, Ealing, W.

SEPTEMBER 18-24.—German Association of Naturalists and Physicians. Königsberg. Secretaries: Prof. Lichtheim and Prof. F. Meyer, Drumstr. 25-29, Königsberg.

SEPTEMBER 27-30.—International Physiological Congress. Vienna. President: Prof. S. Exner. General Secretary for United Kingdom: Prof. E. B. Starling, University College, London, W.C.

OCTOBER 6-12.—Congrès International du Froid. Vienna. Correspondent for United Kingdom: Mr. R. M. Leonard, 3 Oxford Court, Cannon Street, E.C.

DIARY OF SOCIETIES.

THURSDAY, JUNE 2.

ROYAL SOCIETY, at 4.30.—The Influence of Bacterial Endotoxins on Phagocytosis (Preliminary Report): Leonard S. Dudgeon, P. N. Pantan, and H. A. F. Wilson.—The Origin of Osmotic Effects. III. The Function of Hormones in Stimulating Enzymic Change in Relation to Narcosis and the Phenomena of Degenerative and Regenerative Change in Living Structures: Prof. H. E. Armstrong, F.R.S., and E. Frankland Armstrong.—On the Direction of Motion of an Electron ejected from an Atom by Ultra-violet Light: Dr. R. D. Kleeman.—On Scandium. Part II.: Sir William Crookes, For. Sec. R.S.—The Flow of Water in Curved Pipes: Prof. J. Eustice.—On the Occurrence of a Mesocelic Recess in the Human Brain and its Relation to the Sub-commissural Organ of Lower Vertebrates; with special reference to the Distribution of Reissner's Fibre in the Vertebrate Series and its Possible Function: Prof. A. Dendy, F.R.S., and G. E. Nicholls.

ROYAL INSTITUTION, at 3.—Malaria: Major Ronald Ross, F.R.S.
INSTITUTION OF MINING ENGINEERS, at 11 a.m.—Presidential Address: Dr. J. B. Simpson.—A Storage-battery Extension to a Three-phase Colliery Power-plant: W. Maurice.—On Measurements of the Downward Increase of Temperature in Bore-holes, their Technics and their Practical Importance for Geological Prognosis: Prof. J. Koenigsberger and Dr. Max Mühlberg.

LINNEAN SOCIETY, at 8.—A Contribution to our Knowledge of the Flora of Gazaland: Dr. A. B. Rendle, F.R.S., and others.

RÖNTGEN SOCIETY, at 8.15.—Practical Observations on Every-day X-ray and Electrical Work: Filtration of Rays, Measurement of Rays, Rapid Stereoscopic Method: Dr. Howard Pirie.—Recent Improvements in Radiographic Technique: Dr. R. Knox.

FRIDAY, JUNE 3.

ROYAL INSTITUTION, at 3.—The World of Plants before the Appearance of Flowers: Dr. D. H. Scott, F.R.S.

ROYAL INSTITUTION, at 9.—Renaissance Monuments in the Roman Churches, and their Authors: Sir Kennell Rodd, G.C.V.O., K.C.M.G.

INSTITUTION OF MINING ENGINEERS, at 10 a.m.—Experiments illustrative of the Inflammability of Mixtures of Coal-dust and Air: Prof. P. Phillips Bedson.—Testing for Fire-damp: Prof. J. Cadman.—Some Memoranda concerning Coal-dust: H. W. G. Habbaum.

GEOLOGISTS' ASSOCIATION, at 8.—A Preliminary Account of the British Fossil Voles and Lemmings; with some Remarks on the Pleistocene Climate and Geography: M. A. C. Hinton.—Notes on some Igneous Rocks from North Devonshire: H. Dewey.

SATURDAY, JUNE 4.

ROYAL INSTITUTION, at 3.—Electric Heating and Pyrometry: Prof. J. A. Fleming, F.R.S.

MONDAY, JUNE 6.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Yolo-Cross River Boundary Commission, Southern Nigeria: Major G. F. A. Whitlock, R.E.—Journeys in Southern Nigeria: P. A. Talbot.

VICTORIA INSTITUTE, at 4.30.—Determinism: Archdeacon Potter.

ARISTOTELIAN SOCIETY, at 8.—The Nature of Propositions: Sydney Waterlow.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Accuracy obtainable in Fuel Calorimetry: G. N. Huntly.—Differential Distillation: J. L. Foucar.—The Production of Formic Acid by the Atmospheric Oxidation of Turpentine: C. T. Kingzett and R. C. Woolcock.—Proposed Method for the Estimation of Butter Fat, Cocoa Nut Oil, Palm Kernel Oil and the Determination of their respective Proportions in Mixtures: S. H. Blichfeldt.—The first Synthesis of Ethyl Alcohol: Prof. R. Meldola, F.R.S.

TUESDAY, JUNE 7.

ROYAL INSTITUTION, at 3.—Hereditry in Tudor and Stuart Portraits: C. J. Holmes.

MINERALOGICAL SOCIETY, at 5.30.—On the Occurrence of Phenakite in Cornwall: A. Russell.—(1) Phacolite from near Belfast; (2) Crystalline Form of Nitrogen Sulphide: Dr. G. F. H. Smith.—On a new Arsenate

and Phosphate of Lime and Strontia from the Indian Maganese Deposits: Dr. G. F. H. Smith and Dr. G. T. Prior.—A (fifth) List of New Mineral Names: L. J. Spencer.

THURSDAY, JUNE 9.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: The Distribution of Velocity in the β -Rays from a Radio-active Substance: J. A. Gray.—The Decrease of Velocity of the β -Particles on Passing through Matter: W. Wilson.—Rate of Emission of α -Particles from Uranium and its Products: J. N. Brown.—The Effect of Small Traces of Water Vapour on the Velocities of Ions produced by Röntgen Rays: R. T. Lattev.—On the Variation with Temperature of the Viscosities of the Gases of the Argon Group: Dr. A. O. Rankine.—The Effect of Pressure upon Arc Spectra. Part II., No. 4. Gold: Dr. W. G. Duffield.

MATHEMATICAL SOCIETY, at 5.30.—A New Method in the Theory of Integration: Dr. W. H. Young.—The Composition of Finite Screw Displacements: G. T. Bennett.—Note on the Theory of Linear Differential Equations: Prof. M. J. M. Hill.—The Generation of Cubic Curves by Apolar Pencils of Lines: W. P. Milne.—On Semi-integrals and Oscillating Successions of Functions: Dr. W. H. Young.

ROYAL INSTITUTION, at 3.—Malaria: Major Ronald Ross, F.R.S.

FRIDAY, JUNE 10.

ROYAL INSTITUTION, at 9.—The Progressive Disclosure of the Entire Atmosphere of the Sun (in French): Dr. H. Deslandres.

PHYSICAL SOCIETY, at 8.—A Galvanometer for Alternate Current Circuits: Dr. W. E. Sumpner and W. C. S. Phillips.—The Positive Electrification due to Heating Aluminium Phosphate: A. E. Garrett.

ROYAL ASTRONOMICAL SOCIETY, at 5.
MALACOLOGICAL SOCIETY, at 8.—A Revision of the Species of the Family Pyramidellidae occurring in the Persian Gulf, Gulf of Oman, and the North Arabian Sea: Dr. J. Cosmo Melville.—The Anatomy of *Hemiplecta foullioyi* from New Guinea: R. H. Burne.—Further Notes on the Dates of Issue of Sowerby's "Conchological Illustrations": A. Reynell.

SATURDAY, JUNE 11.

ROYAL INSTITUTION, at 3.—Electric Heating and Pyrometry: Prof. J. A. Fleming, F.R.S.

HANDBOOKS ON THE FRESH-WATER FAUNA OF GERMANY.

Die Süßwasserfauna Deutschlands, eine Exkursions-fauna. Herausgegeben von Prof. Brauer (Berlin). i., Mammalia, Aves, Reptilia, Amphibia, Pisces, by P. Matschie, A. Reichenow, G. Tornier, P. Pappenheim. Pp. iv+206; 173 figs. Price 5 marks. . . iii. and iv., Coleoptera, by E. Reitter. Pp. 235; 101 figs. Price 5 marks. . v. and vi., Trichoptera, by G. Ulmer. Pp. 326; 467 figs. Price 6.50 marks. . vii., Collembola, Neuroptera, Hymenoptera, Rhynchota, by R. and H. Heymons and Th. Kuhlitz. Pp. 112; 111 figs. Price 2.40 marks. . viii., Ephemerida, Plecoptera, Lepidoptera, by Fr. Klapálek and K. Grünberg. Pp. 163; 260 figs. Price 4 marks. . ix., Odonata, by F. Ris. Pp. 67; 79 figs. Price 2 marks. . x., Phyllopoda, by L. Keilhack. Pp. iv+112; 265 figs. Price 3 marks. . xi., Copepoda, Ostracoda, Malacostraca, by C. van Douwe, E. Neresheimer, V. Vávra, and L. Keilhack. Pp. 136; 505 figs. Price 3.50 marks. . xii., Araneæ, Acarina, and Tardigrada, by F. Dahl, F. Koenike, and A. Brauer. Pp. 191; 280 figs. Price 4 marks. . xvii., Parasitische Plattwürmer, i., Trematodes, by M. Lühe. Pp. iv+217; 188 figs. Price 5 marks. . xix., Mollusca, Nemertini, Bryozoa, Turbellaria, Tricladida, Spongillidæ, Hydrozoa, by J. Thiele, R. Hartmeyer, L. von Graff, L. Böhmig, W. Weltner, and A. Brauer. Pp. 199; 346 figs. Price 4 marks. (Jena: Gustav Fischer, 1909.)

THE aim of the editor of these volumes has been to provide a *complete* systematic account of the fresh-water fauna of Germany. In addition to the parts named above, others, on the Diptera, Oligochaeta and Hirudinea, Rotatoria and Gastrotricha, Nematelminthes and Cestodes are promised in the near future; a volume on the Protozoa is not at present in preparation, but may be forthcoming later. There are already other accounts which deal with portions of the fresh-water fauna, the organisms therein considered being selected either because they are the commonest fresh-water animals or because of their special interest from a biological or morphological point of view. But in the volumes before us all the known species of each group of fresh-water animals are considered; thus the worker is given the means of identifying any organism he may have under examination provided that it has been already recorded from fresh water in Germany. Whatever piece of work the fresh-water naturalist may desire to undertake, whether it be the study of the life-history of certain animals, their distribution, their behaviour under different conditions of environment, or whether it be the intensive study of the fauna of one pond or the more general study of the fauna of a more extended area, one of the first things necessary will be the determination of the systematic position of the organisms he proposes to investigate. For the first time the naturalist is provided, in this series of handy volumes, each written by a specialist or group

of specialists, with the means of identifying his specimens with the minimum of difficulty and trouble, and without the necessity of consulting expensive monographs. The descriptions and diagnoses given are thoroughly trustworthy and practical; they contain the principal morphological characters, and short biological and faunistic notes are added in many cases. These handbooks are not intended to supply, and do not give, lengthy anatomical or biological accounts of the organisms; their function is to enable the worker who consults them to identify his material as speedily as possible. To this end keys are provided, wherever possible, to the families, genera and species, and figures, for the most part in line, are given to illustrate the diagnostic characters.

As there are no definite boundaries between the fresh-water, terrestrial, and marine faunas, it is difficult to decide whether certain animals should or should not be regarded as coming within the scope of these volumes. The editor has included not only animals which live in or upon fresh water, but those which are found on the margins of ponds, lakes, streams, &c., entering into intimate association with the water; others which seek the water only temporarily have been excluded. On the whole, the limits of the fresh-water fauna have been liberally interpreted. In order to give a more complete account, mention has been made in some cases of developmental stages of organisms, although these stages do not actually occur in fresh water; for instance, the larvæ—*Leptocephali*—of the eel are mentioned and figured. Our knowledge of some divisions of the fresh-water fauna is at present in a very imperfect condition; the adult forms of many animals are well known, while their younger stages are but inadequately described. These volumes, which will reach the hands of the majority of serious workers, will fulfil the purpose, among others, of serving as a record of our present knowledge, and will show the lacunæ which remain to be filled by future observations.

Heft i. deals with the whole of the vertebrates found associated with fresh water in Germany. The treatment of the Amphibia may be instanced as an example of the method adopted in this volume. A table of the diagnostic characters of adult Urodeles is given, by means of which *Salamandra maculosa*, *Molge alpestris*, *palmata*, *cristata*, and *vulgaris* may be distinguished. In the following part, which deals with the Batrachia, there are tables for the identification of (1) the fully adult frogs, *Hyla arborea*, *Bufo viridis*, *vulgaris*, and *calamites*, *Rana temporaria*, *arvalis*, and *esculenta* (three varieties), *Bombinator pachypus* and *igneus*, *Pelobates fuscus*, and *Alytes obstetricans*; (2) their spawn; (3) the young tadpoles with external gills; and (4) older tadpoles with internal gills. The third table is accompanied by the suggestion that it should be used only in case of those specimens which die in this comparatively early stage of development, and that it is preferable, wherever possible, to keep the tadpoles alive until the fourth table can be applied, with more certainty, to their identification. These four tables are illustrated by

forty figures, which clearly show the features upon which the diagnosis depends.

Hefte iii. and iv. form a single volume on the Coleoptera. The introductory pages contain useful figures, on which the structures used in diagnosis are named. The order is divided into Adephaga (Carnivora) and Polyphaga; then follow tables for the separation of the families, genera, and species. The true water beetles, that is, those species in which all stages are passed in water, are first considered; afterwards, those species in which the young stages are found in water, the adults being terrestrial; and, finally, those the whole life of which is passed under stones or on plants on the margin of water.

The single volume on the Trichoptera (Hefte v. and vi.) opens with a detailed description of the imago, following which are tables, supported by line figures, chiefly of wings and genitalia, for the separation of families, genera, and species. Six pages are devoted to the description of the egg masses of some families, genera, and species, and there follows a detailed description of the larva and tables for separating larvæ into their respective families, genera, and species. Lastly the pupa is described, and another series of tables enables the worker to identify the family or subfamily to which a pupa belongs, and he may then complete the identification either by reference to the genitalia of the imago (if they are already formed beneath the pupal cuticle) or to the larval cuticle. These excellent systematic accounts of the larvæ and pupæ, which occupy 112 pages, are alone sufficient to secure for the volume a hearty reception and commendation.

The volumes on the other orders of insects (Hefte vii., viii., and ix.) are on a plan similar to that of the two volumes above noticed, as also are the accounts of the Crustacea. For instance, the Phyllopoda (Heft x.) are divided into Euphyllopoda and Cladocera, each section being in turn subdivided into families, genera, and species, separate tables being given, where necessary, of the characters of male and female specimens. Two hundred and sixty-five outline drawings of the carapace, terminal hooks, setæ, antennæ, &c., make clear the references to these characters in the text.

The account of the Trematodes (Heft xvii.) is admirably arranged and complete. Tables giving the characters of the adult, and in some cases also of immature forms, are provided. There are lists of the Trematodes which have been found encysted in those birds, Amphibia, fishes, molluscs, and arthropods which are associated with fresh water, and there is a useful appendix on cercariæ. The utility of the volume would be increased if a "host-index" were added, by means of which the worker could ascertain what parasites had been recorded from the particular host which he happens, at the moment, to be examining.

The numerous figures, many of them original, which illustrate these volumes are of exactly the kind to elucidate the text; only very rarely is a defective figure met with; here and there a shaded drawing has become rather too dark in the course of reproduction, thus causing part of its detail to be

obscured. The generic and specific names adopted are thoroughly up to date. Synonyms are given in only a comparatively few cases, such as those in which a well-known name has been recently superseded; a few more cases would have been the better for similar treatment; for instance, such well-known names as *Paludina* and *Cyclas* might have been given as synonyms under *Viviparus* and *Sphærium* respectively. One regrets the disappearance of many well-established names, e.g. *Apus* is replaced by *Triops*, and the alteration of others, e.g. *Daphnia* to *Daphne*, *Anodonta* to *Anodontites*, *Artemia* to *Artemisia*; these changes in zoological nomenclature seem to be almost endless, and sometimes, as in the last-named case, to be of doubtful value.

The volumes are of handy size, about 8 inches by 4½ inches, suitable for the pocket; they are printed on thin paper, so that the largest (on the Trichoptera, 326 pp.) is only half an inch in thickness.

So considerable a proportion of the fresh-water fauna of Britain is found also in Germany that the student of the British fresh-water fauna may turn to these volumes with the assurance that, in most cases, he will find there the information he requires to enable him to identify his material. These excellent volumes are certain to prove of the greatest service to workers on the fresh-water fauna, not only of Germany, but of a wider area.

CRETAN ARCHÆOLOGY.

Crete, the Forerunner of Greece. By C. H. Hawes and Harriet Boyd Hawes. With a preface by Arthur J. Evans. Harper's Library of Living Thought. Pp. xiv+158. (London: Harper Bros., 1909.) Price 2s. 6d. net.

MRS. HARRIET BOYD HAWES, better known to us, perhaps, under her maiden name of Miss Harriet Boyd, and her husband, Mr. C. H. Hawes, have written a very useful little book which may be described as a short, popular description of the antiquities of Crete which have been discovered during the last ten years by Dr. Evans, Prof. Halbherr, and by the distinguished author herself. More popular than Prof. Burrows's admirable "Discoveries in Crete" (though, at the same time, in no way less useful to archæologists), and published at half the price of even his book, "Crete, the Forerunner of Greece," should bring the interest and the importance of the Cretan discoveries home to the minds of all. Mr. and Mrs. Hawes have rightly insisted on the fact that the Cretan discoveries should in reality interest us more than similar discoveries in Assyria, or Palestine, or even in Egypt, because the Cretan civilisation of the Bronze age was the forerunner and the ancestor of that Hellenic culture which is ours to-day. In spite of the dark age of mediævalism in Europe, the tradition of Græco-Roman civilisation survived, and we have now returned to it. Greek culture was but a revival, after an analogous dark age of mediævalism, of the great civilisation of the Ægean Bronze age, younger sister, probably, of the ancient culture of the Nile valley. Our civilisation goes back in Greece to the very beginning of things, almost to

the remote epoch when it diverged from the Nilotic culture, and Mr. and Mrs. Hawes's little book is designed to instruct those who wish to know the story of its origins. *Felix qui potuit rerum cognoscere causas.* Religious ideas have largely directed the general interest in our origins towards the "Biblelands," whence sprang the exotic oriental religious element in our culture, but the growth of knowledge and of civilisation is steadily weaning us from our Semitic and mediæval foster-parents, and interesting us more and more in Greece and Rome, the real parents of our minds and thoughts; and the origin of Greece and of Rome was Crete, and Crete may have sprung from the same common source as Egypt.

Of the Egyptian inspiration which we see in the early art of Crete the authors of this little book say little. They have no space in which to discuss disputed points, and their personal bias is, perhaps, rather away from any even so-called "oriental" influences (we do not admit, by the way, that Egypt was ever "oriental" in the sense that the Semitic world was and is). They merely describe what has been found in Crete and is to be seen there, either in the ruined palaces of Knossos and Phaistos, or in the towns of Gourniâ and Palaikastro, or in the museum of Candia, where the treasures found in the course of the excavations of these places are preserved. They conclude with a chapter on Cretan (Minoan) art which strikes us as very correctly appreciative of the peculiar genius of the earliest European artists, so unequal in quality, so good, so magnificent in conception and workmanship at times, at others so weak; yet honest and free, unshackled by any of the conventions that bound the artists of Egypt and Assyria (who, but for these conventions, would have done as well as the Minoans), and the worthy ancestors and forerunners of the artistic genius of Hellas. On this we must always insist; the Minoan art of Greece was the ancestor of that of the Hellenes, who inherited their artistic genius, not from the Indo-European Greek-speaking northern originators of half their blood, but from their other ancestors, the ruddy non-Aryan Mediterraneans, brothers of the Egyptian and of the Etruscan. It is from these, albeit we ourselves in the north have little or none of their blood in our veins, that we have derived most of what makes us civilised beings.

PRACTICAL CURVE TRACING.

Practical Curve Tracing, with Chapters on Differentiation and Integration. By R. Howard Duncan. Pp. vii+137. (London: Longmans, Green and Co., 1910.) Price 5s. net.

THE methods employed in this book, which presents an attractive appearance, are almost entirely independent of the aid of general mathematical principles. For instance, the form of the graph of $y=ax+b$ and its dependence on a , b are explained by plotting graphs of the equations obtained by varying a while b remains constant, and then those obtained by varying b while a remains constant.

Naturally greater difficulties occur in handling the equations $y=ax^2+bx+c$, $y=ax^3+bx^2+c$, &c., by the same method. Inexpert mathematical students of the type for whom the author writes find it very hard to get hold of the notion of a parameter, and a great deal could certainly be done by adopting the plan indicated above, and steadily followed in this book. Even the ordinary student of analytical geometry would probably get at "the facts of the case" sooner if he approached, for example, the equation $x^2+y^2-ax-b=0$ by drawing graphs of the circles of the specified system, keeping b a positive constant and giving a various values, then keeping b a negative constant and varying a .

It is this positive and distinct advantage that is emphasised by the author, and from this point of view are discussed the parabolic, hyperbolic, exponential, and logarithmic curves, together with the sine curve, of the natures of which a good account is given. For students of graphs who have at their disposal algebraic machinery up to division and quadratic equations, the road to a knowledge of the forms of many graphs could be made shorter. The artifices of change of origin and scale-unit, even without those of successive approximation, do not offer a great difficulty to a student of small mathematical ability, and go a long way towards establishing the rough form of the graph of an equation which would appear alarming if it had to be discussed by the plotting of points.

Two chapters on the calculus are added to those on curve tracing. The author knows that "the method of measuring the slope of a curve by actually drawing the tangent is sometimes objected to on the ground of inaccuracy"; but his experience "shows that by good and careful workmanship it is possible to rely on the results so obtained to a degree of accuracy which is sufficient for practical purposes." Yet the degree of accuracy indicated in some of the results tabulated in the chapter on differentiation must be very difficult to attain. Indeed, curves of $y=x^2$, $y=x^3$, &c., are constructed, tangents are actually drawn, dy/dx and x are tabulated and then plotted against one another directly or logarithmically, with so much accuracy that the rules for the differentiation of x^n , e^x , $\log x$, $\sin x$, $\cos x$, are deduced. The reader certainly will have it very definitely impressed upon him that dy/dx measures the slope of a curve. Of course, there remains the difficulty for an engineer, or any other who applies the calculus, of being able to identify the slope with the rate of variation of the corresponding function, and of appreciating the very varied significance of the derivative in its applications; but the book does not profess to enter on this field.

A few examples on each chapter are gathered together at the end of the volume, the purpose of which is evidently that the reader should be clear regarding the facts at the base of the equations and functions discussed before he sets out to equip himself in the practice and applications of the methods explained.

P. P.

AN ALTERNATIVE TO QUALITATIVE ANALYSIS.

Introduction to Experimental Inorganic Chemistry.

By H. Biltz. Translated by William T. Hall and J. W. Phelan. Pp. vi+185. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.)

THIS book is intended to supply the lack of knowledge of descriptive chemistry which has resulted from the omission of "test-tube work" from the curricula of the schools or its restriction to small classes of advanced scholars. As compared with the "qualitative analysis" which it is intended to precede or to replace, as the case may be, the course now suggested has certain obvious advantages, arising more especially from the fact that the experiments are designed directly for the purpose of supplying a knowledge of the elements and their compounds, instead of serving this purpose only indirectly through the medium of a scheme of work designed originally for an entirely different purpose.

The abuse of the older method, by which a student could be trained to "get out" his salts and pass his examinations without acquiring any adequate knowledge of the processes used in doing this, is well known, but the alternative scheme now suggested is by no means free from faults. One of the most serious accusations that may be levelled against it arises from its monotony. Thus, in dealing with the metals, the student is expected to examine one metal after another, to heat it, dissolve it in acids, and then try the effect of a series of different agents on its solutions. After this has been done for a dozen different metals the student would certainly complain of weariness, and it is doubtful whether his mental faculties would be kept sufficiently on the alert to produce any permanent impression at the end of his course. The loss of the interest which is supplied in qualitative analysis by the incessant stimulus of a problem to be solved is a very serious drawback, and the course which the authors present would need very careful handling to prevent the class from going to sleep over its work or gliding through it without effort and, therefore, without profit.

The best use to which the book could be put would be as a duplicate text-book for a student engaged on qualitative analysis, so that when presented with a new element he might, whilst learning how to detect it, acquire at the same time some systematic experimental knowledge of its properties. If blended in this way with a series of problems, the experiments now described would undoubtedly be of considerable value.

The most noticeable fault in the arrangement of the book is due to an uncertainty on the part of the authors as to whether they are giving instructions for, or supplying a descriptive account of, the experiments. This confusion has resulted in a compromise whereby one experiment is described in the imperative tense and the next as a narrative in the present tense. It is also a characteristic weakness of the scheme that formulæ and equations are given without any hint as to the quantitative experiments on which they must necessarily be based. This lack might doubtless be

corrected by a teacher who was aware of the danger that the class might look upon a formula or an equation as an inspired product, to be accepted as a revelation sent down to mankind through the prophetic agency of the writers of text-books; but a course of chemistry which leads off with the words, "Hydrochloric acid, HCl, is a colourless gas. . . ." would (if left to develop its natural effects) be admirably calculated to propagate this all too prevalent heresy.

T. M. L.

THE WELFARE OF WOMEN.

The Health of the Nations. Compiled from Special Reports of the National Councils of Women. Pp. 191. (London: Constable and Co., Ltd., 1910.) Price 1s. net.

THE International Council of Women, of which the Countess of Aberdeen is president, was formed in 1888 by "a company of earnest American women" (p. 7). The result of their efforts was a federation of national councils, or unions, or associations, of women working for the common welfare. Mrs. Ogilvie Gordon sketches in this small volume the history of the council, noting the resolutions of its quinquennial meetings in the various countries, and summarising, for the year 1909, certain "special reports" prepared by representative women in Europe, America, and other continents. The movement is ambitious, and it is almost needless to say that the "special reports" here collated are of the most generalised kind. In a brief 200 pages of well-leaded print, it is not possible to give a passable summary of the "health" even of one nation, not to speak of the twenty-one "nations," or countries, here dealt with. But it is gratifying to find some twenty-two national councils of women (p. 12) sufficiently interested in general hygiene to produce even these somewhat sketchy "reports."

The main point is that the nations are thus showing an increasing concern for one another, and the International Council of Women, in focussing attention on the leading features of public-health progress, is doing, *pro tanto*, a real international service. Such reports are intended to excite interest rather than to provide materials for scientific conclusions, and, from this point of view, there is much to be said for them.

It is, however, to be regretted that there is so little reference in detail to extant official or other trustworthy documents. Had the papers each been supplemented by a short list of definite references, the usefulness of the little volume would have been immeasurably increased. As it is, one has difficulty in taking the statements on trust. For instance, in a "report on public health" for the "countries" of "Great Britain and Ireland," one finds it said—and the date of the "preface" is 1909—that "there is no compulsory notification of tuberculosis in Great Britain, but voluntary notification, instituted by local authorities, obtains in many places" (p. 65). Yet at that date, May, 1909, nearly 25 per cent. of the population of Scotland was under "compulsory notification," a fact that could have been obtained without difficulty, either from published blue-books or from

application to the Local Government Board for Scotland. Incidentally, it may be said that the percentage now probably approaches 50; yet a volume on "The Health of the Nations," issued in 1910, contains no clue even to the fact that Scotland is a separate administrative area of Great Britain.

This kind of report is not reassuring as to the other countries; but doubtless the various correspondents will be able to put inquirers "on the track" of more definite information. The work of collation is well done by Mrs. Ogilvie Gordon, and the volume forms a good intellectual point of repair for the many women everywhere concerned to consider and improve the life and labour conditions of women.

PROGRESS OF CHEMICAL AND PHYSICAL SCIENCE.

Fortschritte der Chemie, Physik, und physikalischen Chemie. Neue Folge des Physikalisch-chemischen Centralblattes. Vol. I., 1909. Edited by Dr. Hermann Grossmann and others. Pp. 386. (Leipzig: Gebrüder Borntraeger; London: Williams and Norgate, 1909.) Price 16 marks.

THIS work on the progress of chemistry, physics, and physical chemistry, which represents the first annual volume of a new series of the "Physikalisch-chemische Centralblatt," is issued in monthly parts, and contains a number of interesting reports by specialists on various branches of chemistry and physics, the period under review being 1908 and a portion of 1909.

Two articles on radio-activity and electronics indicate the interest attached to these rapidly developing branches of science, and it is gratifying to find that a substantial part of the pioneering work in this section results from the labours of British chemists and physicists.

The important subjects of spectroscopy, catalysis, thermochemistry, chemical equilibrium, velocity of reaction, and the theory of gases are dealt with in special reports. Recent observations on the influence of light on chemical change are summarised in the article "Photochemistry," by A. Byk.

The study of colloids is a branch of general chemistry now making rapid advances, and the researches of 1908 in this field are discussed by A. Müller, who also deals with the practical application of these investigations to the technical process of dyeing, tanning, photography, and biological chemistry.

The editor, Dr. H. Grossmann, contributes a memoir on complex chemical compounds, in which he reviews the work done in this branch of chemistry during the first half of the year 1909. He groups these so-called "molecular compounds" under four headings:—(1) Compounds with complex cations; (2) compounds with complex anions; (3) auto-complex compounds; and (4) organic-inorganic complex compounds.

One of the most interesting articles in this volume is that on the incandescent mantle industry, written by C. R. Böhm, who describes the rise and development of this important branch of manufacture, and gives a brief outline of the processes involved in the

production of Welsbach mantles on a commercial scale.

The report on pharmaceutical chemistry is noteworthy because it includes a description of the synthesis of racemic suprarenine by Stolz and Flächer. The latter chemist has since separated this product into its two optical antipodes. The lævorotatory base is identical with the active base of the suprarenal capsules, and, when introduced into animals by intravenous injection, produces a very marked increase in the blood pressure. The dextrorotatory suprarenine, under similar conditions, is practically inoperative.

In addition to the above mentioned monographs, the volume contains reports on the recent development of chemical science under the various headings of physical, inorganic, organic, analytical, physiological, and agricultural chemistry. These summaries contain the same information, and discuss topics similar to those dealt with in the annual reports on the progress of chemistry published in recent years by the Chemical Society, and are therefore hardly likely to be preferred by the English reader.

OUR BOOK SHELF.

Radium. By J. P. Lord. Third edition. Pp. x+103. (London: Harding, Bros. and Co., 1910.) Price 2s. 6d. net.

THIS book, to quote from the preface, consists "of a careful compilation of the more material facts needed for an elementary understanding of radio-active phenomena, especially in relation to therapeutic and kindred progress," and the author's aim has been "to steer a middle course between the popular and the scientific literature of the subject, avoiding over-technicality, on the one hand, and on the other, that looseness of which the popular treatment of a scientific matter is peculiarly susceptible." On the whole the book seems fairly well fitted to fulfil its object. The author has successfully avoided over-technicality, but has not been entirely successful in retaining accuracy. In discussing the energy of radium, the view appears to be taken that because the radiations escaping are limited to a thin layer beneath the surface, the heat generated is also limited by the thickness of the layer. The commercially important ratio of radium to uranium in minerals is given as 700 milligrams of the former per ton of the latter, which is more than twice as great as the actual ratio. The present commercial price of radium is given as slightly more than 1000l. per grain, which is particularly unfortunate in such a book, since small quantities can be bought at the present time at about one-quarter or one-fifth this rate.

The chief interest of the book is the description and photographs given of certain new mines of autunite (hydrated uranium calcium phosphate) near Guarda, in Portugal, in the exploitation of which the publishers of the book apparently are interested. The deposits are described as occurring in lodes, varying from an inch to three or four feet in thickness, containing the uranium ore in crystals. A set of radiographs taken with the new material, of percentage of uranoso-uranic oxide varying from 39 to 1.5, is included, together with some plates of instruments commonly employed in the measurement of radio-activity. The last three chapters are devoted to the medical uses of radium, on the present state of which the author appears well informed.

Artrópodos Parásitos. By Prof. Daniel Greenway. Con prologo del Prof. Dr. Pedro Lacavera. Pp. viii+230. (Buenos Aires: La Ciencia tredica, 1908.) This work, issued in 1908, is mainly a compiled account of some of the various Arthropoda that attack and annoy man and animals, or which are parasites or carry diseases. It commences with a description of the Linguatulidæ and Demodecidæ. Then follows an account of the Sarcoptidæ, especially dealing with the human itch mite (*Sarcoptes scabiei*). Several species of Tyroglyphidæ are figured, and also other mites. Information concerning the Ixodidæ, or ticks, covers twenty-one pages; and two useful tables of the genera are given. The piroplasma-carrying *Boophilus bovis* is shown on three coloured plates in adult male and female and larval stages.

Some poisonous spiders are referred to and figured, including the large *Mygala avicularia*. The insects take up most of the volume, extending from p. 89 to p. 221. After a general account of the Hexapods, the author commences with the parasitic and blood-sucking Hemiptera, dealing almost exclusively with the Pediculi.

The major part of this section concerns the Diptera, including the aphaniptera, or fleas. A good account of the "jigger" (*Sarcopsylla penetrans*) is given.

This is followed by a description of the tsetse-flies, or Glossinæ, including a table of species, ten being tabulated, including *G. bocagei* (G. Franca, 1902). Notes are also given on the screw worm (*Comptosia macellaria*), Dermatobia, and other Æstridæ. A considerable space is devoted to a general outline of the family Culicidæ, with a coloured plate reproduced mainly from Arribalzaga's "Diptera Argentina." The central figure (No. 4) of *Anopheles claviger (maculipennis)* is scarcely recognisable.

Some misprints may be noticed, such as *eolopus* for *calopus* (Fig. 149), *bobis* for *bovis* (p. 181), &c.

F. V. T.

Der Kampf um Kernfragen der Entwicklungs- und Vererbungslehre. By Oscar Hertwig. Pp. iv+122. (Jena: G. Fischer, 1909.) Price 3 marks.

WITH his usual clearness, Prof. Oscar Hertwig sums up the situation as regards the rôle of the nucleus in heredity. After stating the foundations of fact on which theories of heredity and development must be built, he enters upon a careful discussion of the important question whether the nucleus is the sole vehicle of heritable qualities. As Fick puts it, Has the nucleus a "Vererbungsmonopol"? The author defends against all-comers the "Hertwig-Strasburger (1884) hypothesis of the localisation of the idioplasm in the nuclear substances," and his arguments are put with much force. They are seven in all, the three best being the equivalence of ovum and spermatozoon as regards nuclear material, the precise partition of nuclear substance in karyokinesis, and the reduction which obviates an accumulation of nuclear material. The case is argued with fairness, and the difficulties which abound are considered carefully, the general conclusion being that the 1884 hypothesis is consistent with a large series of important facts, and that no well-established fact is inconsistent with it.

There is much interesting discussion in the volume, which is conspicuously lucid throughout. We should also refer here to the revised and enlarged edition (Jena: Fischer, pp. 46) of a lecture which Hertwig gave in 1900 on the development of biology in the nineteenth century. It is interesting to notice from the additions that the author is of opinion that actual advances in knowledge necessitate a re-consideration of the theory of natural selection, the Lamarckian theory of direct adaptation; and the recapitulation doctrine.

(1) *Man in Many Lands: Being an Introduction to the Study of Geographic Control.* By Prof. L. W. Lyde. Pp. vii+184. (London: A. and C. Black, 1910.) Price 2s. 6d.

(2) *Questions on Herbertson's Senior Geography.* By F. M. Kirk. Statistical Appendix by E. G. R. Taylor. Pp. 64. (Oxford: Clarendon Press, 1910.) Price 1s.

(3) *Experimental Geography.* By G. C. Dingwall. Pp. vii+168. (London: George Bell and Sons, 1910.) Price 2s. 6d.

(4) *Cambridge County Geographies. Cornwall.* By S. Baring-Gould. Pp. ix+164. (Cambridge: University Press, 1910.) Price 1s. 6d.

THOUGH all are intended to assist school pupils to learn geography, these books have very little in common, so far as the methods adopted by the various writers are concerned. The books show vividly the present diversity of opinion as to the best way of teaching geography. The teacher has a difficult task just now in deciding the course his lessons should take, for the examining and inspecting authorities he has perforce to serve are not yet agreed among themselves. Fortunately, there is a growing conviction that the best results are obtained only when the pupils participate actively in the lessons; and the plan is becoming more and more common of setting children to work for themselves exercises designed to bring out some important principle or fact. The second and third of the volumes under notice will assist the teacher in this part of his work; the third especially, though it follows lines which have been laid down by previous books, will indicate ways in which the pupil may be taught to make his own textbook.

Prof. Lyde maintains his reputation as an experienced teacher. His book is an excellent example of the way in which the practical teacher can make geography a valuable instrument for training boys and girls to reason intelligently. The well-selected coloured illustrations add greatly to the attractiveness of the book.

The last volume is well up to the high standard of the series to which it belongs.

Highways and Byways in Buckinghamshire. By Clement Shorter. With illustrations by F. L. Griggs. Pp. xix+344. (London: Macmillan and Co., Ltd., 1910.) Price 6s.

A COUNTY or a country may be described from various points of view, and in each case the things seen will depend upon the temperament or sympathies of the observer. In this addition to an admirable series of guide-books, the predominant view is that of prominent persons connected with a county which is rich in historic interest. Of the natural history or geography of the county there is nothing, but the human side, which appeals to a wider circle of readers, is presented in a style that commands attention. A few lines are given to Sir William Herschel in connection with Slough; and mention is made of Sir Kenelm Digby, who first brought Sir Thomas Browne's "Religio Medici" into notice, but little more is said of the association of science with the county. Perhaps the mention of Hester Sandys, who married Sir Thomas Temple, of Stowe, and lived to see seven hundred descendants from the union, will interest biologists. Mr. Shorter acknowledges that he is concerned only with the personal element of Buckinghamshire; so while we may regret the limitations thus imposed upon the county's attractions, it would be unjust to apply to his attractive volume any other standards than those of biography and history. There is no lack of living interest, and the volume is sure to be read widely both within and without the county.

LETTERS TO THE EDITOR.

Meteorological Observations during the Passage of the Earth through the Tail of Halley's Comet.

I HAVE cursorily examined the records from ten registering balloons sent up from Ditcham Park and Pyrtou Hill on May 18, 19, and 20. Nearly all the traces show large fluctuations of temperature; but such fluctuations have been observed before, and there is nothing that leads me to suppose that the passage of the earth through the tail of the comet, if, indeed, it occurred before 7 a.m. on May 20, had any effect on the temperature of the upper air. Five of the balloons reached 17 km. or more, and all exceeded 13 km.

W. H. DINES.

June 6.

THE quantity of ozone in the atmosphere at great altitudes, which for some time has been the subject of an investigation by the writer, was estimated on May 18 and 19. It was thought that, in this way, some light might be thrown on the question as to whether any electrical discharges of any magnitude took place in the higher atmosphere during the transit.

The method of conducting these measurements is described in the Transactions of the Chemical Society (1910, xcvi., 868), and consists in the use of a concentrated solution of potassium iodide. It has been found in this work that very dilute ozone reacts with potassium iodide to give iodine, potassium hydroxide, and potassium iodate, the relative amounts of each varying with the temperature. This reaction enables a distinction to be made from oxides of nitrogen, which only give free iodine, and from dilute hydrogen peroxide, which gives iodine and potassium hydroxide, but no iodate.

Three successful experiments were made with the help of the meteorological balloons at about the time of the transit, and the following results were obtained:—

Time of ascent of balloon	Height attained km.	Amount of ozone per cubic metre air mgrm.
May 18, 9.40 p.m. ...	17 ...	0.51 (or 1 part in about 2.6×10^8)
" 19, 2.10 a.m. ...	12 ...	0.54 (" " 2.4×10^8)
" 19, 6.30 a.m. ...	20 ...	0.43 (" " 3.0×10^8)

The above quantities of ozone are not materially different from the amount usually present in the air at these altitudes. Thus the average of three measurements made on March 18 corresponds to 0.72 mgrm. ozone per cubic metre air.

There was also no appreciable change in the quantity of oxides of nitrogen.

Ooze and Irrigation.

AGES have passed since the cultivator first realised the value of rivers as agents in fertilising the soil. The Nile is the classical illustration, and everyone has learned in early life to think of Egypt as being dependent on the life-giving waters for its fertility. But have the reasons for that ever been sufficiently investigated? Probably the majority of people would say that the waters of the Nile bring down vast quantities of soil and disintegrated rock from the heart of Africa, and this earthy matter, held in suspension or carried down by the river in spate, contains the chemical elements which are essential to the growth of plants. I believe that is the usually accepted theory; but does it go to the root of things? Others find the secret in the action of bacteria. I grant the point, but do not think it fully accounts for the facts. I have for some years been engaged in the study of our fresh-water annelids and their place in the economy of nature. I had occasion a few days ago to bring home from the banks of one of our Midland rivers some of the ooze from its banks. When I collected it I found some half-dozen specimens of a common fresh-water worm wriggling about in the slimy mass; but when I came to examine it at leisure, with pocket lens and microscope, I found it to be teeming with life. Vast numbers of tiny annelids (*Tubifex templetoni*,

Southern, or an allied species), minute larvæ, and other living things were to be seen, and at once the question arose, Would the ooze, detritus, alluvium, or disintegrated rock of itself be so special a fertiliser if this teeming life were absent? The ooze is enriched both by the passing of the matter through the bodies of the animals and by the nitrogen from their corpses.

It seems to me that there is need for careful study of the alluvium of rivers from this point of view. Life has probably much more to do with the soil of the Nile and other rivers than is generally suspected. It would be a profitable thing for students to examine the mud of rivers like the Nile during the different seasons. It would then probably be found that at low water various annelids and other aquatic life-forms were breeding rapidly. The myriads of young would be carried by the flood into the lands which are irrigated by the river, and here they would not only be the food supply for the larger forms of life, but would help to keep the soil from becoming sour, and supply vast stores of nitrogen for the plants. I should be happy to hear from workers in this field, and give any hints which experience has taught me.

Gt. Malvern.

HILDERIC FRIEND.

On the Preservation of Hailstones and the Investigation of their Microstructure.

THE investigation of the microstructure of hailstones in summer having proved very difficult, if not impossible, I constructed an apparatus (Fig. 1) for their preservation

Fig

until winter time. The apparatus consists of three co-axial cylinders; the inner space is intended for hail; the middle space for a mixture of ice and cupric sulphate (approximately in the proportion corresponding to eutectics $t = -1.6^\circ$); the outer space for ice, forming a sort of guard coat.

During the summers of 1908 and 1909 I had only once the opportunity of observing a hailstorm; this was on August 2/15, 1909, when I was at sea near Helsingfors on my way from Åland to St. Petersburg. This hail lasted three to four minutes; the hailstones were very small (2-3 mm. diameter), but I gathered 200-300 grams of them, and, in order to avoid their freezing together, immersed them in glass boxes with a mixture of nearly equal parts of benzol and toluol, which I presumed to be of a density equal to the density of hailstones, but which proved to be lighter. These hailstones I brought later to Tomsk (Siberia), and in December sent them to the twelfth Congress of Russian Naturalists and Physicians in session at Moscow. These facts demonstrate thoroughly the possibility of the preservation and transport of hailstones. My

experiment has also shown that it would be better to preserve one or two hundred hailstones separate from each other than a greater number of them, but partly—especially in lower layers—frozen together. That can be attained by placing the hailstones in some very viscous liquid (e.g. cylinder-oil, vaseline, or castor-oil) of a density nearly equal to that of hail.

For the investigation of the microstructure of a separate hailstone Mr. W. Dudecki and I made a thin section of it by first rubbing one side on emery-paper or by melting it with the warmth of a finger. This side was laid upon an object-glass and frozen to it, after touching for some time with a finger the other side of the glass. The other side of the hailstone was then polished in the same manner as the first until the requisite thickness was attained. These operations were made in free air, and were so much easier, as the temperature of the air was below 0° . Still, it was found possible to grind hailstones in the laboratory at the temperature of the room by means of cooling the object-glass, the emery-paper, &c., in double-walled vessels with a mixture of ice and common salt.

For the optical investigation of thin sections in free air a polarising microscope was used, and in a lecture-room a projecting lantern. In the latter case (Fig. 2) the section

FIG. 2.—L, Projecting lantern; P, polariser; M, mirror; R, refrigerating vessel; O, objective; A, analyser.

was laid in a refrigerating vessel with double walls and double bottom (to avoid the condensation of aqueous vapour from the surrounding air) of plane-parallel glass plates. The space between the walls contained a mixture of ice and common salt. The real image of the section was thrown on a screen or on a photographic ("Autochrom") plate.

The greater part of the hailstones were crystalline individuals, as also was the case with "artificial hailstones"—drops of water frozen in a mixture of cinnamon and linseed oil of suitable density. In those hailstones, which consisted of several crystalline individuals, there was no regularity in the form of the boundaries between crystals, or in the angles between these boundaries, or in the directions of the optical axes, which lay indifferently to each other, as well as to the milky nucleus of the hailstone, which appeared in the section as a number of air-bubbles of different size.

I trust that my attempt will cause similar researches to be undertaken, and I should be very glad if anyone who may be able to preserve or study larger or more peculiar hailstones than I have hitherto done will do so, and in this way improve our deficient knowledge on the origin of hail and the details of its formation.

Institute of Tomsk, Russia.

Thoughtless Destruction of Wild Flowers.

MAY I ask through your widely circulated paper that those who organise the weekly or fortnightly visits of poor town children to country villages may be requested to instruct these children to pluck only a limited number of wild flowers? It is no uncommon sight to see a dozen or more of these children going along a road or railway embankment and plucking every flower they can find, as well as rooting up those which are small enough. In half an hour the flowers have withered, and are thrown away, when the same process is repeated.

GEO. HENDERSON.

Otford, Kent, May 27.

RECENT PROGRESS IN INDIAN FOREST TECHNOLOGY.

THE excellence of the work of any public department depends on the character and ability of the men who direct it, and the Indian Forest Department was singularly fortunate in its first Inspector-General, the late Sir Dietrich Brandis, K.C.I.E., F.R.S. He secured State ownership and State management for the forests both in British India and in the native States, and also a trained staff of forest officers. He placed Indian forest law on a firm basis by selecting as Conservator of Forests, Mr. B. H. Baden-Powell, C.S.I., a member of the Punjab Civil Service, who, after working for a decade of his life in the forest service, became presiding judge of the chief court at Lahore. Baden-Powell drafted the Indian Forest Acts, models of forest law that are followed by all colonial legislators, and his "Manual of Forest Jurisprudence" is the only English book on the subject. No mere forester could have drafted those laws successfully, nor could any mere lawyer, but Baden-Powell was both lawyer and forester.

Brandis also established a forest survey under Lieut.-Colonel F. Bailey, R.E., and Mr. W. H. Reynolds, and their maps gained gold medals at two Paris exhibitions, and were the first Indian maps that showed a good system of contour lines. A forest school for training native members of the provincial and executive staffs of the Forest Department was established in 1881, at Dehra Dun. Useful manuals of forestry, by Mr. E. E. Fernandez, and of botany, were published soon after the establishment of this school for the use of the students. Brandis also published a Forest Flora of Northern India, followed quite recently by his last great work, "Indian Trees," a forest flora for the whole of India. Mr. Kurz had previously written one for Burma and Major Beddome for Madras, while Mr. J. S. Gamble, C.I.E., F.R.S., published a splendid monograph of Indian bamboos. Gamble, under Brandis's direction, published, in 1881, a "Manual of Indian Timbers," and again, in 1901, after collecting material for twenty years, a new and greatly enlarged and improved edition. "The Indian Forester" first appeared in 1876, Dr. Schlich, now Sir W. Schlich, K.C.I.E., F.R.S., being the first editor. Schlich succeeded Brandis as Inspector-General of Forests in 1881, and instituted a proper system of working plans for Indian forests. He came home in 1885 and established a school of forestry at Coopers Hill, and, in conjunction with myself, published a "Manual of Forestry."

The training of men in England for the Indian Forest Service was not at first in accordance with the wishes of Brandis and Schlich. They recommended that the Imperial School of Forestry should be at an English university, and that, as the so-called Civil Service of India is recruited chiefly from university men of good literary and legal attainments, so the Imperial Forest branch of the Civil Service, which manages one-quarter of the land of British India, should be composed of university men of good scientific attainments. But the India Office wished to support the Royal Indian Engineering College at Coopers Hill and kept the forest probationers there until 1905, the year before the college was closed. In 1905, an Imperial School of Forestry was established at Oxford under Sir William Schlich, and is now training more than seventy men for India, the colonies and for forest work at home.

Until 1904 very little progress was made in Indian forest technology, for which Brandis had laid such

splendid foundation. It was found that the class of candidates for the forest service was falling off in numbers and quality, the salaries were not sufficiently attractive, and in 1905 only two candidates appeared for sixteen posts, so that a system of appointment by selection was adopted. The Secretary of State has now raised the pay of the Indian Forest Service, and allows 120*l.* a year to such of the two years' probationers who are B.A.s with honours from any university, so that this year there were sixty candidates for twelve appointments. Besides insisting on the qualification of an honour degree, it is essential to secure that all probationers should join the Oxford School of Forestry, with a sufficient knowledge of English, elementary mathematics (including trigonometry), physics, and chemistry. During the two years' course for a forestry diploma at Oxford, botany, zoology, and geology can be taught, as well as forestry, surveying, and forest law. Strange to say, some of our British universities have such an imperfect entrance examination that men are allowed to enter for and take honour degrees in biology or geology without necessarily knowing more than the rudiments of mathematics, chemistry, or physics, and without passing any test in English. The possession of an honour degree in science at a British university is not, therefore, a sufficient qualification for a forest probationer. A certain knowledge of German also is very desirable for admission to the Oxford School of Forestry, and this is but rarely obtainable from our public-school men. Our best Oxford foresters should be capable of teaching scientific and practical forestry throughout the Empire.

Although the forests of India, between 1885 and 1905, continued to be well managed by a devoted corps of practical foresters, very little, if any, progress in forest technology was made during those twenty years. In 1906, Mr. S. Eardley Wilmot, C.I.E., Inspector-General of Forests, following the initiative of his predecessor, Mr. R. C. Wroughton, established a forest research institute the members of which devote all their time to the study of the various branches of forestry, as well as to zoology, mycology, and the physics and chemistry of forest products. The results of this research are published in "Indian Forest Records." Vol. i., for 1909, of these records contains papers on the lac insect, by E. P. Stebbing; on beetles boring in Chilgoza bark, by E. P. Stebbing and Capt. E. H. James; the development of *Shorea robusta* in volume and money value, and the selection system in Indian forests, by A. M. F. Caccia; Andaman Padank, by B. B. Osmaston; the Cutch trade of Burma, by R. S. Troup; Ngai camphor, and Burmese varnish from the sap of *Melanorrhoea usitata*, by Pura Singh. Several useful and, for the most part, elementary manuals have been prepared by members of the Research Institute and others, the most elaborate of which are "Indian Forest Engineering," by G. M. Rogers, and "Indian Forest Zoology," by E. P. Stebbing.

Unfortunately, the establishment of this institute was followed by a temporary deterioration of the teaching staff in Dehra Dun, for the Government of India did not accept Mr. Wilmot's proposal to retain an adequate staff of instructors there, but handed over the practical teaching to the provincial staff, the research officers considering that their other duties would not allow them time to teach the students. The Dehra Dun Forest School, recently dignified with the title of Imperial Forest College, was overcrowded with students, 120 applications for admission having been received in 1909, and the students had not sufficient respect for their native teachers, so that discipline suffered greatly.

The Indian Universities Act of 1894, which has exerted its influence so widely on higher studies, has failed to reach Dehra. Engineering, medicine, and agriculture, and science generally, have made great advances of late in response to the stimulus of university reform, but at the Imperial Forest College the qualifying entrance examination is still much the same as when it was a school, and its courses still include an amount of rudimentary science that should have no place at a college. This becomes evident when the standards there are compared with those at the agricultural colleges recently established in the various provinces of India. The final examination for the diploma in forestry at Dehra should also be equivalent to those for a B.A. degree, as is the case at agricultural colleges.

The present Inspector-General of Forests, Mr. F. Beadon Bryant, has recognised that the teaching of forest rangers has fallen off since the Research Institute was started, and that it was a mistake to entrust the teaching of classes of sixty students there to members of the provincial service. Research officers in future will give lectures to the students during the four months' monsoon session, and three officers of the Imperial Forest Service are being appointed to teach the students throughout the two years' course for rangers and the three years' course for the provincial staff. Overcrowding at Dehra is to be avoided by the establishment of a school for rangers in the Madras Presidency, with at least two professors from the Imperial staff, and probably another school on similar lines will be established in the Central Provinces. Indian forest schools have to provide foresters for Kashmir, Mysore, Hyderabad, and the other native States, besides for British India, and Mr. Wilmot has recently been deputed to Nepal to organise a suitable forestry department there.

It is evident that schools of forestry, at home, in India, and in the colonies, must be in close touch with the universities; but while Indian universities have a suitable English and scientific entrance examination, this is not yet the case with some of our most important home universities, and this defect calls loudly for reform in the best interests of our Empire. The prospects of forest technology in India are now very high, and it is to be hoped that, following the example there and that of South Africa, where a forest school has been established, the Dominion of Canada, Newfoundland, Australia, and New Zealand will soon bestow sufficient attention on forestry and establish local forest schools. Besides India and South Africa, the scientific forestry of which has been long established, there are regular forestry departments in Ceylon, the Malay States, the Soudan, British East Africa, Mauritius, Cyprus, and in some of the West Indian Islands.

W. R. FISHER.

THE TWENTIETH-CENTURY SPORTSMAN.¹

THIS amazing picture-book (commendable, among a hundred other reasons, in that, though large in size, it is very light to hold in the hand) will probably *faire école*. That it has made a sensation amongst the reading public interested in Africa is already observable by the reviews of it which have appeared in the leading newspapers, and the vogue it has attained in spite of the conflicting interest of current politics. This is little to be wondered at. The author (who is the brother of the Captain W. R. Dugmore who distinguished himself in Uganda and elsewhere as a soldier-pioneer) had, no doubt, supreme

¹ "Camera Adventures in the African Wilds; being an Account of a Four Months' Expedition in British East Africa, for the Purpose of Securing Photographs from Life of the Game." By A. Radclyffe Dugmore. Pp. xviii+231. (London: William Heinemann, 1910.) Price 30*s.* net.

FIG. 1.—Telephoto of Kilimanjaro about eighty miles away. The entire lack of detail on the lower part of the mountain is due to atmospheric effect, which renders distant objects the colour of the sky unless they are above the heated stratum near the earth. From "Camera Adventures in the African Wilds."

FIG. 2.—Large Herd of Giraffe and Grant's Zebra, showing the comparative sizes of the two strongly marked animals. (Telephotograph at about 300 yards.) From "Camera Adventures in the African Wilds."

good luck, but he and his companion, Mr. James L. Clark, were also possessed of singular courage and skill both as photographers and marksmen, and, if need be, mechanics. Good luck gave them the chance of a telephotograph of Kilimanjaro, eighty miles distant, which is one of the weirdest mountain pictures the present writer has even seen, and confirms his old story of twenty-five years ago that Kilimanjaro, in certain aspects, resembled Swift's floating-island of Laputa. Amongst other episodes of singular good fortune was the photographing of the still very rare black Forest pig. This creature, the existence of which was rumoured by Stanley, George Grenfell, and the present writer in the Congo Forests, was actually first revealed to science by Captain Meinertzhagen and Mr. C. W. Hobley, far away from the Congo basin, on the Nandi plateau and round Mount Kenia (though it was soon afterwards obtained from the north-east Congo, and finally from the Cameroons). But specimens of it are still scarcer than those of the okapi, and to have photographed the creature, *wild and in its forest home*, is an episode that probably Mr. Dugmore never anticipated, even in his rosiest anticipations.

The book gives unrivalled pictures of the fauna of Equatorial East Africa, of that singularly fascinating region between Kilimanjaro on the south and the Guaso Nyiro on the north, the Rift Valley on the west and the Tana River on the east. Here there are long ranges of mountains that only fall just short of the level of perpetual snow, and there are the snow-fields and glaciers of Kenya, rendered marvellously well in Mr. Dugmore's pictures. Immense grassy plains, dense thorn scrubs, lakes peopled with flamingoes, splendid equatorial forests recalling those of West Africa, deep water-courses or canyons, broad rivers with great herds of hippopotami and monstrous crocodiles, and patches of camel-frequented desert—all these phases of physical geography are admirably illustrated, in addition to the pictures of beasts, birds, and indigenous mankind. We are getting almost tired of lions since the advent on the scene of the flash-light photographer: the lion and lioness, indeed, seem to be almost like the popular actress or politician in their desire and willingness to be photographed in interesting attitudes. But although this book has some of the best lion pictures I have ever seen, it will probably be more noteworthy for its photographs of charging rhinoceroses, of buffaloes passing through the long grass, or hiding themselves at noon-day in dense forest. Another notable feature is the numerous studies of giraffes, sometimes looking exactly like withered tree stumps, at others suggesting prehistoric monsters. The most striking of these giraffe studies (and the most beautiful) is that where, by means of a telephotograph, a large herd of giraffe, and a smaller herd of Grant's zebra, are shown together in an immense tract of savannah country dotted with acacias. If that does not suggest the Pleistocene at its best, we do not know what does. The geographical scope of the book extends far enough north to include the Samburu and their camels, camels which have suggested to more than one observer, British or Italian, the possibility of their being derived from a wild camel which may still exist in the remotest, as yet completely unexplored, parts of Galaland.

The book opens with an appeal "to the lovers of sport, and perhaps to those who consider themselves as such, but whose only claim is the insatiate love for killing which characterises their idea of sport." The author goes on to state that, like many others brought up to the use of firearms, he considered the man who did not shoot a very inferior person, in fact, unmanly. But as the years went by he himself

became more deeply interested in natural history, and the idea of killing for killing's sake lost its fascination. In time he found that the most thrilling sport of all was the studying of the life of animals in their native wilds rather than in the killing of them merely to possess the skin or other trophies. Enough is said in his book to show that he and his companion ran, perhaps, greater risks in their attempt to snapshot charging rhinoceroses, lions, and buffaloes than would the sportsman who was merely out to kill, while the acrobatics necessitated in natural-history photography are enough to prove that the follower of this sport has to be a far more athletic and courageous person than the mere shooter.

Whether Mr. Dugmore will meet with any more success in his appeal than has followed the work of Mr. E. N. Buxton, and others of like persuasion is a moot question. His unsurpassed photographs have revealed once more the wonderland in bird and mammalian fauna represented in Inner East Africa, and already a company, with an office in Piccadilly, has issued a pamphlet on British East Africa, illustrated by some of Mr. Dugmore's photographs, which offers every inducement to persons of both sexes to proceed to East Africa "to shoot." In this pamphlet it is stated that the report about the country being "shot out" is far from the actual truth. (Nothing, so far as I can see, is said about the attractions to the photographer.) In the list of animals which may be shot under the ordinary licence (and in this the pamphlet is not to blame, for it merely quotes official regulations) is given "four egrets of each species." What of its kind can be more monstrous than this? Egrets—white herons—are quite uneatable, they are supremely beautiful, and we now know—or ought to know—that they are large consumers of noxious flies—*Glossina* (tse-tse), *Stomoxys*, *Tabanus*—and all the larger gnats. For this reason alone all these smaller herons should be rigidly protected.

H. H. JOHNSTON.

WIND STATISTICS AND AERONAUTICS.

THE practical interest shown in Germany in the navigation of the air is widespread, and goes hand in hand with a determination to utilise all auxiliaries that promise to advance the subject. Among such auxiliaries must be included the observations of wind which form part of the stock in trade of the meteorologist. The "Motorluftschiff-Studien-gesellschaft" of Berlin, founded in 1907 at the instance of the German Emperor, has accordingly requested Prof. Assmann, the director of the Aeronautical Meteorological Observatory at Lindenberg, to undertake a detailed analysis of the wind data available for the German Empire. The society has provided a large part of the funds required for the work. The results have now been published. They give average values, generally for the twenty years 1886-1905, for forty-nine stations. The original schedules were prepared in the various offices which are responsible for the meteorological work of the component States of the Empire. The final discussion was undertaken at Lindenberg under the direction of Prof. Assmann.

Some idea of the magnitude of the work involved may be gathered from the fact that the preparation of the primary schedules is estimated to have occupied about 2550 hours of clerk's time. It was decided to limit the discussion to the Beaufort estimates of

1 "Die Winde in Deutschland." Im Auftrage der Motorluftschiff-Studien-gesellschaft in Berlin. Bearbeitet von Richard Assmann. Pp. iv+48; tafeln xiii. (Braunschweig: F. Vieweg und Sohn.) Price 5 marks.

"I Venti in Italia." Estratto dalla Rivista Tecnica di Aeronautica e Boll. della Soc. Aeronautica Italiana. Dott. Filippo Eredia, Meteorologista al R. Ufficio di Meteorologia e Geodinamica. (Roma: Officina Poligrafica Italiana, 1909.)

wind force and direction made at selected stations of the second order. A discussion of the results obtained by anemometer was not attempted, on the ground that differences of exposure and of the types of instruments rendered instrumental results less trustworthy than Beaufort estimates, so far as comparability with one another goes—a striking testimony to the value of the latter, if carefully made. The main tables give for each station the percentage frequency of wind from each of eight principal directions. The winds from each direction are then subdivided according to wind velocity, five gradations ranging up to 15 m.p.s. being distinguished. Values are given for the whole year and for each quarter separately.

The last chapter of the work is devoted to a discussion of the results for the upper air obtained with kites at Lindenberg. Tables of averages, similar to those prepared for individual stations, are given for each step of 500 metres up to a height of 4000 metres.

In "I Venti in Italia" we have a publication which is inspired by much the same idea. It has been prepared at the instigation of the Italian Aeronautical Society, and gives information for 111 stations in Italy. As in the German work, the observations are grouped under the eight principal wind directions, but the subdivision by wind forces is not carried out. To make up for this omission, the results for the country as a whole are shown graphically on a series of coloured plates included in the final section. In a country like Italy, where there is a marked seasonal variation of wind direction, a pictorial representation is very useful. The work has been entrusted to Dr. Filippo Eredia, of the Central Meteorological Office of Italy, whose name is a guarantee of careful workmanship.

We cannot discuss the statistical details; he who is interested in the influence of topography on air currents will find much useful information in the very complete wind-roses given with both works. The results will also be useful to aeronauts when selecting sites for practising grounds or for aerial harbours, or in such matters as the selection of the seasons most appropriate for their experiments.

NEW GUINEA PYGMIES.

IN the last number of *Country Life* (vol. xxvii., p. 797) Mr. W. R. Ogilvie-Grant, under the running title of "The Expedition of the British Ornithologists' Union to the Snow Mountains of New Guinea," published his fourth article, entitled "The Discovery of a Pigmy Race," part of which appeared in the *Times* on June 3. All the information we have at present is that the expedition ascended the Mimika river, and at "an elevation of about two thousand feet they came across a tribe of pigmy people, of whom the tallest stood about four feet six inches, the average height being four feet three inches. Though at present no further details have been received except that they were extremely wild, there can be little doubt that they belong to that distinct division of the human race known as the Negritos." Mr. Ogilvie-Grant added a short account, with illustrations, of the Semang, a Negrito people of the Malay Peninsula.

Although stature cannot be taken as a trustworthy criterion of race, as it is very variable, there are certain peoples who can be described as normally tall, medium, or short; those whose stature falls below 1·5 m. (4 feet 11 inches) are usually termed pygmies, such as the Negrillos of Central Africa, Andamanese, Semang of the Malay Peninsula and Sumatra, and Aetas of the Philippines, the three latter being usually grouped together as Negritos. The Negritos are char-

acterised by having short ulotrichous (woolly) hair, very dark skin, moderate brachycephalism, and pygmy stature.

In a valuable essay, "The Negritos" (1899), Dr. A. B. Meyer critically examined the evidence of the distribution of this race, and, so far as New Guinea is concerned, stated that

"A Negritic race side by side with the Papuan race nobody has been able to discover just because it does not exist, and it does not exist because the Papuan race, in spite of its variability, is on the one hand a uniform race, and on the other as good as identical with the Negritos" (p. 85).

When reviewing this essay in *NATURE* (September 7, 1899, p. 433), I stated that I was inclined to adopt the view that the various types exhibited by the natives of New Guinea "point to a crossing of different elements," and do not "simply reveal the variability of the race," as Dr. Meyer is inclined to believe. While agreeing with Dr. Meyer that the different conditions of existence (p. 80) in New Guinea probably have reacted on the physical characters of the natives (about which, however, we have extremely little precise information), we have now sufficient evidence to prove that the indigenous population, or true Papuans, has in places been modified by intrusions from elsewhere, and of late years data have been accumulating for the probability of the existence of a pygmy population, which may consist of dwarfed Papuans, or more probably represents a Negrito stock.

In *Globus* (Bd. xcvi., May 12, 1910, p. 286), Dr. O. Reche, in describing a journey up the Kaiserin-Augusta River, says that—

"the population consists of three clearly distinguishable types or races, two of which have long, very narrow skulls, and one a short, broad skull. Inland from the river bank there seems to be in addition to these a pygmy-like people of small growth; at all events, I found in some of the villages situated on the upper river, among other skulls, some which were remarkably small and of a special type which must have been taken from enemies living farther inland."

Dr. Rudolf Pöch stayed from December, 1904, to February, 1905, in the Kai area, which lies inland from Finschhafen, also in German New Guinea. In the *Mitt. aus den deutschen Schutzgebieten*, 1907, he writes (p. 225):—

"During the first part of the time I remained chiefly on the Sattelberg itself, and observed and measured the numerous Kai frequenting the Mission station. In them I became acquainted with a mountain tribe entirely differing from the coast peoples previously visited. In fifty men I found the average height to be 152·5 cm. [5 ft.]; the skulls are, as a rule, mesocephalic to brachycephalic. Towards the coast (Jabim) dolichocephaly becomes more usual, and the type also changes. Very small people are not infrequently met among the Kai. I have already dealt with this remarkable phenomenon elsewhere,¹ and will not repeat myself here, but simply give the figures. Among 300 adult males I found 9 [sic] individuals, i.e. three per cent., below 146 cm. [4 ft. 9½ in.] in height. The statures measured were: 133 [4 ft. 4½ in.], 135, 138·2, 139, 139·1, 140, 143, 143·1, 143·2, 145·4, 145·5, 145·6 [4 ft. 9½ in.]. Fig. 1 shows three of these small Kai people. For the present it cannot be determined whether this is merely a variation in stature or whether we have here survivals of an older smaller race not yet entirely merged into the Kai."

In the *Zeitschr. für Ethnol.*, 1907, p. 384, Dr. Pöch states that the median height of the Kai men is 152·5 cm. (5 feet), that 3 per cent. have a stature less than 140 cm. (4 feet 7 inches), and he goes on to say that on the north coast of British New Guinea and in Normanby Island he often came across very small

¹ *Sitzungsbericht der anth. Gesellschaft in Wien*, 1905, p. [40] ff.

people. This agrees with the experience of other travellers.

The English expedition has now discovered a pygmy population in Netherlands New Guinea, which presumably is allied to that inhabiting German New Guinea, and, judging from their stature, which is all we have to go upon, we may regard them as being very little, if at all, mixed with a Papuan element. From the descriptions and illustrations given of the pygmies from German New Guinea, there is little doubt that they are Negritos or Negritos crossed with Papuans, and doubtless the same will be found to be the case for those from Netherlands New Guinea.

Several travellers, such as Guppy and Ribbe, report the occurrence of very short people in the interior of the larger islands of the Bismarck Archipelago and of the Solomon Islands; but there is no evidence of a Negrito race still existing there as such, though the very short statures point to a Negrito mixture. This conclusion is strengthened by the recent investigations of Dr. R. Thurnwald (*Zeitschr. für Ethnol.*). He refers to very small people in the mountainous interior of Bougainville, and he measured (p. 109) one man from Mari mountain with a stature of 1'39 m. (4 feet 6½ inches). These people speak a non-Melanesian language. He informs us that "In the people nowadays met with in these mountains we have before us, however, no unmixed race, but, besides representatives of a small, short-legged, broad-faced, short-skulled, more hairy, wide-nosed people, we encounter types recalling the Solomon Islanders. . . . Whether this mountain type is really dwarfish, as the legend goes, must remain undecided." Rascher states that the existence of dwarfs is commonly believed in New Britain. They are reported to live in clefts in the rocks and steal fruit from the gardens. They are so tiny that one stands on the shoulders of another, and so on, until they reach the fruit. The fruit is not thrown down, lest a noise would be made, but passed from hand to hand, until it reaches the chief, who is on the ground.

A. C. HADDON.

NOTES.

THE annual visitation of the Royal Observatory, Greenwich, will be held on Saturday, June 18.

At the request of the Association of American Agricultural and Experiment Stations, Prof. J. C. Ewart, F.R.S., of Edinburgh, will give a course of lectures on the principles of breeding, at Ames, Iowa, in July.

M. DARBOUX, permanent secretary of the Paris Academy of Sciences, has been elected president of the Société de secours des Amis des Sciences, and M. Picard, president of the academy, has been elected vice-president of the society.

WITH the view of collecting material for the life of the late Prof. Alexander Agassiz, we are asked to state that anyone having any of his letters will confer a favour by sending them to his son, Mr. G. R. Agassiz, Museum of Comparative Zoology, Cambridge, Mass., U.S.A. The letters will be copied if desired, and the originals returned to the owner as soon as possible. If any persons are unwilling to part with the original letters, Mr. Agassiz would be glad if they would have copies made at his expense and send them to him at their convenience.

TO-DAY, at the University of Halle, the sixtieth birthday of Prof. W. Roux, the founder of the modern science of experimental embryology, is being celebrated. His numerous pupils and other admirers are expressing their appreciation of the magnificent work which he has accomplished for

biological science in the manner customary in German universities, by the publication of a "Festschrift" and the presentation of an address. We do not doubt that we are expressing the feelings of all British biologists in offering to Prof. Roux our heartiest congratulations on this occasion, and in hoping that he will long continue to illuminate the study of animal development by his brilliant investigations.

A SEVERE earthquake occurred in the province of Avellino, east of Naples, at 3.5 a.m. on June 7. The disturbance caused considerable damage in Calitri—about fifty miles east of the town of Avellino—and Calabritto, another small mountain town. The shock was felt also in Naples, Benevento, and other places in southern Italy.

DR. DAVID STARR JORDAN, the president of Leland Stanford Junior University, California, will leave at the end of the academic year for Europe, where he will spend his first vacation for a quarter of a century. He expects to devote some of his time to the two-fold "holiday task" of promoting a zoological congress and assisting the peace movement.

AMERICA has lost a veteran science teacher by the death, in his seventy-fifth year, of Dr. G. F. Barker, who was professor of physics at the University of Pennsylvania from 1872 to 1900. He was appointed U.S. commissioner to the Electrical Exhibitions held at Paris in 1881 and at Philadelphia in 1884, and was a member of the jury on awards at the Columbian Exposition of 1893. In 1879 he was president of the American Association for the Advancement of Science. Prof. Barker was the first person to exhibit radium in America. The death is also announced of Dr. Franklin Clement Robinson, who had held the chair of chemistry at Bowdoin College, Maine, since 1874. He was president of the American Public Health Association in 1906. He was a frequent contributor to the *American Chemical Journal*, and had written text-books on the metals and qualitative analysis.

DURING the evening of June 2 Mr. C. S. Rolls travelled with a biplane from Dover to Sangatte, and, after circling over the semaphore station there, he returned to Dover, thus making the first double journey across the English Channel. The whole journey occupied 90 minutes, and was made at an average height of 800 feet. The Army experimental airship *Beta* made a successful flight from the balloon works at Farnborough to London and back during the night following June 3. On the journey to London the *Beta* travelled against a light wind from the north-east, and made a speed of 26 miles an hour. The greatest height attained during the flight was 1800 feet, and the mean altitude about 1000 feet. The engines of the airship are of 35 horse-power. The journey back from Southwark to Farnborough occupied 1h. 28m.

A BUST of Pasteur was unveiled in the garden of the École Normale Supérieure, Paris, on June 5. The *Morning Post* Paris correspondent reports that M. Lavisé, of the French Academy, made a speech in the name of the Normal School. He recalled the fact that Pasteur spent thirty-seven years in the famous college, and that his first laboratory consisted of two garrets in its buildings. He spoke of Pasteur's relentless warfare against the forces of nature hostile to man; it was only after five years' study that he discovered the remedy for rabies. Above all things he was an indefatigable worker. "He called the interval of night 'hours of waiting,' which always seemed to him slow to pass." His method was based on two principles: first, on curiosity; secondly, on the determination to discover. M. Lavisé dwelt on Pasteur's faith in science and the fascination of mystery to his mind.

FOLLOWING upon the invitation to the British Association from the Corporation of Portsmouth to hold the annual meeting at that town next year, a public meeting, presided over by the Mayor, Sir William Dupree, was held recently, at which the names of several influential and well-known gentlemen were submitted as vice-presidents. Two local secretaries were appointed in Mr. G. Hammond Etherton, Town Clerk, and Dr. A. Mearns Fraser, Medical Officer of Health, and various preliminaries in preparation for the reception of the association were decided upon. The Corporation of Portsmouth is looking forward to the meeting with considerable enthusiasm, and a large sum of money has been voted to the Mayor for next year in order to enable him to extend the hospitality of the town to members of the association. Owing to the generous dimensions of the Portsmouth Town Hall, the adjoining Technical Institute, and several other large buildings in the immediate vicinity, exceptional facilities will be available for the various meetings of sections, discussions, and public functions, and everything points to a very successful meeting.

MR. J. B. N. HENNESSEY, F.R.S., whose death was announced in NATURE of May 26, was formerly deputy surveyor-general in charge of the Trigonometrical Surveys, Survey of India. He was appointed to the Trigonometrical Survey so long ago as 1844, and for some years worked in most unhealthy parts of India. For the following particulars of his career we are indebted to an obituary notice in the *Times*. While on long leave in 1863-5, Mr. Hennessey entered Jesus College, Cambridge, and worked under Profs. Adams, Challis, and Walton to improve his mathematical knowledge. He obtained sanction not only to learn photo-zincography at the Ordnance Survey, Southampton, but also to take out on return to duty an extensive apparatus, and to establish the process at the survey headquarters at Dehra Dûn. He taught the process to other officers, and the result was that in a few years hundreds of thousands of good maps were printed in place of those made by uncertain pen transfers. Not less important was Mr. Hennessey's work in taking in hand the vast accumulations of material provided by the labours of Lambton, Everest, and Waugh in their unrivalled trigonometrical operations, and reducing them to order by suitable scientific methods. The final results were brought together in fourteen large quarto volumes distributed gratis by the Government of India to scientific departments and associations throughout the world. Mr. Hennessey took a leading share in other scientific operations in India, including the determination of the standard bar, comparison of standards, and the measurement of base lines. He built two of the Indian observatories, and for the Royal Society mapped the telluric lines of the solar spectrum, and made prolonged actinometric observations. He was elected a Fellow of the Royal Society in 1875.

SIR FRANCIS SEYMOUR HADEN, who died on June 1, at ninety-two years of age, was chiefly known to the present generation as an etcher, and it was for his artistic achievements that he was awarded his knighthood. In his earlier days, however, he took a very prominent and important part in the progress of the medical profession. He was educated at University College, London, and continued his studies at the medical schools of the Sorbonne, in Paris, and of Grenoble. He became a Fellow of the Royal College of Surgeons of England, and honorary surgeon to the Department of Science and Art. He worked actively on various international juries dealing with the progress of surgical science. His report for the International Exhibition of 1862 gave an exhaustive review of European surgery.

This report was chiefly remarkable for his earnest advocacy of the operation of ovariectomy, which had been ill-received up to that time. He was an active vice-president of the Obstetrical Society of London, and was chiefly instrumental in founding the Royal Hospital for Incurables. His name became prominently known in connection with the subject of burial. His investigations into the condition of the graves in a London churchyard which was in the course of being converted into a public garden showed the state of affairs to be indescribably revolting. He invented the *papier-mâché* coffin, and was a strong advocate of earth burial. He was strongly opposed to cremation, principally on account of its legal difficulties.

WE regret to see the announcement of the death of Dr. Elizabeth Blackwell, in her ninetieth year. She was the first woman to become a fully qualified medical practitioner, and the first woman whose name was placed on the British Medical Register. She lived many years in the United States, but never became denationalised. At the age of twenty-six she obtained entrance into the medical school attached to the University of Geneva, in the State of New York, where her "carefully hoarded earnings" just sufficed for her maintenance during her period of study. The professors declined to take the responsibility of admitting her; they referred it to the students. These were unanimously favourable to her admission, and pledged themselves that no conduct of theirs should cause her annoyance. On the completion of her studies at Geneva, N.Y., her degree was conferred in the presence of a great crowd. She came to England in 1849, and found much prejudice in professional circles. On coming to London in 1850 Mr. Paget (afterwards Sir James Paget), then Dean of St. Bartholomew's Hospital, gave her leave to attend the hospital as a student, and she was admitted to every part of the hospital except the department for the diseases of women! She studied for a year in La Maternité Hospital in Paris, where she had the misfortune to contract purulent ophthalmia from one of her patients. It cost her six months' illness and the sight of one eye, and ended her hope of making surgery her speciality. In 1851 she returned to America, and began practice in partnership with her sister Emily. She felt keenly the want of hospital practice, and established a dispensary, from which, in the course of time, there grew the New York Infirmary for Women, which was a women's hospital officered by women. On re-visiting England she had her name placed on the English register, and immediately afterwards an Act of Parliament was passed excluding the owners of foreign degrees from the register. In London she lectured on medicine as a profession for women. Among her audience was Miss Elizabeth Garrett (now Mrs. Garrett Anderson, M.D.). On the outbreak of the Civil War in the United States Dr. Blackwell returned to New York. She held the chair of hygiene in the Medical School for Women in New York, which was then established, and organised the services of sanitary visitors in the slums of New York in anticipation of modern developments. She returned to England, and had the "pleasure and privilege to encourage Dr. Anderson and Dr. Sophia Jex Blake in their pioneer enterprise in England." When the New Hospital for Women was founded she was on the consulting staff, and later, when the London School of Medicine for Women was opened, she held the chair of gynaecology until her health began to fail.

THE Christiania correspondent of the *Morning Post* contributes to the issue of our contemporary for June 6 some interesting particulars of Captain Amundsen's expedition to north polar regions, which started on that day. The

journey will be made in the *Fram*, which is thus now on her third polar expedition. Among the problems which Captain Amundsen hopes to solve are the extent, depth, and character of the polar basin. He proposes to measure exactly the temperature and salinity of the streams of the polar basin, and to work at tide gauging, ice screw measurement, and wind speed. Captain Amundsen is prepared for seven years' absence. Once across the Atlantic, he will return in August to Christiansand to fetch Eskimo dogs. A few days later the *Fram* will shape its course from Cape Horn to San Francisco, where coal and provisions will be taken in. In June, 1911, a start will be made for Point Barrow. The *Fram* will follow the moving ice over the polar basin, and it is hoped that the actual Pole or its near neighbourhood will be crossed. The object of the expedition is purely scientific. Captain Amundsen expects to reach open water between Greenland and Spitsbergen in 1915 or 1916.

In connection with the annual grant voted by Parliament in aid of scientific investigations concerning the causes and processes of disease, Mr. Burns, the President of the Local Government Board, has authorised the following special researches. (1) A continuation of an investigation into protracted and recurrent infection in enteric fever, by Dr. Theodore Thomson, Medical Inspector of the Board, in conjunction with Dr. Ledingham, of the Lister Institute. (2) A continuation of an investigation into protracted and recurrent infection in diphtheria, by Dr. Theodore Thomson and Dr. C. J. Thomas. (3) A continuation of an investigation into flies as carriers of infection, by Dr. Monckton Copeman, Medical Inspector of the Board, in conjunction with Dr. Graham Smith and Mr. Merriman, of the University of Cambridge, Dr. Nicholl, of the Lister Institute, and Dr. Bernstein, of the Bacteriological Laboratory, Westminster Hospital. (4) A continuation of an investigation on the injurious gases evolved during artificial illumination, by Dr. J. Wade, of Guy's Hospital. (5) A preliminary inquiry into the relationship of certain special types of bacteria to the diarrhoea of infants, by Dr. C. J. Lewis, of Birmingham, Dr. Sheila M. Ross, of Manchester, Dr. Thomas Orr, of Shrewsbury, and Dr. R. A. O'Brien, of the Lister Institute.

THE summary of the weather for spring, comprising the thirteen weeks in March, April, and May, just issued by the Meteorological Office, shows that the mean temperature for the period was nowhere very different from the average. The north-east and east of England were the only districts where the thermometer in the shade exceeded 80° ; the highest temperature was 83° in the east of England, and the lowest 20° in the north of Scotland and in the south-west of England. The aggregate rainfall for the period varied in different parts of the United Kingdom, the total measurement being in excess of the average in the north and east of Scotland, in the east, south-east, and north-west of England, whilst in all other districts there was a deficiency. With the exception of the north of Scotland, where there was an excess of 3 inches, the difference from the average was nowhere large. The number of rainy days was in excess of the average in all districts except in the east of Scotland and in the Channel Islands. The largest measurement of rain was 12.91 inches in the north of Scotland, which fell on 60 days; the least measurement was 4.87 inches, in the Midland counties, which fell on 47 days. The duration of bright sunshine was nowhere very different from the average; the greatest excess was 28 hours in the south-west of England, and the greatest deficiency 40 hours in the south of Ireland. At Greenwich

the mean temperature for the three months was 0.3° above the average, the rainfall was 0.93 inch more than the normal which fell on 45 days, and the duration of bright sunshine was 66 hours more than usual.

IN the spring of 1909 the board of governors of the Camp-Fire Club of America decided that the time was ripe for instituting an active campaign for the protection of wild life throughout the United States. With this object in view a legislative committee, consisting of twelve lawyers and a zoologist, was formed. Special attention has been directed to the preservation of the grey squirrel and the fur seal, and to convincing the authorities of the desirability of placing all migratory birds under the control of the Federal Government. We have received a report showing the steps which the club has taken in the direction of saving the fur seal. For fully ten years the fortunes of the Alaskan fur seal, which once furnished a valuable industry, have been rapidly declining. Last November the club decided to appeal to Congress, the President, and the Cabinet for the adoption of a policy that would not only save the seals from further annihilation, but also rehabilitate an industry that, instead of yielding an income, now inflicts an annual loss. The club asked for three things:—no renewal of the lease for killing seals on the Pribilof Islands for commercial purposes; a ten-year close season for the seals; and treaties with Canada, Japan, and Russia for the total suppression of the industry of killing seals at sea. On April 21 a Bill securing some of these ends was signed by the President after having passed both houses of Congress. It is hoped that treaties with the other countries interested will be arranged. It may be predicted that the seal herds, now reduced from 4,000,000 to about 60,000, will have a much needed rest, and that if the killing of seals at sea, called "pelagic sealing," can be stopped by treaty, in ten years' time the herds will breed up to their original strength.

IN the May number of *Man*, Mr. N. W. Thomas commences a series of notes on his recent work in Nigeria. In the present instalment he describes one phase of native decorative art, that to be seen on the walls of houses secular or religious. Human figures, except that of a mischievous imp, Esu, are rare; but numerous animal forms are depicted, and these, particularly when found on the walls of shrines, seem to subserve a magical purpose.

MANY suggestions have been made to explain the term Rom or Romani applied to the Gypsy race. The last is that of Mr. Leo Winer in the *Journal of the Gypsy Lore Society* for April. He points out that the name is coincident with Christian countries only, Europe, America, and Armenia. From the law of Charlemagne it appears that the Gypsies pretended to be pilgrims, and their name was usually connected with that of Rome. Ultimately, he thinks, it originated in the Greek Erimites, "a hermit" and that when the popular etymology connected all hermits and pilgrims with Rome, all other terms designating pilgrims were so transformed as to bring them into keeping with this new conception.

MR. C. L. WRAGGE announces in the *Auckland Standard* of March 7 the discovery at Bay of Islands of a series of engraved rocks, which he supposes to be of enormous antiquity and to be connected with the monoliths of Easter Island, which are a puzzle to antiquaries. Another correspondent, however, states that there are rocks between Whangaroa and Bay of Islands regarding which the Maori have traditions dating back to the days of Captain Cook and that a Government geologist who examined them has found that they are naturally decayed basaltic columns.

Mr. Wragge declines at present to give details of his discoveries, and until these are published it is unsafe to venture any opinion in regard to them.

THE Entomological Research Committee for Tropical Africa, appointed by the Colonial Office, has issued the first number of the Bulletin of Entomological Research, on which the committee and the editor (Mr. G. A. K. Marshall) may be warmly congratulated. Nearly half the number is occupied by Mr. W. Wesché's descriptions of the larval and pupal stages of West African Culicidæ, a most useful paper, giving characters for the identification of the larvæ and pupæ of twenty-nine species of mosquitoes, illustrated by seven excellent plates. The collector of the specimens, Dr. W. M. Graham, adds valuable field-notes, and the facts recorded are important alike to the entomologist and the medical man. Dr. Drake-Brockman contributes a short paper on blood-sucking Diptera from Abyssinia, Mr. R. Newstead writes on Coccidæ from Uganda, and Mr. E. E. Austen describes new African fruit-flies and a new *Cordyllobia*—a muscoid genus the larvæ of which are subcutaneous parasites. In a short preface Mr. A. E. Shipley discusses the general work of the committee, mentioning that two experienced entomologists have been sent out for the purpose of research and instruction—Mr. S. A. Neave to Nyasaland and Mr. J. J. Simpson to Nigeria.

THE following interesting communication has reached us from Mr. Christopher Morse, of 3 Gladstone Road, Deal:—"All your readers have, of course, noticed a cat washing its face, but I expect very few have seen the same operation being carried on by a caterpillar. I observed one engaged in this process yesterday, and thought it a matter of interest. The creature was a smooth-bodied Noctuid larva feeding on grass." Of course, it is well known that butterflies often drink up water eagerly, and even bathe in it; while, as regards caterpillars, the drinker moth (*Cosmotriche potatoria*) derives its name from the caterpillars' fondness for water, often plunging their heads into the drops of water on the grass on which they feed (compare Tutt's "British Lepidoptera," iii., p. 167). Mr. Tutt, to whom we have submitted Mr. Morse's communication, thinks that in most cases the true legs of caterpillars would be too short to be used for washing the face (though in some exceptional cases these are long), and adds, "Of course, butterflies do it, and are well provided sometimes with hooks for the purpose, especially for cleaning their antennæ. They often have the appearance you name when thus employed. I think I noticed it particularly in *Rusticus betulae* and certainly some other species." It would be of interest if Mr. Morse could continue his observations, and especially identify the species of caterpillar which he noticed washing its face.

A NEW geological society, already very well supported, styled the Geologische Vereinigung, has been established at Frankfurt am Main, somewhat on the lines of the English Geologists' Association. While international in character, it aims especially at providing summaries of important geological work, which shall reach the increasing number of teachers of geology. By organising excursions, it hopes to come into touch with those who have charge of classes in schools. The subscription is only 10 marks annually, and each member will receive the society's journal, the *Geologische Rundschau*, the first number of which, published on April 26, is now before us. As the six numbers of this journal cost 12 marks a year (Leipzig: W. Engelmann), it is clearly profitable for readers also to become members of the society. The journal is

edited by Drs. G. Steinmann, W. Salomon, and O. Wilckens, and is another sign of the activity of already busy men. Two original papers appear in this number which might easily have found a place in the older journals; but the signed reviews of geological knowledge are the main feature, and rank with those on current subjects in the English quarterly, *Science Progress*. The professional worker can, of course, rely on Keilhack's *Geologisches Zentralblatt*, which notices practically everything. The *Rundschau* is at once more literary and more limited in character, and has a critical usefulness of its own.

PROF. E. A. MARTEL makes a vigorous contribution to the controversy regarding the existence of *Grundwasser*, or a water table supported by an impermeable stratum, in the Karst region, in a recent number of *La Géographie*, p. 126. Prof. Martel considers that definite proof of the non-existence of such an underground reservoir feeding the subterranean rivers of the Karst is now available, and that the question is finally settled.

IN NATURE of May 12 (p. 319) reference was made to the important additions made to the monthly meteorological charts of the North Atlantic issued by the Meteorological Committee by the publication of current daily weather charts of barometrical pressure, temperature, and wind, compiled from reports by radio-telegraphy and through other sources. The value of these data is still further enhanced in the chart for June by a short discussion of the predominant features indicated by the maps. These show, e.g., that from May 5-11 inclusive an area of high barometric pressure occupied a considerable portion of the Atlantic, and, in connection with the low pressure existing over these islands and Europe, was responsible for the abnormally cold and squally weather then experienced over this country. At the close of the period the advance of an anticyclone, shown to be moving from Barents Sea to Scandinavia, and the shifting of continental disturbances towards north-west, tended to modify those conditions. The unique reports of ice received by the committee show that icebergs were being sighted with increasing frequency between 42° and 52° N. latitude, and 39° and 52° W. longitude.

IN two papers contributed to the Proceedings of the American Academy of Arts and Sciences (xlv., 8, 9) Mr. Harvey F. Davies discusses the applicability of the law of corresponding states to the Joule-Thomson effect in water and carbon dioxide, with special reference to temperatures above 100° C., and gives a new formula for the total heat of saturated steam, which holds good within limits of error between 65° and 190° C. This formula really represents the difference of the total heat from that at 100° C., the value of which is assumed from previous work.

At the 1908 Mathematical Congress at Rome Profs. C. Burali Forti and R. Marcolongo were appointed to draw up a report on the various notations of vector analysis with a view to unification. A critical review of their publications on this subject is contributed to the May Bulletin of the American Mathematical Society. It appears that the writers propose to avoid the use of the familiar "nabla," observing that this operator has different meanings as applied to scalar and vector functions; but this and the other points raised in the paper do not admit of adequate discussion in the present brief reference. The subject is of interest both to mathematicians and physicists, but it is clear from Prof. E. B. Wilson's reviews that much remains before a final system can be adopted.

It is now more than twenty years since Profs. Hertz and Hallwachs showed that when a metal plate charged with negative electricity and insulated is illuminated by ultra-violet light it loses its charge, and the rate of loss under standard conditions decreases with time. To the latter effect the title "photo-electric fatigue" was given. It was thought by some to be due to oxidation of the surface, by others to the direct action of the impinging light. Although Hallwachs disproved both these views six years ago, a considerable amount of work has been done recently by experimenters, who apparently still approach the subject from the point of view of the direct action of light, e.g. Dr. Aigner, of Vienna, Dr. Allen, of London, and, according to the *Résumé des Communications* of the Société française de Physique for May 6, M. Eugène Bloch, of Paris. All doubt as to the possibility of the incident light being the direct cause of the fatigue appears now removed by the experiments of Dr. Ullmann (*Annalen der Physik*, 1910, No. 6), who has traced it in the case of both copper and zinc to the formation of ozone in the air surrounding the plate by the passage of the light through it.

MESSRS. F. DAVIDSON AND CO., 29 Great Portland Street, W., have given us an opportunity of examining the thermo-generator—a new form of the old thermopile—of which they are the agents for England and the colonies. The thermo-electromotive-force is produced by copper-antimony couples, fifty of these couples being connected in series. Each couple consists of a vertical, hollow, cylindrical copper tube, to the top of which is soldered a flat strip of antimony, which passes horizontally inwards and then downwards around a block of a porcelain-like substance. The copper tubes are arranged in two parallel rows of twenty-five each, and the antimony strips approach one another at the top. These strips are heated by means of a horizontal burner running the whole length of the apparatus immediately beneath the antimony strips. Gas or methylated spirit vapour is used for producing a number of jets, and the heat is retained in the white blocks which are in close contact with the antimony strips. An electromotive force of about 4 volts is obtained, and this is sufficient to illuminate a small lamp for medical or other purposes, or to run a small model lathe or fan. A total current of 3 amperes can be obtained through a galvanometer provided there be no appreciable external resistance. Less than one minute is required to heat the apparatus sufficiently to give its full yield. A slight deposit of oxide forms upon the surface of the antimony in the course of time, and requires to be removed by running a stick lightly between the rows while the apparatus is hot; otherwise it appears to give no trouble whatever. The thermo-generator may be used for hours continuously, and takes the place of dry batteries for running small illuminating lamps.

SIR WILLIAM WHITE contributes an interesting article on marine steam turbines to the *Engineer* for May 27. In reference to the excessive complication which has been charged against the Parsons type, and the greater simplicity credited in some quarters to the German arrangements, the author points out that, after large experience in the great Cunarders and in swift armoured cruisers, no serious practical difficulty has been experienced with Parsons turbines. Their advantages in regard to economy of steam consumption, greater ease of handling the engines, and smaller individual weights to be lifted when opening out turbines, have been proved to be considerable. Sir William is convinced that, on the whole, the Parsons type of turbine still maintains its superiority for marine purposes; but he is

also of opinion that neither it nor any other type will secure universal adoption or be absolutely the best suited for all the varied cases which occur in practice.

An account of the trials of the Brazilian battleship *São Paulo* appears in *Engineering* for June 3. This ship is the product of Sir W. G. Armstrong, Whitworth and Co. and Messrs. Vickers, Sons and Maxim. The full speed on trial—21.623 knots—was realised with 28,645 indicated horse-power, while the guarantee was for 21 knots. Of special interest are the gunnery trials, which took place on June 1 off the Clyde. A complete broadside of eleven 4.7-inch guns was fired simultaneously with a broadside of ten 12-inch guns, establishing a record in the way of broadsides. Admiral Bacellar, the president of the Brazilian Naval Commission, pressed the firing key which fired this tremendous broadside; every one of the twenty-one guns responded. Excellent practice was also made at a target. Another important feature was the firing of two 12-inch guns in an upper turret, laid horizontally and fore-and-aft directly over a lower turret. Several Brazilian and two British officers remained in the lower turret during this test, and were able to state that they were not inconvenienced by any concussion. The ship is fitted with an electrical firing system, which renders it quite impossible to fire any gun in a position which is dangerous to any other gun or any ship's fitting.

We have received from Mr. E. Merck, of Darmstadt (and 16 Jewry Street, E.C.), his catalogue of chemical preparations for April, 1910. The list is remarkably complete, and it would be difficult to name any preparation required for general laboratory use which is not included. Many additions have been made to the last list, especially in therapeutical and bacteriological preparations.

THE current number of the Bulletin of the Société d'Encouragement pour l'Industrie nationale (April, 1910) contains a very readable and interesting paper by Capt. Nicolardot on the rare earths and incandescent lighting. The pioneer work of Auer is described in detail, together with the history of the search for ceria and thoria, and an account given, with illustrations from photographs, of the manufacture of a mantle, starting with the quarrying of the monazite sand, and finishing with the burning of and fixing the mantle. The chief types of burner are also figured and described, including the latest forms of inverted burner.

A CATALOGUE of the first eight hundred negatives made by the Geological Survey to illustrate subjects of geological interest, and of which prints or lantern slides are supplied at a fixed tariff, has just been published by the Board of Agriculture and Fisheries. The districts included lie chiefly in Cornwall and Devonshire, South Wales, and the counties of Cardiganshire, Derbyshire, Leicestershire, and Nottinghamshire. Copies of the catalogue may be obtained from any agents for the sale of Ordnance Survey maps, or directly or through any bookseller from the Ordnance Survey office, Southampton, price 6d. each.

MESSRS. HEYNES MATHEW, LTD., of Cape Town, have sent us a copy of a very complete illustrated catalogue of scientific apparatus, pure chemicals, and reagents. The list shows strikingly the improvement which has taken place in recent years in the supply of apparatus and material for scientific work in distant parts of the Empire. Messrs. Mathew have established a dépôt in Cape Town where a full range of laboratory requisites can be obtained from stock. That they find it worth while to do this suggestive testimony to the growth of science teaching in South African schools and colleges.

MESSRS. HARPER AND BROTHERS announce for publication during June "The Science of Happiness," Dr. Henry S. Williams; "The Elements: Speculations as to their Nature and Origin," Sir William A. Tilden, F.R.S.; "Religion and Art in Ancient Greece," Prof. E. A. Gardner; "Electric Trains," H. M. Hobart; and "Continuous Current Machine Design," W. Cramp.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE:—

- JUNE 9. 5h. 3m. Neptune in conjunction with the Moon (Neptune $4^{\circ} 40' S.$).
 „ 16h. 16m. Mars in conjunction with the Moon (Mars $3^{\circ} 6' S.$).
 15. 1h. 56m. Jupiter in conjunction with the Moon (Jupiter $3^{\circ} 9' S.$).
 17. 2h. 0m. Mars at greatest heliocentric latitude N.
 19. 1h. 0m. Venus at greatest heliocentric latitude S.
 „ 14h. 0m. Mercury at greatest elongation ($22^{\circ} 43' W.$).
 21. 19h. 49m. Sun enters sign of Cancer.
 24. 3h. 58m. Uranus in conjunction with the Moon (Uranus $3^{\circ} 50' N.$).
 27. 17h. 0m. Jupiter at quadrature to the Sun.

HALLEY'S COMET.—With clear intervals between clouds during the past week, Halley's comet has not been a difficult naked-eye object for anyone who knew its position approximately.

Mr. Langton Cole reports that it was well seen at Sutton, Surrey, on May 22 and 31, and on the former occasion a short tail was visible to the naked eye; he estimates that on May 31 the comet was about as bright as a star of the third magnitude. At Gunnersbury on June 1 a naked-eye observation revealed the comet as early as 9.15 p.m., when it was apparently fainter than η Leonis (mag. 3.6).

A number of interesting notes on observations of the comet at various European observatories appears in Nos. 4413 and 4414 of the *Astronomische Nachrichten*. In the earlier number Dr. Franz records that on May 13, at the Breslau Observatory, the comet did not appear to be so bright as on earlier days; a variability of brightness is suggested, and it will be interesting to see if this is confirmed by other observers.

In No. 4414 many observers record that no trace of the comet could be detected on the solar disc during the time of transit. Dr. Wolf directs attention to the Bishop's rings surrounding the sun and moon on May 19, and suggests that they were more intense than if due solely to atmospheric effects. Meteors and auroræ were looked for at the Königstuhl Observatory, but were not seen.

Polariscope observations at several observatories gave similarly negative results. Prof. Franz records that on May 19 two bright arcs of light were seen in the north-west at Breslau, and may have been due to the comet. According to a telegram from Prof. Sykora, the projection of the comet on the sun was observed at Tashkent at 2h. on May 18. An increased intensity of the twilight at Odessa on May 18 is ascribed by Prof. Donitch as possibly due to cometary matter. Herr Archenhold reports a second comet-like object 1° south of Halley's comet at 9h. 30m. (Berlin M.T.) on May 22, but the observation is not confirmed by special reports from Bergedorf and Heidelberg. At Sonnwendstein, where, at an altitude of 1523 metres, several German observers had gathered for observations of the comet, the tail was observed from May 12 to 19. During this period its apparent length increased from 32° to 140° ; its apparent position was the same on May 19 as on May 18. Dr. Hartmann, who was one of the party at Sonnwendstein, submits a special report dealing with the various aspects of the tail, and directs attention to the yellowish colour of the nucleus on May 20.

A number of notes dealing with observations of the comet were read at the meeting of the Paris Academy of Sciences on May 30, and appear in No. 22 of the *Comptes rendus*.

M. E. Marchand reports that observations made on the Pic du Midi and at Bagnères-de-Bigorre were badly interrupted by clouds. No striking special phenomena were witnessed on May 18 and 19, but it was noted that the dawn was especially bright and the sky tinted, as though

there were an exceptional amount of dust in the atmosphere; the appearance is likened to that which was observed in 1902 and 1903 after the Martinique eruption. The unusual halos around the sun and moon support this view, as do also the observations of solar radiation subsequently made at the Pic du Midi station. Observations of the sun and of terrestrial magnetic and electrical effects revealed no abnormal condition attributable to the presence of the comet.

M. Popoff reports on the observations made at the Sofia Observatory (Bulgaria), and could not detect the comet projected on the sun's disc.

Further observations made at Athens are dealt with by M. Egnitis, who describes the forms of the nucleus and tail on May 18–20. No extraordinary atmospheric effects were recorded, and only two meteors were seen during the night of May 18. A splendid bolide was observed in Thessaly at 13h. 15m. (M.T. Athens), but is not connected with the comet. Between 7 p.m. and 8 p.m. on May 20 the comet's tail was seen with the equatorial, and was still apparently directed towards the west. The curvature was so great that the earth could not pass through the tail before the night of May 20.

MM. J. Baillaud and G. Demetresco describe photographs taken at the Paris Observatory on May 23, 24, and 28. Only very short exposures (thirty seconds to five minutes) were possible, and the tail is not shown. The nucleus is shown as an ellipse, the axes being $18''$ and $14''$ long. On May 23 this ellipse, otherwise uniformly dense, showed a condensation of $6''$ diameter at its N.E. extremity, but this had disappeared on May 24. The nebulosity surrounding the nucleus showed changes from one day to another, and on May 24 recalled that surrounding the Pleiades star Maia.

THE SPECTROSCOPIC BINARY β AURIGÆ.—In No. 22, vol. i., of the Publications of the Allegheny Observatory Mr. R. H. Baker discusses at length the observations of β Aurigæ as a spectroscopic binary. Since the duplex character of this star was announced by Miss Maury in 1889, many observations have been made at Harvard, Potsdam, Pulkowa, and Allegheny in an endeavour to remove certain apparent anomalies from the observed orbit. Assuming that the period was 3.9838 days, Miss Maury found, from the discussion of some 200 plates taken at Harvard, that there was an apparent reciprocal variation of intensity between the two components, but Mr. Baker now shows that this is not so; owing to the assumed period being slightly in error, the two components were alternately misidentified. The discussion of the Allegheny observations with those previously published shows that the orbit is practically circular ($e=0.0 \pm 0.0057$), and that there is probably a slight variation in the period, amounting to 0.000010 day, or 0.86s. per annum. The period now given is 3.960027 days $\pm 0.000010 \pm 0.000004$ days, the present elements being referred to the epoch 1905 September 11.7324, G.M.T.

An investigation of the secondary oscillation found by some observers is not confirmed, nor was Mr. Baker able to find evidence for the dispersion of light during its passage through space from β Aurigæ to the earth.

THE BRIGHTNESS OF THE SKY.—Commenting upon M. Fabry's recent determination of the brightness of the sky, Mr. Gavin Burns brings together, in No. 422 of the *Observatory*, the results obtained by various observers; they are as follows, each value being the brightness of one square degree of non-galactic sky expressed in terms of a fifth-magnitude star:—Newcomb, 1.15; Burns, 2; Townley, 2; Yntema, 5.76; Fabry, 1.46. Mr. Burns remarks that if, as seems probable, the brightness is a variable quantity, the results obtained by different observers are bound to vary considerably *inter se*.

THE ACCURACY OF RADIAL-VELOCITY DETERMINATIONS.—In No. 4, vol. xxxi., of the *Astrophysical Journal* Prof. Frost issues a timely warning against attributing too great an accuracy to present-day determination of radial velocities. A tabulation of twelve values recently obtained by various observers for Arcturus, a simple problem, shows that they vary between -3.7 km. and -6.6 km., whilst the extreme range for any one observer varies from 1.2 km. to 4.5 km. Prof. Frost questions if we know the radial velocity of any star to the nearest kilometre.

MARS DURING THE RECENT OPPOSITION.

SO far as can be judged from those yet published, the results accruing from the observations of Mars made during the opposition of 1909 are, in a sense, disappointing. The favourable conditions of the opposition, as regards the altitude and the apparent diameter of the planet, engendered the hope, in many minds, that most of the outstanding problems in the Martian enigma would be solved more or less definitely. Yet the camps into which areographers are divided are still at issue, and the differences appear to be at least as sharply accentuated as before. To the one side the *canali* are still continuous channels, set out with a rectitude more or less geometrical, and having "oases" around the reservoirs upon which they appear to converge; but to the opposition these clearly cut channels are but alignments of dark spots merged into apparent continuity by a physiological illusion.

However, many of the larger features are beyond dispute, and many valuable observations of their appearances and changes have been made since July last. One very remarkable phenomenon was noted, and has been discussed by practically every observer, viz. the apparent veiling of the planet's surface during the earlier part of the opposition.

In June, July, and August the details, and even some of the larger features, were not discernible; there was a general lack of contrast between the light and the dark areas. Thus M. Antoniadi, using the 24-cm. refractor at Juvisy, reported (*Bull. de la Soc. astron. de France*, September, 1909, p. 386) that, on August 11 and 12, the surface of Mars was hardly recognisable, and it was with great difficulty that he assured himself that it was the region of the Mer de Sablier on which he was looking. M. Jarry Desloges also emphasised the unusual appearance of the planet, which he illustrated (*Comptes rendus*,

vol. cxlix., No. 17, p. 666) by two charts (Fig. 1), one of which M. Fournier had recorded the features seen during June, July, and part of August, whilst the other showed the increased contrast of the same features later in August and during September.

It was not until the beginning of the latter month that the accustomed contrasts and details completely reasserted themselves and permitted the work of confirmation and discovery to proceed normally.

M. Antoniadi suggests that this masking effect was

FIG. 1.—Comparison of the appearance of the surface of Mars on different dates in 1909.

caused by the interposition of light, cirrus cloud in the planet's atmosphere, such cloud being filmy in structure and yellowish in colour, so that it reduced the usual contrasts without totally obscuring the features. This is in accordance with Prof. W. H. Pickering's observations in 1895, when he found that his photographs suggested some such yellow screen.

The importance of the acknowledged existence of clouds must not be lost sight of in the discussion as to the aqueous

contents of the planetary atmosphere. The observations of Beer and Mädler, Secchi, Lockyer, Denning and others, of apparent changes caused by clouds have been generally accepted as strong evidence for the existence of the cloud-producing compound of our own atmosphere.

Turning now to the actual observations of features, and their modifications, during the recent opposition, we find

probably indications of inequalities in the relief of the polar areas.

M. R. Jonckheere, observing with a 14-inch refractor at the Hem Observatory (Roubaix), also directs attention to this feature. On August 12 he observed (*Astronomische Nachrichten*, No. 4354, p. 159) a "land" become detached from the cap, although itself still covered with ice, and

identified it as Schiaparelli's Novissima Thyle. On these grounds he suggests (*Comptes rendus*, No. 22, vol. cxlix., p. 970) that the "lands" remain covered with ice much longer than do the "seas," thus producing apparently irregular variations in the measured diameters of the cap; when, by the planet's rotation, such an ice-covered "land" is brought to the extremity of the apparent ellipse, the major axis will appear to be longer than when the "land" is carried further round. M. Jonckheere's measures of the cap show the following progression:—July 16, 32° (Martian arc); August 15, 18° ; September 17, 9.3° ; October 18, 11.8° ; November 18, 10.2° . On September 2, Argyre II. was seen, and its position determined as long. 60° , lat. -80° ; this is nearer the pole than it has hitherto been placed, and M. Jonckheere deduces, generally, that the latitudes ascribed to the polar lands are usually too small. Another mass was seen, on the same evening, in long. 120° , lat. -84° , which apparently had not been recorded before, and to this

M. Jonckheere gives the name "Stella," on account of its brightness. "Thaumas" is the name given to another new land which suddenly appeared in the Aonius Sinus, touching Thaumasia, long. 100° , lat. -43° .

According to Prof. Lowell (*Astronomische Nachrichten*, No. 4371, p. 47), the first snowfall of the season in the Martian antarctic region took place on November 17—about two months after the summer solstice—when two

FIG. 2.—Changes in the southern polar cap of Mars.

that the diminution and transfiguration of the southern polar cap was recognised quite early in the season.

M. Jarry Desloges, observing with a 29-cm. refractor at Masegros (Lozère), recorded (*Astronomische Nachrichten*, No. 4340) a dark cutting—shown on the first drawing in Fig. 2—in longitude 190° on June 20–23, and at the Revard station Lowell's crevasse in long. 350° was easily seen, cutting right through the cap. A large and

FIG. 3.—Chart of Mars as observed by M. Antoniadi.

brilliant spot near the edge of the cap, in long. 30° , was also seen on July 4. The progressive diminution in size and the changes in form, as observed by M. G. Fournier at the Revard Observatory, are shown in Fig. 2, reproduced from a note by M. Desloges (*Comptes rendus*, No. 26, vol. cxlix., p. 1347), who remarks on the increased rate of diminution about August 15, and suggests that the variations in detail and the time of disappearance are

patches in latitude -65° were seen in longitudes 100° and 190° .

M. Antoniadi also made observations, at the invitation of M. Deslandres, with the 33-inch refractor of the Meudon Observatory, the third largest refractor in general use. He observed on thirty nights between September 20 and November 9, but on about five nights only were the atmospheric conditions really good. The results of his

observations are shown in the chart here reproduced (*Comptes rendus*, vol. cxlix., No. 20, p. 837), Fig. 3. The most noticeable change since 1907 was in the Syrtis Major, which he found had returned to its form of 1864 and 1877. The Lac Moeris, too, had reappeared as a large, indefinite dark patch, and a multiple island was seen in the eastern part of the Mare Cimmerium.

The Solis Lacus region also presented many striking features, and, among others, M. J. Comas Solá devoted special attention to it (*Bull. de la Soc. astron. de France*, November, 1909, p. 497). In his opinion, the recent opposition "peut être considérée comme la dérouté définitive du réseau géométrique des canaux."

It is in regard to these all-important "canali" that the battle of observers rages most intensely. Among European observers, at least, there appears to be consensus of opinion that the term should be used in a more restricted sense, or should only be employed as a generic term embracing several species. There is too great a diversity between the broad, persistent, half-tone patches and the narrow, evanescent streaks, glimpsed for one fraction of a second to be lost the next, for them all to be grouped under the one designation. M. Antoniadi strongly insists on this point (*Comptes rendus*, vol. cxlix., No. 20, p. 836), and classifies eight varieties. Even then he does not include the fugitive right lines, visible only for the fraction of a second, which he considers may be illusions; but he very definitely negatives the existence of any geometrical réseaux, of which he finds no trace. At intervals of exceptionally good seeing he sees considerable structure, visible for several consecutive seconds, on the continental areas, and this he describes as "a grey irregular marbling, complex and cloudy, such as only an artist could render."

The Rev. T. E. R. Phillips, observing at Ashted with his 12-inch Calver reflector, was led to substantially the same conclusions (the *Observatory*, No. 416, p. 463) as M. Antoniadi regarding the canals.

The necessity for the classification of these features is also advanced by M. Desloges, who suggests (*Comptes rendus*, vol. cxlix., No. 17, p. 664) three species, and also directs attention to numerous changes observed during this opposition. The fine canaux of his third class were apparently the most affected by the seasonal changes, and M. Desloges finds it difficult to disbelieve their objective existence; one argument advanced in its favour is that they all appear to start in small gulfs, just as the broad, indubitable, dark bands, of the first and second classes, generally have their origins in the larger gulfs.

An encouraging feature of the opposition, which in future developments may lead to a settlement of this vexed question of "objective" and "subjective" phenomena, is the advance made by photography in the recording of the planet's markings. On Prof. Hale's striking photographs (*Monthly Notices*, vol. lxx., No. 2, p. 175) the contrast between the dark and light areas is remarkable, the bolder features standing out with a distinctness usually seen only on carefully prepared drawings.

Results of great interest were also obtained by MM. de la Baume Pluvinel and Baldet (*Comptes rendus*, vol. cxlix., No. 20, p. 838) at the Pic du Midi Observatory, where the conditions are especially favourable for such observations. The observers intend to make a detailed study of the 1350 images recorded on their set of eighty plates, but, from a brief survey, they are able to state that anyone conversant with Martian topography would immediately recognise nearly all the features observed visually. The canals of the first order, the broader bands such as the Indus, the Ganges, Araxes, Cyclops, Euphrates, &c., are all recognisable, but there is no trace of the geometrical network of fine canals recorded visually by many observers.

Whilst in London recently, Prof. Lowell pointed out that while many of the recent photographs form striking pictures by reason of their strong contrasts in the large areas, the treatment which brings out these contrasts is not that calculated to show also the finer details.

Thus the evidence for the actual existence of the canali-form "canals" is still "mixed." A number of experienced, careful observers still proclaim, with no lack of decision, that they exist; others just as emphatically state that they are, at the most, but the physiological integration of the elements of a mosaic groundwork which covers

the planet. Prof. Frost states that the 40-inch refractor at Yerkes is "too powerful" to show them, and Prof. Hale refers to Prof. Barnard's description of 1894 (*Monthly Notices*, vol. lvi., No. 4, p. 166, 1896) as describing exactly what he sees with the 60-inch reflector at Mount Wilson.

This question of aperture is not a simple one: Thus Prof. Lowell has repeatedly stated that a large aperture is not infrequently a positive barrier to the seeing of such fine details as occur on planetary discs. Attached to his 24-inch refractor he has a system of diaphragms, and the first operation in making an observation is to determine what aperture is most suitable for the conditions obtaining at the moment. A similar procedure was followed by Dawes, whose observations in the 'sixties of last century did so much to forward areography. When discussing the work with Sir Norman Lockyer—who also, at that time, was making valuable drawings of Mars—Dawes repeatedly referred to the conditions of seeing as "a 5-inch night" or "a 6-inch night," &c. Asked for an explanation, he stated that he often found it necessary to reduce his aperture, which normally was 8 inches.

We also learn from Sir Norman Lockyer that when his drawings were discussed at the Royal Astronomical Society, some doubt was expressed because some of the details shown thereon were not shown on the drawings made at the same epoch by the observer using Lord Rosse's reflector; yet when the Leyden drawings arrived, later, these details were confirmed.

Thus Prof. Frost's somewhat enigmatical statement may, logically, be understood to convey a meaning other than that which has generally been ascribed to it, and the failure of the 60-inch reflector to show the straight, hard, sharp lines may not be conclusive evidence of their non-existence.

So far, the employment of the photographic plate has not provided the hoped-for solution of this special question, because the exposures necessary are too long. Each image on the plate is an integration, the moments of fine seeing are overlaid by periods of tremor, and, by their very nature, fine lines would be the first to disappear; it is a case where negative evidence is of little value. Nor does it seem logical to say that these lines do not exist because their appearance can be explained otherwise—physiologically, for instance. Their recognition in the same positions by independent observers, at different times, points to the existence of some material objects, and their changes with the change of season exclude the proposition that they are completely solid markings. Even the suggestion that they are alignments of darker spots does not prove that they are disconnected items. In desert areas the streams dry up, leaving "water holes"—apparently disconnected if viewed from a great distance—and these holes are surrounded by vegetation throughout the dry season, becoming, therefore, isolated objects; but the river bed is there, and in due season—as on Mars—is filled with water and edged by vegetation.

But their great size, their prolific distribution, and their rectilinear character, even when seen away from the planet's central meridian, are phenomena which are difficult to explain in the case of the Martian canals; and the problem yet remains.

A suggestion made by Dr. Aitken, of the Lick Observatory, might possibly solve this vexed question to some extent. Prof. Lowell's unanswerable argument is that, as the "canals" are so near the limit of vision, it is only in the very finest atmosphere that they can be seen. All observers agree as to the first part of this statement, and Dr. Aitken suggests that the second part might be put to the test by arranging that such experienced protagonists as Prof. W. H. Pickering, M. Antoniadi, and Prof. Barnard should forego at the Flagstaff Observatory and, with Prof. Lowell, observe Mars during the next favourable opposition. The 24-inch refractor is, as Prof. Lowell has demonstrated, a superb instrument, and for astronomical observations of this character the Arizona atmospheric conditions are unexcelled. The suggestion is a most excellent one, and, could the arrangements be made, the meeting would no doubt lead to an illumination of what, at present, is a very obscure problem.

There are some problems in astronomy which seem to be indeterminate. First, we get a positive solution in one

direction, and then appears the amendment, which is a direct negative; as an example one might cite the rotation periods of the inner planets; but one that is nearer to the present question is the problem as to the spectroscopic evidence for the existence of water vapour in Mars.

Since Huggins compared the Martian and lunar spectra in 1867, a number of observers have made similar observations under various conditions, and with contradictory results. The summarised history of the research is given by Prof. Campbell in a recent Bulletin (No. 169) from the Lick Observatory, and the majority of the conclusions are in favour of the presence of water-vapour bands; whether the conclusions were supported by the evidence, when adequately analysed, is the question. Observations made at Mount Hamilton in 1894 demonstrated to him that, to obtain satisfactory evidence, they should be repeated at an altitude sufficient to escape the greatest possible proportion of the terrestrial atmospheric effects, and, to this end, he examined the conditions obtaining on the summit of Mount Whitney, the highest point in the United States, in 1908. The preliminary survey satisfied Prof. Campbell as to the atmospheric conditions, and he decided that, if the necessary money could be obtained for shelters and equipment, an expedition from the Lick Observatory should take advantage of the favourable opposition of 1909 to carry the

posed of hoar-frost, demanding a small quantity of vapour, would probably not be out of harmony with his observations. In Bulletin No. 43 of the Lowell Observatory Mr. Abbot's report is quoted to the effect that he and Prof. Campbell were on Mount Whitney during unusually unfavourable weather, under conditions which would probably not be met with at that season one year in ten. This is important, because, no matter how much of the theoretical water-vapour content of the terrestrial atmosphere was left below, it is absolute evidence that water vapour was present, in quantity, above.

The Mount Whitney plates, at the most, only afford negative evidence, and it is not contended that they do more. Thus the question of water vapour becomes one of amount rather than of existence or non-existence, and its settlement is rather academic than practical. There is no doubt as to the difficulty of securing absolute evidence—so many variables have to be eliminated before the sought-for residual is attained.

But, as stated above, the question is now generally accepted as settled in favour of the presence of water vapour in the Martian atmosphere. The darker edge of the melting "snow" caps, the proved existence of clouds, and the changes of intensity and shape of many features, point definitely to the existence of a fluid material, and, without any violent assumptions, to that fluid being water. We note that Prof. Campbell suggests that the observed yellowish colour of the clouds may indicate for them some other chemical compound than H_2O , but, if this is so, should not the spectrum of Mars indicate some other absorption which is not mentioned?

WILLIAM E. ROLSTON.

THE RESEARCH DEFENCE SOCIETY.

THE annual meeting of the Research Defence Society was held on Friday, June 3, at the Royal College of Physicians, and was very largely attended. The chair was taken by the Earl of Cromer, president of the society. The other speakers were the Hon. Sydney Holland, chairman of committee, Sir Richard Douglas Powell, Sir David Bruce, Mr. Anthony Hope Hawkins, and Mrs. Scharlieb. The work and the literature of the society are by this time well known to the public, and the annual report shows a great

increase in the membership and in the extent of the work.

Perhaps, of all the speeches, the most interesting was Sir David Bruce's account of his observations on the African sleeping sickness and other African diseases. In 1903 it had been hard or impossible to persuade the Uganda chiefs that the sleeping sickness is carried by the tsetse-fly. "But these same so-called uncivilised natives, whose untutored minds could not perhaps at once grasp the position, a few years later were so convinced of the truth of what we told them that they cleared the lake-shore and islands of their inhabitants, with the result that, so far as I am aware, at present not a single new case of sleeping sickness is being contracted in Uganda proper, and the toll of human lives to this plague has ceased to be paid. This toll has been estimated at 200,000 out of a population of 300,000. In one island alone, Buvuma, with a population of 32,000, 18,000 are reported to have perished." From this fact Sir David Bruce went on to speak of experiments which had shown how long the fly, once infective, may remain infective, and of the question of the infectivity of animals. Then he referred to a disease which destroys 70 to 80 per cent. of the calves born in Uganda; the cause and the nature of this disease had been discovered by experiments on animals. "By animal experimentation we found out the nature of several of the most important diseases of the

Fig. 4.—Temporary Observatory on Mount Whitney, for the investigation of water-vapour in the atmosphere of Mars.

research a step further. As is usual in, and, one might say, peculiar to, America, funds were forthcoming, with the result that, at the end of August, 1909, the summit of the mountain was occupied by an especially equipped expedition ready to take spectrograms when the conditions of Mars and the moon were favourable.

Such spectrograms, six in number, were secured on the nights of September 1 and 2, and it is to the discussion of the evidence afforded by these that Bulletin No. 169 is devoted. This evidence does not appear to be positively conclusive, but Prof. Campbell deduces "that the quantity of any water vapour existing in the equatorial atmosphere of Mars at the time these observations were made was too slight to be detected by present spectrographic methods. . . . it is difficult to conceive that the quantity of vapour above unit area on Mars could exceed or equal the quantity of terrestrial vapour above the same area of Mount Whitney."

It should be remarked here that the altitude of the summit of Mount Whitney is 14,501 feet, and, according to Hann's empirical formula, 0.79 of the terrestrial water vapour would be below. A photograph of the shelter and part of the equipment is reproduced, from the Journal of the Royal Astronomical Society of Canada, in Fig. 4.

Prof. Campbell expressly states that it is not contended that Mars has no water vapour, and that polar caps com-

domestic animals in Uganda, and on more than one occasion nipped an epidemic in the bud, thus earning, if they had known it, the gratitude of the animals themselves."

Of no less interest was his account of "muhinyo," a fever among the Uganda natives, which had been mistaken, by clinical observation, for diverse other fevers. The Sleeping Sickness Commission, by animal experimentation, proved it to be, practically, Malta fever, and further proved that the germs of muhinyo were present in some of the goats from an infected district. The evidence thus appears complete that the fever, like Malta fever, might be transmitted in the goat's milk.

Finally, Sir David Bruce spoke of the discovery that the common sand-fly is capable of transmitting simple continued fever. Here the experiments were made on volunteers in the cause of science. "The study of the habits of the sand-fly is being pursued with energy, and I hope that within a short time simple continued fever will have disappeared as completely from Malta as Malta fever has done." Of the completeness of the disappearance of Malta fever from our army in Malta, since the goat's milk was prohibited, the following figures are proof:—in 1905 there were 643 cases; in 1906, 147; in 1907, 11; in 1908, 5; in 1909, 1; and in 1910, thus far, 0.

We hope that the Research Defence Society will see to it that such a record of the experimental study of diseases shall not be allowed to drop out of the public mind.

METEORIC FIREBALL OF JUNE 1.

ONE of those brilliant meteors which often appear in the twilight of our midsummer skies was seen on Wednesday, June 1, at 9.40 p.m. The atmosphere was fairly clear, and the object formed a fine spectacle to many persons in the southern counties of England. Excellent descriptions of the apparent path it traversed have come in from various places, including Coventry, Bristol, Cheshunt (Herts), and Ealing, Sydenham, and Herne Hill, London.

The meteor was much more brilliant than Jupiter, and as it sailed slowly along it apparently changed its colour from electric blue to gold, and threw off a short trail of reddish sparks. Viewed from the metropolis, the observed flight was a descending one from west to north-west, and the whole trajectory occupied about four seconds.

There is no doubt that the meteor was directed from a radiant near Antares, in Scorpio, which has furnished many June fireballs in past years. Its height was from about 62 to 48 miles, and the path of some 100 miles, traversed at a velocity of about 25 miles per second. First visibly appearing over a point near Chippenham, it passed to north-west, crossing the Severn, and disappearing south of Montgomery, in Wales. Other reports will doubtless come to hand, and enable this result to be tested, but it cannot be far wrong. The fireball supplies further corroboration of the activity of the Scorpiid shower, and of the almost unique brilliancy of its meteors. There was a fireball seen in Scotland by several observers on May 24, at 11h., and this had a height of about 70 to 44 miles over the sea north of Ireland. This object also was directed straight from the radiant in Scorpio.

W. F. DENNING.

INTERNATIONAL CONGRESS ON TROPICAL AGRICULTURE AND COLONIAL DEVELOPMENT.

A NOTE on the organisation of this congress was published in NATURE of April 7, and it is only necessary to say now that the congress was arranged by the International Association of Colonial Agriculture, with the assistance of the Belgian Society for the Study of Tropical Agriculture. British contributions to the congress were provided for by a British committee, including agricultural and forestry officials throughout the Empire, and of which Prof. Wyndham Dunstan, F.R.S., was president, and Dr. T. A. Henry secretary.

The congress met from May 20 to May 23 in the Palais de Congrès of the Brussels Exhibition. The date of the

first meeting coincided with the funeral of the late King, so that the president, Colonel Thys, merely declared the congress open, and the meeting was adjourned as a mark of respect to the memory of His late Majesty.

The work of the congress was divided into three sections, (1) dealing with agriculture and forestry; (2) with animal industries; and (3) with labour, transport, and trade. Altogether nearly 200 reports and papers were presented to the congress, and of these more than one-third were submitted through the British committee. It is only possible to refer briefly to a few of the more important matters discussed.

In July, 1909, the International Association appointed "General-Reporters" to collect information on various subjects connected with tropical agriculture, and to present reports on them to the congress, and the reading and discussion of these reports occupied much of the time devoted to sectional meetings.

Prof. Dunstan submitted a general report on the practical results of cotton cultivation in various countries, with observations on the scientific and economic causes of its success or failure. He pointed out that the successful development of cotton cultivation in West Africa and other suitable territories in the future will depend on the establishment of a variety of cotton suited to the country and to the requirements of manufacturers, and that this can best be achieved by persistent scientific work carried on by Government. The position of cotton cultivation in the United States, Egypt, India, and other producing countries was then reviewed. Prof. Dunstan also presented special reports from countries in which cotton cultivation is carried on commercially or experimentally, each of these recounting the difficulties met with and the experimental work in progress in the area considered. These reports were contributed by authorities on cotton cultivation in each of the countries dealt with.

A similar inquiry on the rubber plants of tropical countries resulted in the presentation of a number of reports, each of which dealt with the rubber plants, native or introduced, of the country considered, the methods of obtaining rubber therefrom, and, in most cases, the improvements needed in native methods of preparation. Reports from the following countries were submitted:—Belgian Congo (MM. Kindt, Pynaert, and Ghislain), French West Africa (M. Yves Henry), British West Africa (Mr. H. Brown), British East Africa (Mr. A. C. MacDonald), German African colonies (Dr. Warburg), Java and Sumatra (Prof. Berkhout), Mexico (Señor Flores), Brazil (Señor Argolo), &c. Special papers were also contributed by Dr. Heim (Rational study of rubber plants) and Prof. Carmody (New method of preparing Castilleo rubber).

Other inquiries undertaken were the place of botanical gardens in agricultural research in the tropics, and legislation against the spread of insect pests and fungoid diseases; but comparatively little progress was made with these, though special reports in connection with the first-named were submitted by M. Capus for Indo-China, and by Profs. A. Engler and G. Volkens, of Berlin.

Apart from these reports, many papers were submitted on more general subjects. Mr. A. E. Humphries read a useful paper on the wheat requirements of the United Kingdom, in which he outlined the characters which miller in this country seek in imported wheat. Mr. I. B. Pole Evans described the results of investigations undertaken in the Transvaal with a view to the development of rust-resistant cereals, and Mr. Guthrie, of New South Wales, submitted two papers, one describing chemical investigations in connection with the production of improved wheat and the other giving an account of the work of the late W. J. Farrer, who initiated wheat-breeding work in New South Wales. Only two papers on tobacco were submitted, one by Mr. Odium, of Rhodesia, describing the cultivation of bright pipe tobacco, and the other by Dr. Henry and Auld on the burning quality of tobacco, in which they pointed out that defective burning quality is one of the first difficulties met with in growing tobacco in a new country, and showed, as the result of numerous analyses of tobacco ash, that good burning depends on the nature and quantity of mineral constituents in the leaf, and

eventually, therefore, on the composition of the soluble components of the soil and the manures applied. Mr. R. N. Lyne presented a paper on the causes contributing to the success of the Zanzibar clove industry, in which the importance of soil and climate in this connection was insisted on, and not less the success of the Arab proprietors of the plantations in accommodating their business methods to the habits of the native population.

Dr. S. S. Pickles submitted a paper in which the characters and composition of the essential oils obtained from a large number of *Cymbopogon* grasses grown in Ceylon were given. These results are of great importance in connection with Dr. Stapf's recent botanical revision of this genus.

In section 2 the principal topic of discussion was the essential factors in the acclimatisation of European cattle in the tropics, on which useful reports were submitted by M. Meuleman, who is General-Reporter for this inquiry, M. Douarache, of Tonquin, M. Peralta for Costa Rica, Mr. Jarvis for Rhodesia, and Prof. Carmody for Trinidad. The only general paper read in this section was one by Mr. Barwick, of the Imperial Institute, on African wild silks.

The papers submitted in section 3 were of economic and administrative importance rather than of scientific interest, though reference may be made to the reports, mainly by officials in British colonies, submitted by M. Batalha-Reis on agricultural labour conditions in the tropics.

During the congress a special meeting of the International Association of Colonial Agriculture was held, at which Prof. Wyndham Dunstan, director of the Imperial Institute, was elected president of the association in succession to M. de Lanessan, formerly Governor of Indo-China, who had held this office since the foundation of the association in 1905.

INDIAN PALÆONTOLOGY.

THE Geological Survey of India continues to publish well-illustrated and exhaustive memoirs on the fossil invertebrate faunas of the region with which it deals. Two more on the Himalayan Trias have lately appeared, and are of much interest for study in connection with recent work on the Triassic fossils of other areas. The first memoir (*Palæontologia Indica*, ser. 15, vol. vi., No. 1, 1909), on the Lower Triassic Cephalopoda from Spiti, Malla Johar, and Byans, was begun several years ago by the late A. von Krafft, who collected much of the material. It has now been revised, completed, and brought up to date by Prof. C. Diener. It begins with a synopsis of the marine Lower Triassic formations of the Himalayas, which are proved to constitute a remarkably complete series. The detailed descriptions of the fossils which follow show that at least four distinct and successive faunas occur in the rocks of the district under consideration. Of these, the lowest or earliest is perhaps the most interesting, because it seems to represent the dawn of Triassic life in the sea. It is noteworthy for the complete absence of the numerous types of Palæozoic Brachiopoda, which are the predominating element in the Permian rocks of the Salt Range and the Himalayas. Both in the Alps and in the Himalayas the Permian and Trias are connected by an uninterrupted sequence of sedimentary deposits. The second memoir, by Prof. Diener (*loc. cit.*, No. 2), is more special, treating of the fauna, chiefly Cephalopoda, of the Thaumatoerinus Limestone of Painkhand. He returns to a discussion of the age of this limestone, and shows that enough of its ammonites are identical with (or closely allied to) species found in Europe to justify its correlation with the Julic horizon, or zone of *Trachyceras aonoides*.

Another memoir just received from the Geological Survey of India, though dated 1908, contains a valuable description of the Devonian faunas of the northern Shan States, by Mr. F. R. Cowper Reed (*Palæontologia Indica*, N.S., vol. ii., No. 5). The fossils are chiefly corals, Bryozoa, and Brachiopoda, with only few representatives of other groups, but they constitute the richest collection of Devonian age hitherto described from south-eastern Asia. Most of them were obtained from Padaukpin, and many

appear to be identical with European species which characterise the lower part of the Middle Devonian. The marine faunas of Middle and Upper Devonian times prove to have been remarkably cosmopolitan; but in all cases, as at Padaukpin and other places in eastern Asia, there is also a local element giving them a special character.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. R. H. Rastall, of Christ's College, has been appointed additional demonstrator in geology from June 1, 1910, to May 31, 1915.

The electors to the Frank Smart studentship in botany give notice that they will shortly proceed to the election of a student. Any graduate of the university is eligible for the studentship, provided that not more than fourteen complete terms have elapsed after his first term of residence. The successful candidate must devote himself to research in botany under the direction of the professor of botany. The studentship is ordinarily tenable for two years. The student is in special cases eligible for re-appointment for a third year; he may be appointed for one year only. The value of the studentship is 100*l.* per annum. A candidate must send his name, with a statement of the course of research which he proposes to undertake, and such evidence of his qualifications as he thinks fit, to the Vice-Chancellor, Pembroke College Lodge, on or before Tuesday, June 21.

OXFORD.—In a convocation held on Tuesday afternoon, June 7, in the Sheldonian Theatre, the Chancellor of the University, Lord Curzon, of Kedleston, presiding, the honorary degree of D.C.L. was conferred on ex-President Roosevelt, who then proceeded to deliver the Romanes lecture. Taking as the subject of his discourse "Biological Analogies in History," Mr. Roosevelt enlarged upon the phenomena of the rise and extinction of species, especially instancing the history of the mammalian fauna of South America from the Eocene epoch onwards, and drawing parallels between the changes taking place in the course of evolution among the lower animals, and the vicissitudes of human political societies. The treatment of the subject was interesting and suggestive, and the lecturer met with a cordial reception.

A TELEGRAM from the *Times* Ottawa correspondent on June 2 announced that a commission has been appointed by Federal authority to investigate the need for technical education in Canada. Mr. J. W. Robertson, late principal of the McDonald Agricultural College, has been appointed chairman of the commission.

THE current issue of the *Battersea Polytechnic Magazine* is a double number, with an unusually varied and interesting table of contents. Instances are given in one of the articles of the lively interest shown by King George and the late King in the work of the polytechnic. Among other contributions are an account of Brennan's monorail, and the biological disposal of sewage. The reports of the doings of the clubs and societies of the polytechnic are good evidence of the activity of the institution.

By the will of the late Mr. Isaac C. Wyman, of Salem, Mass., a graduate of Princeton College, who died on May 18 last, most of his estate, says *Science*, is bequeathed to Princeton University. The daily papers estimate the value of the bequest to be from 400,000*l.* to 2,000,000*l.* From the same source we learn that the Jefferson Medical College of Philadelphia has received a gift of 12,000*l.* from Mrs. M. G. Horwitz, daughter of the late Prof. S. D. Gross, to endow the "Samuel D. Gross Chair of Surgery."

THE fifth issue of the "Girls' School Year Book (Public Schools)" is now available, and it may be remarked that the annual is, for the first time, the official book of reference of the Association of Head Mistresses. The book continues to be useful, providing parents, schoolmistresses, and girls themselves, as it does, with trustworthy information respecting secondary education for girls. The second part of the work deals chiefly with the future career of girls on leaving school, and will appeal specially to parents and guardians, since the particulars given are of a thoroughly practical nature.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 2.—Sir Archibald Geikie, K.C.B., president, in the chair.—L. S. **Dudgeon**, P. N. **Panton**, and H. A. F. **Wilson**: The influence of bacterial endotoxins on phagocytosis (preliminary report). Extracts were prepared from most of the common pathogenic organisms by grinding them up in the presence of sterile sand or glass, and adding a definite amount of sterile salt solution; this was then centrifuged at high speed, and the final supernatant layer employed as the endotoxin. *The Action of the Endotoxic Substance on the Leucocytes.*—The authors' experiments, although limited, failed to indicate that there was any direct action on the leucocytes, as in no instance was there any appreciable variance from the control experiments. *The Action of the Endotoxic Substance on the Serum.*—The following facts were evident as a result of these experiments:—(1) that the endotoxic substance was capable of exerting a specific action on the serum in a large proportion of cases; (2) that the endotoxic substance was unaffected by heat; (3) that dilution of the endotoxic substance correspondingly diminished its toxic effect upon the serum, but in a few instances, when diluted, it appeared to play the part of "stimulin," so that the degree of phagocytosis was far greater than in the control experiments.—Prof. H. E. **Armstrong** and E. Frankland **Armstrong**: The origin of osmotic effects. III.—The function of hormones in stimulating enzymic change in relation to narcosis and the phenomena of degenerative and regenerative change in living structures. When a leaf of cherry-laurel is exposed to the vapour of an anæsthetic, hydrogen cyanide is at once liberated; as this is easily detected by means of Guignard's sodium-picric acid paper, the liberation of the cyanide affords a delicate indication of the occurrence of enzymic change in the leaf. Not only the common anæsthetics, but most organic vapours, appear to act as excitants, e.g. toluene, volatile alcohols, and especially ethereal salts of acids of the acetic series. Ammonia is very active, and it is noteworthy that even carbon dioxide, hydrogen cyanide, and benzaldehyde condition the breakdown of the cyanophoric glucoside in laurel leaves. When solutions are used, it is found that weak solutions of mineral acids, alkalies, and most salts are inactive, but the simpler organic acids, mercuric chloride, cadmium iodide and sodium and potassium fluorides all pass into the leaf from solutions. Apparently, the behaviour of the laurel leaf resembles very closely that of the barley grain (cf. Adrian J. Brown, Roy. Soc. Proc., B, 1909, vol. lxxxi., p. 82). It is proposed to divide substances other than colloids into two subclasses, according as they will or will not pass through differential septa such as occur in the barley grain and the laurel leaf; also to apply to the former the term *hormone* introduced by Starling. The change brought about by hormones may be attributed largely, but not entirely, to the influence they exercise in causing alterations in concentration of the fluids within the leaf. Experiments are adduced showing that water actually passes into the leaf, together with the hormone; also that not only is hydrogen cyanide liberated and water absorbed, but that the amount of reducing sugar in the leaf is increased. The hypothesis is advanced that when substances which are not attractive to water are introduced into the living cell they exercise stimulative effects that are primarily mechanical, molecules of the hormone being interposed between the molecules in the cell and the activity of the medium raised by the change in the osmotic state, so that a flux of water from other regions takes place. Possibly the mere dilution thus effected is determinative of change; contact being established between hydrolyte and hydrolyst, degenerative changes are set up which tend to increase in intensity as the products of change in turn exercise a similar stimulative influence; gradually enzymes are set free which can attack the various hydrolytes stored in the cell. The phenomena of change in living structures, especially muscle and nerve tissue, are considered from this point of view; also the phenomena of narcosis, the regulation of respiration, and the physiological effect of alcohol and of drugs generally. It is pointed out, also, that the hypothesis may afford an explanation of a number of more

recent observations on plant metabolism. Partially sterilised soils, for example, which Russell has shown to be so fertile, are rich both in carbon dioxide and ammonia: it is suggested that these are two factors of prime importance as stimulants of plant growth; for a similar reason, sulphate of ammonia may have special value in comparison with other nitrogenous fertilisers. The deleterious effect of grass growing over the roots of fruit trees may be more or less due to the removal, which the grass effects, of ammonia, and the consequent withdrawal of the stimulus which this hormone affords to the roots of the trees.—Dr. R. D. **Kleeman**: The direction of motion of an electron ejected from an atom by ultra-violet light. Experiments were carried out to see whether the cathode radiation from substances exposed to ultra-violet light moves initially in the direction of propagation of the light. The amount of cathode radiation from a platinum film deposited on a quartz plate in a discharge tube was measured with the film facing the source of ultra-violet light, and with it facing in the opposite direction. It was found that if the intensity of the pencil of light used is denoted by unity, the intensity of the light after passing through the quartz plate and film is 0.55; and if we denote by unity the intensity of the cathode radiation from the film when it faces the source of light, the intensity of the radiation when the film faces in the opposite direction is 1.15. Since the intensity of the light decreases as it passes through the quartz plate and platinum film, it follows that the larger leak in the latter case than in the former would not be obtained if the cathode rays were ejected equally in all directions, but might occur if they have a component in the direction of propagation of the light.—Sir William **Crookes**: Scandium, part II. This is a continuation of the paper read in April, 1908, in which, after describing the mode of extracting scandia from the mineral wilkita, the principal salts, twenty-three in number, were described, their formulæ and analytical results being given in detail. The scandia used in the preparation of some of the salts now described was not absolutely pure. Chemically, no other earth could be detected in it, but the spectrograph revealed traces of yttria and ytterbia. These traces could have been removed by one or more operations, but the author thought it advisable to leave them in, for the following reasons: in each operation of purification some loss is unavoidably incurred, and when chemical reactions are insufficient to find the other earths it is not worth diminishing his lessening stock of scandia for the sake of academic purity. The chief reason, however, for leaving these traces in is that they might afford evidence of a difference of behaviour between one earth and another in the presence of some of the acids used. After each quantitative determination the scandia was dissolved in acid, and a spectrogram taken to see if yttria or ytterbia were present. The residual earth was then collected from the mother-liquor, and a photograph taken of its spectrum. A comparison of the pair of spectra shows at once if any separation has been effected between the earths present. When separation is apparent, further experimentation on a larger scale is reserved to a future occasion. The following salts are described, and details of their analyses given:—scandium borate, scandium mono-chloroacetate, scandium lactate, scandium fumarate, scandium α -dibromopropionate, scandium citrate, scandium orthochlorobenzoate, scandium metanitrobenzoate, scandium phthalate, scandium tetrachlorophthalate, scandium 2-nitrophenyl-4'-tolylamine-4-sulphonate, and scandium octamethyltetraminodihydroxy-paradixanthylbenzenetetracarboxylate. More than once the author has been asked why he chose such out-of-the-way acids wherewith to prepare scandium salts. He gives his chief reason. Attempts on several occasions have been made to discover a means of separating some of the "rare earths" from their companions by forming compounds with weak organic acids. Thus, in 1897, Kosmann employed citric acid in the separation of thoria. Urban used acetylacetone of sodium for the same purpose. Metzger tried maleic acid, cinnamic acid, picric acid, phthalic acid, and fumaric acid. In 1904 Neish tried many organic acids for the separation of the rare earths, chiefly thoria. Among other acids he tried gallic, tannic, citric, salicylic, oleic, linoleic, paratoluic, oxyisophthalic, benzoic, meta-, ortho-, and para-nitrobenzoic, and fumaric. Of

these, metanitrobenzoic acid proved most effectual, the process being capable of accurate quantitative results. Soon after those experimental papers appeared the author commenced similar researches, hoping to find an organic reagent which would be a precipitant for some of the yttria earths—if not with quantitative accuracy, at all events with sufficient separation to allow a fractionation method to be based on the reaction. His results, not being sufficiently definite, were never published; but as the organic acids were in his laboratory when the scandium research was commenced, he preferred to use these acids, of which the purity and the history were known, rather than start afresh with acids of unknown history.—J. **Eustice**: Flow of water in curved pipes. Experiments were made on a flexible tube with the object of ascertaining the increased resistance to the flow of water which is due to the curvilinear motion of the water in coils of uniform radius. The tube, which was about 0.37 cm. internal diameter in its normal condition, was sufficiently small to admit readily of experiments both below and above the critical velocity. In order to separate the effect of curvature and change of cross-section, special apparatus was employed to change the section of the straight tube from circular to oval form. Comparisons were made between the flow in the straight tube and the flow in the tube when it was coiled, the straight tube and the coiled tube being of the same form and area of section. The results obtained show that:—(a) The flow in a straight flexible tube of circular section follows the laws of flow in metal tubes as investigated by Prof. Osborne Reynolds, and that the velocity at which turbulence commences is given by Reynolds's formula. (b) The critical velocity, which is so well marked in the flow in a straight tube, appears to be entirely absent when the tube is coiled, that is to say, the index law for straight tubes does not hold for coiled tubes. (c) The increased resistance due to the curvature of the tube length is represented by the formula $(\Delta V/V) = CR^{-1}$, where ΔV is the loss of velocity due to coiling the tube, V is the velocity in a straight tube of the same form and area of section, R is the radius of the coil, and C is a constant for any given velocity V , but both n and C vary with V .—Prof. A. **Dendy** and G. E. **Nicholls**: The occurrence of a "mesocœlic recess" in the human brain and its relation to the sub-commissural organ of lower vertebrates, with special reference to the distribution of Reissner's fibre in the vertebrate series and its possible function. The authors find in the adult human brain a small cavity, lined by a characteristic columnar epithelium, imbedded in the roof of the *iter* at the back of the posterior commissure, and in close relation to this another irregular cavity, which apparently represents the remains of a communication with the lumen of the *iter*. In the five months' foetus this communication is still widely open, and the cavity in question is evidently part of a structure lying beneath the posterior commissure, and corresponding to the so-called "ependymal groove" of lower vertebrates. For this structure the authors now propose the more distinctive term "sub-commissural organ." It consists, in the human foetus, of two bands of high columnar epithelium with deeply situated nuclei, invaginated posteriorly into the roof of the *iter* to form a "mesocœlic recess," as in certain lower vertebrates. In the adult man it is in a vestigial condition, being represented by the mesocœlic recess alone. In the chimpanzee the sub-commissural organ is better developed than in man, and the mesocœlic recess still opens into the lumen of the *iter* in the adult, the recess itself having a diameter nearly ten times as great as in the human subject. The condition of the sub-commissural organ in the cat and the mouse is also described and figured for purposes of comparison. In these two types it is very well developed, and there is also a Reissner's fibre. The latter, in the cat (and probably also in the mouse), breaks up into slender branches, which are connected with the modified epithelium of the sub-commissural organ, exactly as in lower vertebrates (e.g. lamprey, frog). Considering this well-defined relation of Reissner's fibre to the sub-commissural organ, it seems highly improbable that in man, where the sub-commissural organ is reduced to a mere vestige altogether shut off from the remainder of the cavity of the brain, a Reissner's fibre exists. It is maintained that these observations support the view already put forward that Reissner's

fibre has a mechanical and not a nervous function, and that, in connection with the sub-commissural organ, it forms an apparatus for automatically regulating (in lower types) the flexure of the vertebral column; this function is supposed to have become obsolete with the assumption of the erect position and the loss of the tail.

Zoological Society, May 24.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—D. G. **Lillie**: Observations on the anatomy and general biology of some members of the larger Cetacea. This paper was the outcome of seven weeks spent at the Irish whaling station during the summer of 1909. The object of the visit was to make a preliminary survey of the opportunities which are now offered for a study of the larger Cetacea by the recent establishment of whaling stations off the shores of the British Isles. A list was given of the species captured at the Irish station during the two years of its existence, with notes on the species *Balaenoptera musculus*, Linn., *B. sibbaldii*, Gray, and *Physeter macrocephalus*, Linn., which were seen by the author. The paper also contained observations on the occurrence of hairs in whales, the auditory organ of the Balænoptera, the asymmetry of the odontocete skull, and a few remarks upon the habits of whales. In conclusion, attention was directed to the present difficulty in obtaining information as to their method of copulation, period of gestation, rate of breeding, &c., and a means of overcoming this difficulty was suggested.—C. F. **Rousselet**: Collection of rotifera made by the third Tanganyika expedition, 1904-5. Amongst the specimens brought back by Dr. W. A. Cunningham were a number of tubes containing fine surface plankton nettings from Tanganyika and other lakes of that region. These the author searched for rotifera, and the result was contained in the present paper. From Lake Tanganyika only eleven species were obtained, all already known in other parts of the world, whilst the River Lofu, which enters the lake at its south-western corner, yielded twenty-three species, one of which is a very remarkable new kind. In Lake Nyassa only six species were found, and a single gathering of Victoria Nyanza yielded nine species. This collection is interesting and important from the fact that no previous record of rotifera from Lake Tanganyika had been made, and very few species were known from the Central African region.—J. **Ritchie**: (1) The hydroids of the Mergui Archipelago, collected by Mr. J. J. Simpson and Dr. R. N. Rudmose Brown; (2) the hydroids of Christmas Island, collected by Dr. C. W. Andrews, F.R.S. The chief interest of these two papers was faunistic. In the former thirty species were recorded, in the latter thirteen. It was apparent that the hydroid fauna of the eastern Indian Ocean, of which hitherto little had been known, lacked distinctness, and that its closest affinities were with the faunas of the neighbouring Malay Archipelago and Australian areas.

Institution of Mining and Metallurgy, May 26.—Mr. Edgar Taylor, president, in the chair.—T. J. **Hoover**: A standard series of screens for laboratory testing. This paper represents an attempt on the part of the author to reconcile the conflicting elements in the existing series of screens, such as the "common" series, Ritinger's, Richards's, De Kalb's, and the I.M.M. Standard Screens, and to present in their place a "cube root" series, for which he claims merits hitherto wanting; also to present a practical mechanical method of making screen analyses. With these ends in view, after a brief reference to the functions required in laboratory screening, the author proceeds to analyse in detail the various series of screens mentioned, and of his proposed substitute, and to compare them with silk bolting cloth. Subsequently he directs attention to a machine calculated to simplify the operation usually accomplished by means of hand-sizing tests. An ample bibliography concludes the paper.—H. **Stadler**: Grading analyses and their application. This paper gives in detail the results of a number of tests made by the Mines Trials Committee in South Africa, from which the author proceeds to show how the various portions of certain standard sizes of particles may be valued in units of energy which will allow of an exact expression of the efficiency of the crushing operation for purposes of useful comparison. He claims that the most rational and logical system of

classification into grades is undoubtedly to base it on the reduction of the volume or weight of the particles, and for this purpose he reduces the cube of the unit successively by one half its volume, thus obtaining a reduction scale in the "common" ratio of 2, or by eliminating alternate grades preferably in the ratio of $1/4$. The scheme does not standardise the screens as such, but establishes an unerring standard for the sizing and classifying of the screen products into grades, and is consequently valid for screens of any description, independent of purely practical and commercial considerations. An examination of the practical application of grading analyses follows, and, as a result of the trials made, the author states that investigators are now in a position to determine with a comparatively high degree of accuracy the relative merits of different crushing appliances or the mechanical efficiency of one and the same machine working under varying conditions.—**T. A. Rickard**: Standardisation of English in technical literature. The author protests against the corruption of the English language, and pleads for more exact definition in technical literature. He deals in detail with various aspects of the subject, giving examples of the faults to which he makes objection, as, for instance, "spurious" words adopted from other callings, vulgarisms or slang terms, and the practice of giving variable meanings to words, all these tending to destroy the proper significance of language, and so enfeebling it. Objection is taken to the use of the "unnecessary" plural in such words as slimes, sands, concentrates, middlings, tailings, &c.

CAMBRIDGE.

Philosophical Society, May 23.—**Dr. Fenton**, vice-president, in the chair.—**Prof. Pope** and **J. Read**: The resolution of externally compensated bases into their optically active components.—**Prof. Pope** and **C. S. Gibson**: The resolution of dihydropapaverine.—**Dr. Sell**: Further study of the products of chlorination of α -picoline.—**Dr. Fenton** and **W. A. R. Wilks**: Formation of uric acid derivatives.—**C. T. Heycock**: Water of crystallisation in calcium phosphate.—**S. Ruhemann**: (1) The diketopyrrolines and their analogues; (2) the formation of α - and γ -pyrones from acetylenic acids.—**H. O. Jones** and **J. K. Matthews**: The reduction of nitrosyl chloride.—**W. A. R. Wilks**: Absorption of bromine by lime.—**F. Robinson**: Note on the absorption of acids by carbohydrates.—**Sir George Greenhill**: A hollow vortex in a polygon.—**R. T. Beatty**: A dissymmetry in the emission of kathode particles excited by homogeneous Röntgen radiation. Homogeneous radiations were allowed to pass through a thin silver leaf, and the ionisation due to kathode particles emitted from the leaf on the emergent and incident side respectively was measured. On allowing for the absorption of the homogeneous radiation in the leaf, this ionisation was greater on the emergent side; and this dissymmetry, while but slight for soft radiation, increased with the hardness. The same values for the dissymmetry were found when a copper leaf was substituted for the silver leaf. The results show that the dissymmetry is unaltered whether much homogeneous radiation be excited in the leaf or not.—**J. A. Crowther**: Note on the transmission of β rays. The author has recently shown that the absorption of a beam of homogeneous β rays by aluminium follows a law approximating to that lately suggested by **Sir J. J. Thomson**. The absorption of such a beam in platinum, however, follows an exponential law. This result is ascribed to secondary β radiation excited in the platinum. It is now further shown that the absorption by aluminium of a pencil of homogeneous β rays, after transmission through a small thickness (0.001 mm.) of platinum, is also exponential, resembling the absorption law obtained for the rays from a single radio-active substance.—**A. L. Hughes**: The mobilities of the ions produced in air by ultra-violet light. The experiments show that air is ionised by ultra-violet light of very short wave-length. The mobilities of the ions so produced are found to be identical with the mobilities of the ions produced by X-rays.

MANCHESTER.

Literary and Philosophical Society, May 3.—**Mr. Francis Jones**, president, in the chair.—**H. Sidebottom**: Report on the recent Foraminifera from the Bay of Palermo, Sicily. A special account was given of the genus

Lagena, which comprises many very elegant flask and decanter-shaped chambers. Some of the members of this genus adhere together at their bases in clusters of three or more, and others show the peculiarity of having two or three slender necks instead of the normal one. Examples of these clusters were shown under the microscope, and many beautiful drawings were exhibited.—**C. Bailey**: A third list of the adventitious vegetation of the sandhills of St. Annes-on-the-Sea, North Lancashire, Vice County 60.—**H. Bateman**: The physical aspect of time. The point of view adopted was that our ideas of space and time were part of our interpretation of the processes of electromagnetism, and were purely relative inasmuch as any measurement of them involved some properties peculiar to the mode of measurement. The transition from one interpretation to another must depend upon a transformation which leaves the fundamental equations of electromagnetism unaltered in form. A brief discussion of the nature of these transformations may be based upon a consideration of the conditions which must be satisfied in order that at a given time an observer may be in a position to witness an event which occurred at some other point at a given previous time. A transformation may be compared to a translation of a poem from one language to another; the words may be different in the two cases, but the ideas are the same. It is somewhat similar in the case of two different interpretations of the same electromagnetic process.

DUBLIN.

Royal Dublin Society, May 24.—**Prof. Sydney Young**, F.R.S., in the chair.—**R. J. Moss**: An improved method of milk analysis. The milk is dried on tinfoil, which is then rolled up, and the fat is extracted in a Soxhlet apparatus. The non-fatty solids are dried at 100°C . in a vacuum with the aid of sulphuric acid. These solids are obtained in a form suitable for further examination. The process occupies from three to four hours.—**Prof. W. Brown**: Magnetism and torsion in iron, in which some results were given for iron wire of different degrees of hardness, and when under different longitudinal loads.—**Prof. J. Wilson**: The separate inheritance of quantity and quality in cows' milk. The author made use of the recently published report of the milk-testing scheme carried out among Ayrshire cattle in 1908. There were more than 8000 cows tested; but, in order to have a fair comparison, all under four years old, and all that had milked for less than thirty or more than forty weeks, were eliminated. That left about 3000 cows. When these were divided into four groups, viz. those giving less than 500 gallons of milk, those giving from 500 to 600 gallons, those giving from 600 to 700 gallons, and those giving more than 700 gallons, it was found that the qualities of the milk given by all the cows in all groups was the same; that is to say, of the numbers of cows giving all the various qualities of milk, from that containing about 2.7 per cent. of fat up to that containing about 5.5 per cent., the resulting curve starts at zero near 2.7, rises to a maximum of about 3.6, and declines again to zero near 5.5 per cent., and exactly similar curves were given by the cows in the other three groups. The author infers that the proportion of fat in a cow's milk is unconnected with the yield.

PARIS.

Academy of Sciences, May 30.—**M. Émile Picard** in the chair.—The president announced the losses sustained by the academy by the deaths of **Robert Koch** and **Sir William Huggins**.—**E. Bouty**: The dielectric cohesion of neon and its mixtures. The dielectric cohesion of neon is very low in comparison with that of other gases, and upon this fact is based a delicate quantitative method for measuring the amounts of impurities in neon. Mixtures of neon with carbon dioxide and air were studied, the increase of the cohesion due to the addition of either of the latter gases being somewhat greater than that calculated from the ordinary mixture law.—**Armand Gautier**: Some remarks, from the geological and chemical point of view, relating to the action of heat upon carbon monoxide. Experiments are described which lead the author to the conclusion that at a temperature of 1300°C ., and at the ordinary pressure, carbon monoxide in porcelain tubes, and in the absence of organic matter and of metal, undergoes no sensible dissociation, and no carbon is set free.—**A. Lacroix**: The

optical properties of the holocrystalline phosphorites of Quercy.—**A. Müntz**: The struggle for water between living organisms and natural media. Different soils require different amounts of water for saturation, and if the water actually held is under the saturation figure no water can be absorbed by a seed, and no germination takes place. Several cases are considered at length.—**Albert, Prince of Monaco**: The twelfth scientific campaign of the *Princesse Alice*, and also the oceanographic work of the Monaco Museum.—**M. de Forcrand**: The heat of formation of caesium peroxide. A thermochemical study of the solution of caesium peroxide in water and dilute acids.—**Lecoq de Boisbaudran**: Can the truffle be replanted? The separation from the mycelium hinders the growth of the truffle, but does not altogether stop it.—**M. Pérez** was elected a correspondant for the section of anatomy and zoology in the place of the late **M. Lortet**.—**Fr. Marchand**: Phenomena observed at the Pic du Midi on May 18-19 (passage of Halley's comet across the sun). From the whole of the observations no clear conclusion can be drawn as regards the possible electric action of the cometary material.—**K. Popoff**: Observations of Halley's comet made at the Observatory of Sofia, Bulgaria, May 18, 1910.—**D. Eginitis**: Observations of Halley's comet made at the Observatory of Athens. The changing aspect of the tail is discussed from the point of view of its curvature and the change in the curvature on approaching the sun. No sign of the comet was visible as it crossed the sun's disc.—**Jules Baillaud** and **G. Demetresco**: Photographic observations of Halley's comet at the Paris Observatory. The conditions were unfavourable, photographs being possible on May 23, 24, and 28 only.—**P. E. Gau**: The search for the intermediate integrals of the equation $s=f(x, y, z, p, q)$.—**S. Lattès**: Taylor's series with recurring coefficients.—**J. Le Roux**: The distribution of torsion in the infinitesimal deformation of a continuous medium.—**H. Larose**: Two sets of solutions of the equation of telegraphists.—**W. Duane** and **A. Laborde**: Quantitative measurements of the radium emanation. The relation between the initial value of the saturation current due to the presence of a given amount of the radium emanation, the interior surface and volume of the condenser given by **W. Duane** in 1905 has been confirmed, and the constants in the equation re-determined. When these constants are known for a given condenser, a single determination of the initial saturation current is sufficient to determine the amount of radium emanation present.—**L. Boutan** and **J. Feytaud**: Stereoscopic colour photography and its scientific applications. The arrangement described permits the use of artificial light; photographs in colour of a medusa and of a branch of coral were made.—**Maurice de Broglie**: The electrification of the air by the carbon monoxide flame and by the radium rays; comparison of the mobilities of the ions present in the two cases. The ions liberated by chemical action and high temperature in the combustion of carbon monoxide and those which are produced by the radium rays have very similar mobilities, and are probably identical.—**M. Driot**: Some six zinc oxychlorides have been described, but by the direct action of zinc oxide upon solutions of zinc chloride only two distinct substances have been indicated, according to the author's experiments. These are

—**Gustave Vavon**: The rotatory power of pinene hydrochloride. The results given are in complete accord with the hypothesis first put forward by **Semmler**, and developed by **Ahlström** and by **Aschan**, according to which the α and β pinenes give the same solid hydrochloride. The yields furnished by the two hydrocarbons are the same.—**P. L. Viguier**: α -Bromocrotonic aldehyde. Crotonaldehyde is treated with bromine, and then the product distilled with a solution of sodium acetate. From the distillate the bromocrotonic aldehyde can be isolated. The yield is not very good, about 25 per cent., but the method is rapid. The oxidation and condensation of the bromaldehyde with malonic acid is described.—**Fr. Reverdin**: A trinitro- β -anisidine.—**L. Tchougaeff** and **W. Fomin**: Some cholesterol derivatives. Two cholesterylenes have been prepared by heating methyl cholesteryl xanthogenate, and formulae given for the constitution of these hydrocarbons.

—**Paul Becquerel**: Experimental researches on the latent life of the spores of *Mucorinæ* and *Ascomycetes*.—**J. E. Abelous** and **E. Bardier**: The influence of bleeding on the resistance of animals to urohypotensine.—**M. Lioret**: The transformation of phonograph traces into curves.—**L. Cuénot** and **L. Mercier**: Studies on the cancer of mice. Heredity and sensibility to cancerous grafting.—**Pierre Girard**: The electrostatic mechanism of the semi-permeability of living tissues to electrolytes.—**J. Chaine**: Spinal curvature.—**Armand Dehorne**: The number of chromosomes in batrachians and in the parthenogenetic larvae of the frog.—**Jules Courmont**, **Th. Nogier**, and **M. Rochaix**: Does water sterilised by the ultra-violet rays contain hydrogen peroxide? The sterilising power of hydrogen peroxide. The first question is answered in the negative, and it is shown that considerable proportions of hydrogen peroxide acting for some hours are not equivalent to the sterilising power of ultra-violet light acting for a few minutes only.—**L. Fortineau**: The curative treatment of anthrax by pyocyanase. The injection of pyocyanase has a curative effect on malignant pustule.—**A. Besredka**: A means of avoiding anaphylactic accidents.—**Marcellin Boule** and **R. Anthony**: The encephalus of the fossil man of La Chapelle-aux-Saints.—**Fr. de Zeltner**: The decorated grottoes of the French Sudan.—**A. Quidor**: Protandry in the *Lernæopodidæ*.—**Louis Gentil**: The Tertiary movements in the Moroccan Haut-Atlas.

NEW SOUTH WALES.

Linnean Society, March 30.—**Mr. C. Hedley**, president in the chair.—**C. Hedley**: Presidential address. The submarine slope of New South Wales. (1) *The Notonectian Current*.—Past Sydney there flows south a warm and rapid current well known to sailors and fishermen. Neither its origin nor its conclusion has been satisfactorily determined. Two recent maps give contradictory views of its course. It has been assumed, rather than proved, that this current is derived from the south equatorial current, the path of which, after encountering the Melanesian Islands, is indefinite. The investigation of this current is the largest, most fruitful, and fascinating problem within the reach of the Sydney marine biologist. (2) *The Continental Shelf*.—The continental shelf may be defined as that area extending outwards from the land to a depth of about one hundred fathoms. This distinction is not arbitrary, for at or about this point the sediment alters to finer, and the slope of the sea-floor to steeper. These features indicate the approaching limit of sediment. Wherever the profile of the New South Wales coast be examined, a terrace is found to project from the beach to the hundred-fathom line, whence the ground quickly changes to a steeper grade. Compared with most other coasts, the continental shelf is here exceptionally narrow, resembling in this respect that of western South America. Off Cape Dromedary the shelf contracts to a dozen miles, and off Newcastle it broadens to thirty-four. This narrowness of the shelf renders it impossible that extensive trawling grounds may be discovered in the waters of the State. It is now suggested that the continental shelf of New South Wales owes its profile to the Notonectian current. (3) *The Continental Base*.—In illustration of the slope below the shelf, here termed the continental base, a profile is selected extending seventy miles east-south-east of Ulladulla, and produced backwards to include the coast range. Without excluding faulting as a minor agent, it is suggested that the whole sweep of the diagram portrays an earth-fold of the first magnitude—that it represents the further wall of a pressure-trough driven by a thrust from the east, a gigantic buckle which is bending down the whole eastern coast of Australia. If so, it must be a component of a vast system. The uniform and recent subsidence which extends from Torres Strait to Tasmania is in harmony with this suggestion.—**Dr. R. Greig-Smith**: The slime of the household bath-sponge. The formation of slime is due to the action of bacteria-attacking spongin, the chief constituent of the sponge, and producing a slime. One of those which produced the phenomenon in experimental sponges is described. The slime contains one of the galactan class of gums.—**Dr. R. Greig-Smith**: The bacterial flora of rachitic stools.

April 27.—**Mr. C. Hedley**, president, in the chair.—**E. J. Goddard**: Contribution to a knowledge of Australian

Hirudinea, part v., leech-metamerism.—E. J. Goddard: Contribution to a knowledge of Australian Hirudinea, part vi., the distribution of Hirudinea, with special reference to Australian forms, and remarks on their affinities, together with reflections on zoogeography.—H. J. Carter: Revision of the genera *Sympetes* and *Helæus*, with descriptions of new species of Sympetronidae.

CALCUTTA.

Asiatic Society of Bengal, May 4.—A. C. Son: "The fight for the cows" in the Rigveda. The prevailing opinion is that "the fight for the cows by the Angrases," mentioned in the Rigveda, is a highly anthropomorphosed description of the monsoon storm in the Panjab. The author of the paper has tried to prove that the story refers to an actual fight for cows between two people, the Indo-Aryans, commanded by their king *Trita*, and a non-Aryan people called the *Panis*, under the leadership of their chief *Vala*.—Rev. H. Houston: Who planned the Táj? The subject has come up for discussion several times of late years. Mr. Havell, in particular, is of opinion that the Italian or French origin of the Táj cannot be held. The present paper advocates a return to the traditional view, and offers the contemporary evidence of Friar Sebastian Manrique (1670) to show that Sháh Jahán approved of the plans of Jerome Verones, a Venetian architect. Mr. H. G. Keene in his "Turks in India" and his "Handbook of Agra" had come to the same conclusion from a study of Manrique. His conclusion has been set aside. A full translation of Manrique's Spanish account is now presented, and it is hoped that the evidence will be found satisfactory.

DIARY OF SOCIETIES.

THURSDAY, JUNE 9.

ROYAL SOCIETY, at 4.30.—The Distribution of Velocity in the β -Rays from a Radio-active Substance: J. A. Gray.—The Decrease of Velocity of the β -Particles on Passing through Matter: W. Wilson.—Rate of Emission of α -Particles from Uranium and its Products: J. N. Brown.—The Accumulation of Helium in Geological Time. IV.: Prof. The Hon. R. J. Strutt, F.R.S.—The Effect of Small Traces of Water Vapour on the Velocities of Ions produced by Röntgen Rays: R. T. Lattey.—On the Variation with Temperature of the Viscosities of the Gases of the Argon Group: Dr. A. O. Rankine.—The Effect of Pressure upon Arc Spectra. Part II., No. 4. Gold: Dr. W. G. Duffield.—On Radiation in a Gaseous Explosion: Prof. B. Hopkinson, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—(1) A New Method in the Theory of Integration: (2) On Semi-integrals and Oscillating Successions of Functions: Dr. W. H. Young.—The Composition of Finite Screw Displacements: G. T. Bennett.—Note on the Theory of Linear Differential Equations: Prof. M. J. M. Hill.—The Generation of Cubic Curves by Apolar Pencils of Lines: W. P. Milne.—On Geiser's Method for the Bitangents of a Plane Quartic Curve: Miss M. Long.—The Transformation of the Equations of the Theory of Electrons for Quasi-stationary Motion: H. R. Hassé.

ROYAL INSTITUTION, at 3.—Malaria: Major Ronald Ross, F.R.S.

FRIDAY, JUNE 10.

ROYAL INSTITUTION, at 9.—The Progressive Disclosure of the Entire Atmosphere of the Sun (in French): Dr. H. Deslandres.

PHYSICAL SOCIETY, at 8.—A Galvanometer for Alternate Current Circuits: Dr. W. E. Sumpner and W. C. S. Phillips.—The Positive Electrification due to Heating Aluminium Phosphate: A. E. Garrett.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Photographs of Nebulae made with the 60-inch Reflector of the Mount Wilson Observatory: G. W. Ritchey.—Note on Sodium in Comets' Tails: T. W. Backhouse.—Remarks on Mr. Backhouse's Paper: A. Fowler.—The Long-period Variable V Cassiopeiae: A. N. Brown.—Note on a Paper on Periodic Orbits: Sir G. H. THE FACE OF THE EARTH.

Das Antlitz der Erde. By Prof. E. Suess. Vol. iii., pt. ii. Pp. iv+789; 3 plates, 5 maps. (Vienna: F. Tempsky; Leipzig: G. Freytag, 1909.)

Namens und Sachregister für Sämtliche Bände. By Dr. L. Waagen. Pp. 158. (Vienna: F. Tempsky; Leipzig: G. Freytag, 1909.) Price, including index vol., 50 marks.

The Face of the Earth. Vol. IV. Translated by H. B. C. Sollas, under the direction of Prof. W. J. Sollas. Pp. viii+673. (Oxford: Clarendon Press, 1909.) Price 25s. net.

ALL geologists will join in hearty congratulations to Prof. Suess ^{on} the completion of his great work, the influence ^{of} which has been spreading steadily since the appearance of its first part in 1883. Prof. Suess's views were opposed to such cherished traditions that they were naturally at first regarded with suspicion; but many of his conclusions have been now generally accepted, and his illuminating suggestions have stimulated much fertile research. The last section of the work (vol. iii., part ii.) is accompanied by a series of most valuable maps and a detailed locality index of 158 pages, prepared by Dr. Lukas Waagen. The concluding part shows Prof. Suess's wide acquaintance with the whole literature of stratigraphical geology, which he interprets with characteristic insight and originality. The summary of recent geological work on various remote regions would alone ensure this volume a warm welcome from its usefulness as a work of reference, apart from its place as the completion of one of the standard works in geological literature.

The conclusion has been awaited in the hope that it would be largely devoted to a general summary of Prof. Suess's results and his explanation of the existing plan of the earth. This expectation has, however, not been fulfilled. This part includes the tenth to twenty-seventh chapters of the third volume, and thirteen of the eighteen chapters continue a revision of the mountain systems of the world, dealing with those of Europe, America, Africa, and Oceania. The remaining five chapters discuss various general problems, including the three zones of the earth's crust, which, from the chemical symbols of their leading constituents, Prof. Suess calls Nife, Sima, and Sal, the trend of mountain folds, isostasy, the process of igneous intrusion, the structure of the moon, and a final chapter on some lessons from the distribution of life. There is no attempt at a complete general theory of the distribution of land and water on the earth, as Prof. Suess apparently holds that none such is yet possible. He recognises on the earth several superposed plans, but makes no suggestion as to their causes. Thus the reason for the difference between the Atlantic and Pacific types of coast structure he describes as still unknown, and he leaves "to the future" (p. 724) the explanation of the great marine transgressions, the fundamental importance of which he was the first to appreciate

correctly. The explanation that they are due to the shallowing of the ocean basins by the spheroidal recovery of the earth after periods of deformation is not mentioned, though it may once be vaguely alluded to.

The first impression made by a perusal of this volume is the greatness of the changes between it and its predecessors. Prof. Suess's essential principle that the face of the earth owes its expression to dimples and wrinkles due to the earth having shrivelled with age is maintained; but the view that all vertical movements are necessarily downward is abandoned. The ingenious explanations by which Prof. Suess endeavoured to explain away Darwin's evidence as to the vertical uplift of the coast of Chile after the earthquake of 1822 are resigned, in face of the well-established vertical uplifts along the western coasts of North America. Prof. Suess, however, does not admit uniform regional elevation, and he therefore necessarily rejects the principle of isostasy. He discusses this question in one of his final chapters, and expresses his strong distrust of mathematical evidence on such problems. Its uncertainty is illustrated by his proposal to alter the widely accepted conclusions by simply modifying the formula by which they were reached. Suess points out (p. 703) that the omission, as suggested by Faye, of the second factor in the formula used in deducing the weight of the earth's crust from gravity observations would remove the evidence obtained in some cases that the weight of mountains is compensated by a deficiency in material underneath. As the factor in question is a correction for the weight of the material between the point of observation and sea-level, its inclusion seems reasonable. Prof. Suess's further statement that deficiencies in mass beneath mountains "would be contradictory to all geological knowledge" (p. 708) is unexpected, as it is the weight of the geological evidence for the action of isostasy that has induced so many geologists to accept the mathematical arguments in its favour. Less stress is laid in this volume upon variations of the shore line in consequence of local disturbances of sea-level; and Prof. Suess remarks (p. 694) that there is no precise knowledge of the effect of continental attraction upon it. He also changes the meaning of the term batholite, which he proposed for masses of plutonic rocks injected into cavities due to radial contraction; he now attributes the formation of batholites to the replacement of the original rock by absorption and assimilation. Though most geologists are prepared to admit that igneous absorption takes place to some extent, many will probably hesitate before accepting it on so vast a scale.

Some modification was expected in the definition of the Atlantic and Pacific coast types, the establishment of which was one of the great contributions of Prof. Suess's earlier volumes. The Pacific coast type was originally characterised as bounded by mountain chains folded towards the ocean; this view has proved untenable without considerable modifications, and Prof. Suess now accepts (p. 577) the absence of mountain-making activity on the Atlantic coasts as the essential difference; he seems, however, disposed to regard the structural basis of this classification as

less important than the petrographic; he retains the terms for Harker, Becke, and Prior's two petrographic regions, of which the Atlantic is characterised by igneous rocks rich in alkalies, and the Pacific by those rich in lime and magnesia. Both the characters of recent mountain formation and the chemical composition of the lavas can only be applied with numerous exceptions; and we cannot but think it would be regrettable if the great geographical truth in Suess's original view were abandoned, and his two terms retained with a meaning so changed and inappropriate as to be misleading.

Though no general theory is advanced in this volume, Prof. Suess gives in an appendix (pp. 783-5) his final classification of the lands of the earth. He arranges them in the following ten divisions:—

(1) Eurasia, including part of North America; (2) Laurentia; (3) Gondwanaland; (4) Australia, Oceania, and parts of Antarctica; (5) South America and the western mountains of North America; (6) the British Isles, excluding the southern counties, but including part of Norway and the mountains of the western Sahara; (7) the volcanic islands of the Atlantic type, with which are grouped some of the islands of the eastern Pacific, Indian and Southern Oceans; (8-10) the Cape Mountains, the north-western peninsula of New Guinea, and the Fiji Archipelago are each independent elements.

This classification, embodying the conclusions that have been reached by Prof. Suess after thirty years of most careful research, must command respectful consideration from all geographers, though objection may be taken to some parts of it.

The first seven chapters (Nos. x. to xvi.) describe the mountains of western Eurasia, of which the most important are referred to two groups, the Altaids, including the Hercynian Mountains of Bertrand, and the Alpids, formed by Cainozoic foldings in areas that had foundered in the frame of the older Altaids. The Caucasus are now transferred from the Alpine to the Altaid system. There are unquestionably important differences between the Alps and the Caucasus, but these two chains and the Pyrenees were all due to earth movements that probably had a connected origin, though they affected western earlier than eastern Europe. Thus the Pyrenees were folded at the end of the Eocene; the Alps in the Upper Miocene, and the Caucasus in post-Sarmatian times. No doubt the Caucasus has a foundation of older mountains; but so also have the Pyrenees, which have indeed a more typical Altaid basis than the Caucasus.

No one can differ from Prof. Suess on mountain classification without great hesitation. But a classification which correlates the Caucasus with the hills of Devonshire instead of with the Pyrenees is obviously not intended for general geographical use. The geological evidence still seems consistent with the conclusion of Fournier, who, in his monograph on the Central Caucasus, reports "*que la Caucase, par sa direction, par l'âge et le sens de son dernier plissement, par le parallélisme même des stades de sa formation, est le prolongement direct de la grande chaîne Alpine.*"

The African representatives of the Altaids include

the Atlas Mountains, to the south of which is a mountain band composed of Archean rocks with a north to south strike. From this fact Prof. Suess identifies them as a section of the Caledonian mountains. In Scotland the general trend of the foliation in the gneiss and crystalline schists is not from north to south, which is the direction characteristic of the Archean rocks of equatorial and northern Africa; there seems no very convincing reason for correlating these mountains of the western Sahara with the British rather than with the African Archeans.

The discussion of the Eurasian Mountains closes with an especially valuable chapter, in which Prof. Suess traces the Altaid system through the Appalachians and across the United States as far west as Texas and the frontiers of Mexico. Then follow two chapters, one on the African fractures and the other on the Oceanids, the island-estons of Australasia. In dealing with Australia, Prof. Suess's most important proposal is its separation from Gondwanaland, on the ground that not enough is known of the intervening area to show their relations. The evidence, however, of the fossil flora and fauna of Australia seems conclusive of the former land connection of Australia and Gondwanaland.

Prof. Suess next discusses the western mountains of America, and traces the Asiatic structure into America through Alaska. He re-classifies the mountains of North America, and again, as with the correlation of the Caucasus, appears to attach undue weight to the early history and materials of the mountains in comparison with the movements to which they owe their existing forms and geographic importance. He divides the western mountains of North America into three groups. The eastern group is that of the Rocky Mountains, which Suess shows by a masterly study of Alaska, belong to the Asiatic Structure. The westernmost group is the Mount St. Elias chain, which passes out into the Pacific through the Alexander Archipelago. All the mountains between the Rockies on the east and the chain of Mount St. Elias, and the Coast Range of California on the west he calls the Intermediate Mountains; they reach the Pacific coast in British Columbia and the northern part of the United States. On the strength, mainly, of these "Intermediate Mountains," Prof. Suess now maintains the essential unity of structure between North and South America, though of the four chief mountain elements in the former only the Intermediate Mountains occur in both. The view of the unity of the two Americas is based partly on these Intermediate Mountains and partly on the Andes, of which the low Archean Coast Range of California is regarded as the northernmost representative. Prof. Suess represents the Andes as formed by pressure from west to east, so that where the movement was not obstructed by the great mass of the Eastern Highlands of South America the Andean line projected eastward in two great loops, the northern Antilles in the West Indian area, and the "Southern Antilles," including Tierra del Fuego, the South Shetlands, and Graham Land. In both the "Antilles" the Pacific is represented as having advanced into the Atlantic region. The writer once

visited the West Indies to investigate this problem, and, in spite of the nature of the lavas, felt bound to reject the conclusion owing to the palæontological and tectonic evidence.

South America itself, according to Prof. Suess's interpretation, has a uniform structure without any trace of the earlier geographical plans which he admits in other continents. The mountains trending from north-west to south-east in the Argentine he explains as connected with the Andes, an opinion different from that of some Argentine geologists; and as it is conceded that the Sierra de Tandil does not belong to the Andes, there seems evidence for the existence of an older mountain system.

The English translation has been issued as vol. iv., without the plates, maps, appendices, and index, which are to follow. The translation shows evidence of haste, and it has missed the revision by several distinguished geologists of which the preceding volume had the benefit. Miss Sollas has done her part of the work well, as the translation reads easily; but in a work of such geographical importance it is a pity that the geographical terms were not more carefully revised. Thus the depressions on the oceanic floors known in German as "Rinnen" are translated as "channels" (p. 294), a term which connotes the idea of flow, so that the term "trench," recommended by the International Geographical Congress, is preferable. "Die Stauung der ersten Welle" (p. 438) is translated (p. 382) as "the stowing of the first wave," whatever that may mean. More serious objection can be taken to the translation of "Das Zwischen Gebirge," in which Prof. Suess includes all the mountains in Canada and the United States west of the Rockies with the exception of the Mount St. Elias chain, as the Intermediate "Range." The term range is so unsuitable to a vast area of mountain country, which includes many mountain ranges, that the translation cannot always adopt it; so when Prof. Suess says (p. 479), "Das Zwischengebirge in ein Meer von submeridionalen Zügen aufgelöst," the English version reads, "The Intermediate Chain, broken up into a sea of submeridional ranges."

As an illustration of the inconsistency in the translation of geographical terms, it may be remarked that Gebirge, Züg, and Kette are all sometimes translated as range; while Gebirge and Kette are also both sometimes translated as chain. British students will find the irregular treatment of place-names inconvenient and puzzling. Such variations as Brazilia and Brasilia are unimportant, though hardly to be expected in a work issued by a University Press; but many of the variations introduced are confusing. Thus, Prof. Suess speaks of the Sea of Ochot'sch, and calls some adjacent mountains the Ochitiden. The translation, by adopting Okhotsk (p. 328) for the sea and Ochotides for the mountains, obscures their connection; the latter name is once spelt Okhotides. The Yana of p. 331 is the Jana of p. 332; and the Chuchki Peninsula of p. 338 is the Chukchi of p. 377. The Chaja of Suess is sometimes repeated in that form (p. 334), sometimes as Khaja (p. 335), and as Chaya (p. 337). Kegyl (p. 334) is Kygyl on p. 339.

Many of the names in the translation appear in German forms, and are difficult to find in British atlases; thus the lake, which in the *Times* atlas appears as Yege—a reasonable transliteration—is spelt Eche or Esse. Yezo appears as Hokkaido, and Gilolo as Halmahera. The Vistula is mentioned thrice, but its identity is each time concealed by the retention of its German name, Weichsel; "from the Weichsel to Dakota" (p. 88) does not give much information to a student limited to British atlases or gazetteers. Further confusion is added by the differences between the text and the figures; thus Werchne in Fig. 28 is the Verkhne of the text, and Werchojanskij in the same figure occurs as Verkhoiansk in the text.

In the French edition the original technical terms are often quoted in brackets after the translation, and as that excellent precedent has not been followed it would be convenient if, in the index-volume, a list were given of Prof. Suess's geographical terms with the translations adopted.

J. W. GREGORY.

EXPLORATIONS OF INDIA.

The Gates of India. Being an Historical Narrative. By Colonel Sir Thomas Holdich, K.C.M.G. Pp. xv+555. (London: Macmillan and Co., Ltd., 1910.) Price 10s. net.

THESE "Gates of India" are the gates beyond the Indus, the difficult tracks through which all the great historic invaders of the country made their way prior to the days of oceanic exploration. There are few men more competent to write about them than Sir Thomas Holdich, who knows them from the Pamirs to Makran, though he hardly refers to his own achievements as a geographer, but treats the matter mainly from the historic standpoint, beginning with the Medes and Persians, and ending with Pottinger and Burnes and their contemporaries.

For the purposes of review we may divide the book into three parts. The first part—a quarter of the whole—deals mainly with what may be called the conjectural period of Assyrian and Persian and Greek. The second part—another quarter—is taken up by the Arabs; here the observer, describing country as wonderful as it is inaccessible to ordinary people, keeps conjecture subordinate to facts of observation. The third part, occupying nearly half the book, reviews the explorations and adventures of the modern European period; here facts predominate, and the romance of the story is of an individual kind.

We propose to give precedence to the second or Arab period, as this part of the book is the most original and certainly the most novel.

Everyone, of course, knows in a general way that Arab merchants and slave-dealers went everywhere—their footprints have been left all over Africa; Algerian slave-hunters even raided the coasts of Iceland once upon a time—but amid the alarums and excursions of historians and archæologists intent on Macedonian and Mogul invaders and Buddhist monuments, most people nowadays need to be told that "the whole of the Indian north-west frontier was much traversed by and thoroughly well known to the Arab trader."

Sir Thomas Holdich has much to say about these

old Arab caravan-routes and trade-centres, and much that is surprising to tell of the oblivion that has overwhelmed them. In Sind he has stood upon the site of an Arab city of which nothing whatever is left but traces of its cemetery. In the Helmund valley he has seen broken pottery "literally in tons"—the only remaining evidence of a vanished polity. In Central Afghanistan one may follow in the footsteps of the old Arab traders, with the story of their travels in hand, and may recognise the physical features of the road, but of the flourishing market towns that they mention there may be nowhere discernible "the faintest outward indication"—everything is now by Time's fell hand defaced. Only in southern Baluchistan did the author find, besides pottery and graves, undoubted ruins of cities and huge masonry dams that once held water-supplies.

The mediæval Arab traders used two main systems of communication, one through Herat and Afghanistan to Kabul and Afghan Turkestan, the other through southern Baluchistan (Makran) to the lower Indus valley. The routes of both systems are followed out by the author, and are illustrated by most excellent maps. In the account of the northern routes there are some short but interesting descriptions of those parts of the country that are least generally known. Something is said of Seistan, "the great central basin of Afghanistan, where the Helmund and other Afghan rivers run to a finish in vast swamps, or lagoons." The author speaks of it as a flat, unwholesome country, with remains of a really fine system of irrigation, and thinks that it does not justify its olden reputation as the granary of Asia. It must be remembered, however, that the Babylonian country, which in the time of Herodotus was by far the most fruitful known, and where the millet grew to such a height that Herodotus, though he well knew it, would not mention it lest it should appear incredible, does not at the present time justify its ancient reputation. Incidentally we also learn that Zamindawar, to the north-east of Seistan, and also watered by the Helmund, is a prolific region; that in northern Afghanistan the economic value of the Murghab river is still great; and that much of Afghan Turkestan is rich in agricultural possibilities. The author thinks that some of these "roads of the old khafila travellers may again be the roads of modern progress"; and he extols the route from Kabul and Ghazni to the Helmund as one of the "grandest high-roads in Asia, from the days of Alexander to those of Roberts."

The chapter on the "strange land of Makran"—the land of Gedrosia, where Alexander discovered that a trackless and waterless desert under a burning sun was an enemy against which even his unconquerable energy was impotent—is perhaps the most interesting and novel of the whole interesting story.

In days contemporaneous with the Heptarchy, the Arabs ruled Makran, and it was through Makran that they invaded India and conquered Sind.

"For three centuries there existed through Makran one of the great highways of the world, a link west and east such as has never existed elsewhere on the Indian border, save, perhaps, through the valley of the Kabul river and its affluents."

This highway ran about fifty miles north of the Makran coast that proved so disastrous to the Macedonian army, and behind the successive ranges of hills that face that coast. The author thinks that it may yet develop into a line of railway between India and Europe, particularly as it would enjoy the unique advantage, from a British point of view, of command and protection from the sea.

We get glimpses of some of the natural wonders of the Makran coast that almost remind us of pages of Hakluyt; submarine mud volcanoes, weird and fantastic strata, piles of sea-shells on upraised mud-flats, desiccated forests with the trees waiting to be fossilised as they stand; stiff, straight, spurless ranges of hills lying east and west like parallel lines of ramparts, with long, narrow, flat-bottomed valleys between them; and the curiosity of the archæologist will be whetted by allusions to ruined cities and tombs and gigantic irrigation works.

The interest of the latter half of the book is of quite a different kind. We now shake off the fascination of a dim storied past, and come face to face with the facts and political intrigues of the nineteenth century. Here we find an abstract and brief chronicle of the adventures of Christie and Pottinger, of the extraordinary Masson, of Lord and Wood, of the ill-fated Moorcroft, of Burnes, of Vigne, of Broadfoot and of Ferrier.

The author remarks, as a strange fact, that we are indirectly indebted to Napoleon Buonaparte and his nefarious designs on India for these early explorations of Afghanistan. On the same chain of causes, we may note in passing, hang the discovery of the Rosetta stone and the key to the arcana of ancient Egypt. Thus do we by indirections find directions out, and thus he that increaseth sorrow sometimes increaseth knowledge.

The author thinks nobly of his predecessors in the exploration of the gates of India. As explorers he calls them "magnificent." He in no way approves the opinion that their work is superseded, and he is inclined to doubt whether the superior mechanical equipment of the modern explorer altogether balances the superior methods of the pioneers who lived among the people, adopted their dress, ate their salt, and talked their "shop."

A few words may be said about the first part of the book, which contains, *inter alia*, an introduction and an account of Alexander's invasion of India. Here we think that the author hardly does himself justice: there is too much conjecture, not always relevant, and there are some statements and rather airy assertions that are hard to accept. For instance, the delightful history of Herodotus, which was written to the point of intent that the great and wondrous deeds of men might not be effaced by time, is referred to, almost barbarously, as a "geographical treatise," and, worse still, as a "gazetteer." Again, on p. 13, there is an extraordinary assertion about sailors and geography. If we have not misinterpreted it, it implies, if it does not actually assert, that sailors are not of much account as geographers. Now, among the things that we have kept from our youth up—and we fancy we are not singular in this respect—is a firm belief

that the greatest of all geographers were sailors, and we venture to adduce the names of Magellan, Columbus, Drake, Baffin, Davis, Hudson, Cook, Franklin, Ross, and McClintock in support of it, not to mention any names of those now living. Once more we demur to the use, in any literal sense, of such metaphorical expressions as "early Persian Department for geographical intelligence." The early Persian expeditions that we know anything about—namely, those against Greece—relied on spies and on guides picked up at the moment. Finally, where so much is said about Greeks and Alexander one is disappointed to find the famous Macedonian pike (*sarissa*) disguised as "*sarina*"; and *ballistæ* and *cata-peltæ* (did Macedonians use the Roman *ballista*?) translated as "mounted infantry and artillery"; and Nearchus appearing now (correctly enough for those who like that fashion) as *Nearkhos*, and now (to suit no fashion) as *Nearkos*. In the case of a name like Nearchus, the free and easy fashion approved by Mr. Tony Weller is hardly to be commended. These things are blemishes which we should not care to remark if the book were not so good and so fresh in its essentials.

GENERAL BIOLOGY.

Allgemeine Biologie. By Oscar Hertwig. Dritte Auflage. Pp. xviii+728. (Jena: Gustav Fischer, 1909.) Price 16 marks.

IN the review of the second edition of this work, which appeared in this journal in 1906, it was pointed out that for any single man to undertake to give a circumstantial and critical account of the numerous problems of modern biology, and to support his conclusions arrived at by a sufficient record of the facts on which they are founded, is too stupendous a task, and one which certainly cannot be adequately carried out in a single volume. The third edition of Dr. Oscar Hertwig's book follows soon after the second, and it is to be inferred that it has been useful to a large circle of readers in Germany and elsewhere, though it has not attracted so much attention in England. It is doubtful whether the third edition will be more successful in this country than its predecessor. It is enlarged by the addition of eighty pages, and the illustrations in the text, which are well chosen and for the most part admirably executed, have been increased in number from 371 to 435.

Dr. Hertwig is a lucid writer, and has a style which attracts the reader and carries him easily through many difficult places, but in almost every chapter he leaves a certain sense of disappointment. There is a vast amount of information, and the argument is clear, and in many places convincing, but the detail is insufficiently worked out. This, perhaps, is no great fault in a text-book, if such information as is given is founded on the best and most recent authorities, and the references to literature are sufficiently full and up-to-date. But it cannot be said that this is always the case. To take some examples,

the author informs us in the preface that the sections on the maturation divisions of the germ-cells, on natural and artificial parthenogenesis, on hybridism and the biogenetic law, have been largely re-written and revised in this edition.

In the section on the maturation divisions we are disappointed in finding that the discussion turns mainly on the phenomena observed in *Ascaris*. The work of vom Rath, Rückert, and Korschelt is also dealt with, but there is no mention of Farmer and Moore's important papers on the Maiotic phase in animals and plants, and their papers, which surely are old enough to be incorporated in a text-book published in 1909, are not even quoted in the list of literature. The section on natural and artificial parthenogenesis is more satisfactory, as a fair summary is given of the more important experimental researches on this subject up to the year 1908. The discussion of the results is, however, somewhat unconvincing.

Mendel's law, which was ignored in the second edition, is concisely dealt with in the latter half of chapter xiii. Here only a few simple cases are quoted to illustrate Mendelian principles, and no discussion of more complicated and unconformable cases is attempted. As in many other parts of the book, the experiments of Continental authors are quoted, but the large amount of English work on the subject is not taken into account.

Dr. Hertwig is quick to take advantage of the results of Mendelian work in support of his own theories of inheritance, but it is not always easy to understand in this connection, as in many others, what his real opinion is. It might be described, in Mendelian terms, as a polyhybrid of several theories promulgated by different authors; and sometimes one is inclined to think that, under stress of argument, his system resolves itself, by a process of segregation, into its original elements. He maintains, as he was one of the first to assert, that the chromosomes are the bearers of the heritable qualities of the organism, and it may be said in this connection that he disposes too easily of the evidence furnished by Crampton, E. B. Wilson, and others, that specific organ-forming materials are located in the cytoplasm of the egg. But while admitting the existence of a nuclear idioplasm, he will have nothing to do with Weismann's theory of biophors and determinants, but holds with Nägeli that the idioplasm has a micellar structure, and that it is distributed equally to every product of cell-division. None the less, he speaks of particles (*Teilchen*) which are bearers of inheritable qualities, and comments on the fact that Mendelian experiments show that these particles must be mobile and capable of forming new combinations. Hence, he says, it is clear that the chromosomes cannot retain their individuality, but must be regarded as tactical combinations of smaller units. Few will be disposed to quarrel with this conclusion, but it is not obvious wherein these "smaller units," capable of entering into tactical combinations, and representative of the specific or racial characters (*Merkmale*) of the adults, differ from Weismann's determinants.

Here, as in several other places, Dr. O. Hertwig appears to be inconsistent, but it would be an injustice to press this charge of inconsistency too closely. He is a champion of an epigenetic theory of development, and argues with admirable clearness in favour of the view promulgated at the same time by Driesch and himself, that the destiny of any given cell in a developing organism is a function of its position. At the same time, he brings into account the indisputable fact that the characters of the organism, and therefore of the cells composing it, are determined beforehand by the constitution of the fertilised ovum from which it is derived. In other words, he admits preformation, but preformation tempered by the mutual interaction of parts and the influence of external conditions.

There are many indications that the impartial position adopted by Dr. O. Hertwig is the right one, and, after all, it is the position taken up by Darwin, who wrote that "there are two factors, the nature of the organism, which is much the more important of the two, and the nature of the conditions." But latterly opinion has been sharply divided on these questions, and to partisans of the preformationary or epigenetic schools any attempt to reconcile such apparently irreconcilable theories exposes the author to the charge of inconsistency. In truth, it is very difficult to draw certain conclusions from the available evidence, much of which appears to be contradictory. It is the chief merit of Dr. Hertwig's work that he refuses to take extreme views, and no better exposition of the middle position can be found than is contained in this volume.

COMMERCIAL ORGANIC ANALYSIS.

Allen's Commercial Organic Analysis. A Treatise on the Properties, Modes of Assaying, and Proximate Analytical Examination of the Various Organic Chemicals and Products employed in the Arts, Manufactures, Medicine, &c. Fourth edition, vol. i. Edited by Dr. H. Leffmann and W. A. Davis. Pp. x+576. (London: J. and A. Churchill, 1909.) Price 21s. net.

THE first volume of the last edition of this well-known treatise was issued in 1898, and was remarkable for the introduction of two features, which have become the most striking characteristics of this first volume of the new edition. These are the recognition of the fact that the subjects to be dealt with are so numerous and important that a single compiler can no longer cope with them, and that in publishing a large and important work of this kind in English it is desirable to endeavour to meet the needs both of readers in this country and in the United States. This latter consideration is a very important one, and it is to be hoped that its recognition will facilitate the re-publication of other large works of reference in English.

This volume is divided into ten sections, and each of these is written by an expert in that branch. It will be a matter of satisfaction to those familiar with "Allen" to find that in bringing the subject-matter

up to date it has been possible to retain the old arrangement. The introduction is written by the English editor, Mr. Davis, and shows perhaps less change than most of the other sections, the most important additions being useful chapters on (1) refractometers, (2) spectrometers and spectrographs, and (3) the determination of moisture, "crude fibre," and ash, all these being of sufficient general importance to warrant their discussion in the introduction. This section is, on the whole, a very satisfactory piece of work, though it is rather doubtful whether it was worth while to devote about three pages (53-6) to an illustrated description of an arrangement for maintaining a temperature constant to within a few thousandths of a degree, since the commercial analyst is not likely to want refinements of this description in practice. Further, the space devoted to the "Employment of Immiscible Solvents" (pp. 79-82) might have been much curtailed, as the present-day analyst is probably perfectly familiar with the separating funnel and its use. The table at the end of this section is reprinted from the third edition, and should have been omitted, as it is too general to be of any value, and moreover, contains the inaccurate statement that cantharidin, picrotoxin, and santonin are glucosides. It is also a mistake to refer to "saponin" as if this were a single definite substance.

Dr. Leffmann, the American editor, contributes two sections, the one entitled "Neutral Alcoholic Derivatives," and the other, not very happily named, "Acid Derivatives of the Alcohols."

Notable additions are the very useful article on "Yeast" by Mr. Emil Schlichting, and the excellent section on "Papers and Paper-making Material" by Mr. Sindall. Mr. G. C. Jones contributes the sections on "Alcohols" and "Wines and Potable Spirits." Both these seem to contain all the data an analyst is likely to need, but in the second section something might have been said regarding the analytical work on rum carried out in recent years in Jamaica and British Guiana.

The remaining sections are those on "Sugars" and "Starch and its Isomerides," both written by Dr. E. F. Armstrong. In the main, these are excellent *résumés* of the present position of the chemistry of these subjects, and the omissions are of a trifling character. In the first some reference should have been made to the detection and estimation of such glucosides as salicin and strophanthin, used in medicine, but possibly it is intended to deal with these under "Drugs" in a later volume. Under "Starch" no mention is made of the analytical characters of the "sugar substitutes" that are now prevalent in commerce. The article on gums in this section is little more than a replica of that in the third edition, and it is unfortunate that the author did not take the opportunity of correcting the errors in it.

The book as a whole is very well edited, but there are a few curious mistakes; thus in three places the name of one of the authors is written "Schlichting" and in the fourth and most important place, viz. at the head of his contribution, it is given as "Schlighting." The heading of one section is printed

as "Starch and Isomers" in the list of contents, and as "Starch and its Isomerides" above the text of the section itself. Finally, the book is described as "printed in America." Printers in the United States do not apparently believe that "the whole is greater than its part."

T. A. H.

TROPICAL CLIMATOLOGY.

Handbuch der Klimatologie. By Prof. Julius Hann. Band ii., Klimatographie. 1 Teil, Klima der Tropenzone. Dritte, wesentlich umgearbeitete und vermehrte Auflage. Pp. xii+426. (Stuttgart: J. Engelhorn, 1910.) Price 14 marks.

THIS is the first part of vol. ii. of the third edition of Prof. Hann's "Handbuch der Klimatologie." Vol. i. dealt with general principles, and we now come to the detailed consideration of the climates of different parts of the world. The volume before us concerns itself with the tropics, the consideration of temperate and polar regions being reserved for subsequent volumes. The author has not confined himself strictly to the area lying between $23\frac{1}{2}^{\circ}$ north and south of the Equator. When desirable he has gone outside this region. Roughly speaking, he discusses that portion of the earth's surface which has an annual mean temperature of 20° C. or above. The isotherm of this value may be taken as marking the polar limits of the trade winds, when definable, and of the palm tree.

A great part of the book is taken up with tables, interspersed with descriptive paragraphs taken from the writings of travellers or residents in the regions under review. The tables refer for the most part to the elements, temperature, and rainfall, but where the data are available, tables of wind direction frequency, humidity, cloud amount, and pressure are added. The additional matter incorporated since the second edition appeared in 1897 is considerable. For some areas the author has had the advantage of consulting works such as Captain Lyons's "Physiography of the Nile Basin," but for others he has had to go into the byways of meteorological literature. The labour involved in collecting and working up the scattered fragments must have been prodigious even for so indefatigable a worker as Prof. Hann, and we can but admire and marvel at the thoroughness with which the task has been completed. Much time has been expended over the calculation of true means of temperature from daily extremes or from readings at fixed hours. Even so, Prof. Hann regards many of the values as still uncertain, but in the absence of adequate knowledge of the course of the diurnal variation, no more can be done at present.

The introductory chapter discusses the general characteristics of tropical climate. A special section is devoted to its physiological action on the human organism, particularly that of the white man, and affords an opportunity of referring to the recent advances in the domain of tropical medicine. After that we are introduced successively to West Africa and the Congo, East Africa with the Sudan, the monsoonal area of Asia and northern Australia, the Pacific islands, and finally to tropical America.

NO. 2120, VOL. 83]

OUR BOOK SHELF.

The Fourth Dimension Simply Explained. Edited by Prof. H. P. Manning. Pp. 251. (New York: Munn and Co., Ltd., 1910.) Price 1.50 dollars net.

THERE are few fallacies which have done more to mislead the unscientific public than the misconception known as the fourth dimension. The use of this term is calculated to convey the false impressions, first, that hypergeometry is limited to space of four dimensions instead of being extended to space of n dimensions where n is any positive integer; second, that even not going beyond four dimensions, there is one particular coordinate called the fourth dimension which stands out from the rest, and alone is worth considering.

Now so long as we regard four-dimensional space as a geometrical conception, there is no difference between its fourth dimension and its first, second, and third dimensions, just as in ordinary solid geometry there is no third dimension distinguishable in any respect from a first and second dimension. On the other hand, as soon as we introduce the concept of a fourth coordinate differing essentially from the other three, this coordinate ceases to be a geometrical conception, and may be taken to represent time, density, or anything else we like.

Some American who had some money to get rid of and had no better use for it offered, in the *Scientific American*, a prize of 25l. for the best popular explanation of the fourth dimension, and the present volume is a collection of selected essays that were submitted in the competition, with an introduction by Dr. Henry P. Manning. It must be admitted that what the authors have written is mostly sensible and reasonable enough, and in no way contradicts the remarks that have been made above. If the book had been brought out under the title "Hyperspace Simply Explained," and the titles of those essays where the words occur had been altered by the substitution of "four" for "the fourth," the utility of the book would have been considerably increased. It contains very little that can be described as unscientific.

Diagram showing the Classification of the Elements: Periodic Arrangement. Size 44×68 inches. (London: Baird and Tatlock, Ltd.) Price, mounted on cloth, rollers, and varnished, 25s.

THE "periodic" classification of the elements plays such an important part in courses of inorganic chemistry for students that a large wall diagram illustrating this classification has now become a prominent feature in the equipment of the chemical lecture theatres of colleges and technical institutions. Such diagrams have usually had to be prepared by the staff of the department concerned. Many teachers of chemistry will therefore welcome the issue of a large printed chart, suitably mounted on stout linen, giving the usual periodic classification of the elements with their names and atomic weights. The lettering is bold and clear, although, perhaps, a little wider spacing might have been allowed with advantage.

The chart fails to show, however, the differentiation of each vertical group into "odd" and "even" series. From a teaching point of view there is much to be said for placing the helium and argon group of elements before the alkali group and not after the halogens. The method of classification used for the iron-platinum group is perhaps not quite the most satisfactory one, though this is, of course, at present largely a matter of individual opinion. The chart as a whole would probably gain in clearness by replacing in future issues the names of the elements by their customary symbols.

Apart from the relatively minor points just mentioned, the chart will probably prove of considerable service to lecturers of chemistry by relieving them of the necessity of preparing the large diagram illustrating the periodic classification which is now essential for class teaching of chemistry.

Leitfaden der Biologie für die Oberklassen höherer Lehranstalten. By Dr. O. Rabes and Prof. E. Löwenhardt. Pp. x+248. (Leipzig: Quelle and Meyer, 1910.) Price 3 marks.

THIS book is intended for the use of pupils who have already had a certain amount of biological training in school. It covers a very great deal of ground in a very superficial manner, but in the hands of a capable teacher it should serve as a good foundation for an extremely interesting course of general biology. It commences, in what we conceive to be a very logical manner, with a general account of the cell, but the fact that this occupies less than one page is typical of the superficial method of treatment. A few unicellular organisms are then dealt with, chiefly from the physiological point of view.

The general physiology of multicellular organisms comes next, and the first part concludes with a description of seventeen types of plants and animals, ranging from bacteria to the bean in the vegetable series, and from *Paramœcium* to the rabbit amongst animals. The descriptions and illustrations of these seventeen types occupy twenty-six pages! The type system has become almost vestigial.

The second part of the book is devoted to the dependence of organisms upon their environment (œcology), including geographical distribution and an appendix on the geological history of plants and animals and the theory of descent. The third part deals with man, mainly from the physiological, ethnological, and palæontological points of view.

The book is very copiously and admirably illustrated, but four or five volumes of its size would be required to do justice to the subject-matter.

Tarr and McMurry's Geographies. The Five Book Series. First part, Home Geography. Pp. xi+112. Price 2s. 6d. Second part, The Earth as a Whole. Pp. ix+168. Price 2s. 6d. Third part, North America. Pp. xix+469. Price 4s. 6d. Fourth part, General Geography, South America and Europe. Pp. xvii+378. Price 3s. Fifth part, Asia and Africa. Pp. ix+214. Price 2s. 6d. By Prof. Ralph S. Tarr and Prof. Frank M. McMurry. (New York: The Macmillan Co., 1908, 1909, 1910.)

THE authors, who are well-known writers on geographical subjects from the point of view of the school, have evidently taken great pains to adapt themselves to the needs and capabilities of young pupils. On the whole, they have been successful in producing a good, workable course of school geography. Written primarily for American boys and girls, great prominence is given to the geography of the United States and less importance to that of the British Isles. When it is pointed out, however, that while 230 pages are devoted to the United States, the British Isles are disposed of in 35 pages, it will be seen that the volumes are hardly suitable for adoption as class-books in our schools. But they should prove of great assistance to our teachers in showing how geography may be taught in a way to arouse interest and develop thought. Every part is well and profusely illustrated with views, diagrams, and photo-relief maps. In addition there are numerous coloured political maps, but no use appears to be made of coloured orographical maps.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

Koch's Discovery of the Method of Plate-culture of Micro-organisms.

READING the interesting notice of Robert Koch which appeared in NATURE of June 2, I was reminded of an incident mentioned concerning his early scientific career in the preface to Cohnheim's "Gesammelte Abhandlungen." Cohnheim, the pioneer of what has been sometimes termed physiological pathology, died in 1884 at the early age of forty-five. The preface to his collected works, published in the following year, contains a charmingly written memoir of him from the pen of his friend W. Kühne, the accomplished Heidelberg physiologist. The obituary notice of Koch in NATURE rightly stressed the immense value to bacteriology of his invention of the plate-method for obtaining pure cultures of micro-organisms. The incident reported by Kühne in his memoir of Cohnheim has reference to that, and to Cohnheim's contact with Koch in consequence of it in the year 1875. At that time Cohnheim was already full professor of pathology in the University of Breslau, and his brilliance as an investigator was already attracting to his laboratory men of promise from all parts. Koch, on the other hand, was in country practice in Silesia, and quite unknown to the scientific world. Koch's discovery of the plate-method led to Cohnheim's discovery of Koch, and the enthusiasm and remarkable prevision at once shown by the young professor of pathology regarding his unknown compeer, only two years younger than himself, are strikingly told by Kühne. His words run:—

"In November, 1875, Robert Koch wrote begging Cohnheim, the celebrated botanist, Professor of Botany in the University, to look at cultures of anthrax bacilli which he (Koch) had prepared pure; and for that purpose Koch went to Breslau to see him. Cohnheim had had many tiresome and disappointing experiences of cultures of pathogenic organisms brought to him with the assertion that they were of pure and isolated species; in the present instance he naturally felt at first little confidence, but after interviewing Koch he sent a messenger to the Pathological Institute asking someone to come over because a visitor, Dr. Koch, had something to show which was 'quite right and very interesting.' In the Pathological Institute, Weigert, Cohnheim's assistant, was about to perform an autopsy; Cohnheim himself therefore went across to the Botanical Laboratory, and when he returned he said, 'Now leave off everything here and go over to Koch. The man has made a tremendous discovery, which for its simplicity and its accuracy of method deserves admiration all the more because Koch himself is living entirely remote from scientific intercourse, and has done it all by himself and finished it right out. There is nothing whatever to add to it.' I regard it as the greatest discovery in the whole field of bacteriology, and I believe Koch will surprise us all in times to come with further discoveries and put us all to the blush for our laurels."

Perhaps this picturesque reference to a turning point in Koch's earlier career, being contained in a volume little likely to be sought for information about him, might escape the notice of some whom it would interest, especially at the present time.

C. S. SHERRINGTON.

The University, Liverpool.

Crocodiles and Sleeping Sickness.

IN the obituary notice of Prof. Robert Koch in NATURE of June 2 (p. 404), it is stated that "Koch suggested that the crocodile might be the reservoir host of the trypanosome that gives rise . . . to sleeping sickness." This is a statement that has been made very often, especially in the daily Press, but which I, for my part, have never been able to verify, although I have some acquaintance with Koch's writings on the subject of sleeping sickness. Since this idea has been attributed so often to Koch, it is doubt

less safe to assume that there is some foundation for doing so, and I should be very glad to learn when and where Koch made the suggestion that the crocodile is a reservoir host for sleeping sickness. The point is merely one of historical and bibliographical interest, since in his latest writings Koch expressly repudiated the idea of any such connection between crocodiles and sleeping sickness (see NATURE, February 18, 1909, p. 458, and May 5, 1910, p. 279; also the Bulletin of the Sleeping Sickness Bureau, No. 11, November 5, 1909, p. 421, footnote).

E. A. MINCHIN.

Lister Institute of Preventive Medicine, Chelsea Gardens, S.W., June 8.

PROF. MINCHIN's letter comes as a reminder, so often repeated, and apparently not too often, that one should verify one's references. I had read a leading article in the *Lancet* of October 30, 1909, on the work of the German Commission, but I had not referred to the original report, and I am afraid that the statement that the *Glossina palpalis*, on occasion, takes its nutriment from the unprotected parts of the crocodile led me somewhat astray as to the exact significance of Koch's observations and recommendations. I am glad that Prof. Minchin has directed attention to the matter. My excuse must be that the article had to be in the hands of the editor within a few hours of my receipt of a re-directed telegram, and that I had to depend upon my memory for almost everything but a few dates and data which appear in "Wer ist's."

THE WRITER OF THE ARTICLE.

The Earth and Comets' Tails.

IN spite of the unreserved predictions of astronomers, the earth did not pass through the tail of Halley's comet on May 18-19, nor subsequently. The tail as seen in the morning sky, previous to the transit of the comet across the sun's disc, appeared like a long and straight beam of light stretching from the horizon to Aquila. It was noticed from day to day that the tail was practically fixed in position in the sky. We rather expected the tail to get nearer to Venus and Saturn as the comet approached the ecliptic, but it remained stationary. On the morning of transit, May 18-19, the tail was unchanged, but a second branch to the south was now noticed. It joined the northern branch to the east of the Square of Pegasus. Unfortunately, this southern branch was near the zodiacal light, and only distinguished from it with difficulty.

Both these tails were seen morning by morning, including this morning (May 22, Civil day), but they have diminished in brightness, and were difficult to see. Further observation of these will be impossible, because of the moon remaining above the horizon until after dawn during the next ten days. The whole eastern horizon where the tails meet and where the zodiacal light is was suffused with a dim and indefinite glow, which was particularly noticeable on May 18-19 and 20-21. This glow was not so definite in boundary as the zodiacal light. When the comet was seen on the evening of May 20 we were surprised to see it had the ordinary tail pointing away from the sun as usual. It had been noticed for several days that in the neighbourhood of the sun the sky was not so blue as usual, but this was the case even a week before the transit, and is probably merely a meteorological phenomenon. This brief summary of the facts will suffice here; the observations in detail will be published elsewhere.

We have now to explain the reason why the earth did not pass through the tail of the comet, and why the tail broke up so that some of it was left in the morning sky, where it remains, and is slowly losing its luminosity, and some (or another tail) appeared in the evening sky. It is well known that a comet under the sun's radiant action (I do not attempt to define it more closely) expels corpuscles towards the sun which the sun repels, and these luminous corpuscles form the tail. This process goes on even when (as in the case of Halley's comet) the distance between the comet and the sun exceeds the distance of the earth from the sun. If the nearer planets do not show tails it is because these corpuscles have been shed by the planets ages ago. In short, a comet and a planet under the radiant action of the sun, and the sun itself, all repel

these corpuscles. This being so, it is impossible for the earth to go through the tail of a comet—it simply repels the tail, and, as a consequence, instead of a passage through it, a disruption near the time of passage must occur, one part being left in the (in this case) morning sky, whilst a new one is developed in the evening sky. Here I may remark that on the evening of May 20 the measured length of the new tail was 19° , on May 21 32° , and on May 22 it was 40° .

Again, the earth is bombarded with meteorites, which are also throwing off corpuscles. These will be repelled by both earth and sun, so that if we look at the part of the sky opposite to the sun we should, and do, see the faint tail thus formed which is known as the Gegen-schein. This simple theory explains all the facts of observation, and, if it is correct, will save nervous individuals some worry when the next near approach of a comet's tail is imminent.

R. T. A. INNES.

Transvaal Observatory, May 22.

P.S.—Mr. H. C. Reeve, of Lorentzville, under date May 22, has sent me a letter conveying the same idea. He says:—"Whatever nature the stress between the sun and the comet may be which causes the repulsion of the tail . . . the same stress must also exist between the earth and the comet . . . under these circumstances the earth could not possibly pass through the comet's tail."

ON the morning of May 19, at between 4 and 4.30 a.m. standard Indian time ($5\frac{1}{2}$ hours from Greenwich), the tail of Halley's comet could be seen stretching as far as the Milky Way near Sagittarius, if not beyond. The tail was much fainter than it had been two or three days previously, but was still quite distinct.

In the constellation Sagittarius, however, a dark band, like a shadow, stretched diagonally right across the tail upwards from east to south at an acute angle of about 20° to 30° with the direction of the tail. The edges of the band were approximately straight and parallel, and the width of the band was perhaps two or three degrees.

No luminosity could be noticed within the band.

If, as seems probable, the tail was then entering into the shadow of the earth, it would appear that at any rate the major portion of the light of the tail was light reflected from the sun.

Government College, Lahore, Punjab, May 26.

The Term "Radian" in Trigonometry.

NATURE of April 21, containing Mr. Thomson's letter, has just reached me, and I hasten to say that, had I known that his father had ever claimed to have originated the word "radian" I should, of course, have mentioned the claim in my communication to NATURE of April 7. As a matter of fact, Prof. Thomson never did so in my presence, and he certainly knew shortly after he came to Glasgow that I had on my own initiative proposed the word, and had made use of it for some years. One day when I met him accidentally he told me that he had found a college student who had been a pupil of mine using the word "radial" for a unit-angle, and that, while agreeing with me as to the need of such a word, he had doubts as to the suitability of the terminal syllable. My reply, as may be guessed from my recent communication, was that "radial," "radian," "rad," had all something to be said for them, and I referred him to my letter to NATURE dated April 4, 1870. On at least two subsequent occasions we spoke of such things, and he supported the termination *-an* in this particular case, because of a supposed analogy with the geometrical term "median." All this, you will see, does not preclude the possibility of an independent origination of the term by him in July, 1871, as stated by Mr. Thomson, and I therefore regret that here there is no chance of me having the satisfaction of seeing the printed word in the Calendar of Queen's College, Belfast, for 1873-4.

May I direct attention to the fact that in justification of his letter Mr. Thomson unfortunately represents me as saying that it was in 1874 that "the word was finally adopted"? This is quite incorrect. If he will kindly

glance at my letter again, he will see that, speaking of the various forms which I had used or had under consideration during the preceding five years, I said that in that year (1874) "the form *radian* was definitely adopted by me." It is the words *form* and *by me* that here make all the difference.

The same mail steamer which brought Mr. Thomson's letter brought for delivery a few hours later a tattered copy of the third edition of Todhunter's "Plane Trigonometry," sent to me as evidence of a still earlier use of the word "*radial*" to denote the unit-angle in question. This text-book was the property of a pupil of mine in 1867, and it contains in my handwriting of that date the words " $1 \text{ radial} = 180^\circ/\pi$, $1 \text{ degree} = \pi/180 \text{ rad.}$ " When next in England I shall offer it for your own and Mr. Thomson's inspection.

THOS. MUIR.

Cape Town, South Africa, May 11.

I SHALL be very pleased to send Dr. Muir a copy of my father's examination questions of June, 1873, containing the word *radian*; and when Dr. Muir returns to England I should like to show him my father's copy of the "Imperial Dictionary" containing a note in his own hand saying that he had proposed the word in July, 1871. So far as I know, he did not meet Dr. Muir until he came to Glasgow in October, 1873.

It thus appears that *radian* was thought of independently by Dr. Muir and my father, and, what is really more important than the exact form of the name, they both independently thought of the necessity of giving a name to the unit-angle.

JAMES THOMSON.

22 Wentworth Place, Newcastle-on-Tyne, June 1.

The Nutritive Value of Black Bread.

IN the issue of NATURE for June 2 (p. 398) there is a letter from a correspondent in reply to the article on "The Nutritive Value of Black Bread." The correspondent points out that the writer of the article overlooked one all-important question, viz. how much of the nitrogen present in each form of bread is actually digested? In the original article the writer complained that misleading statements were made by some politicians during the last Parliamentary General Election with regard to German black bread. No doubt some of your readers expected to see a letter or two in reply to this complaint. There has not been one.

Now what are the facts with regard to German black bread? What the people of the United Kingdom care about is what their bread will cost. They do not care whether that bread, which the Germans themselves call "black bread," is black, or brown, or grey. The following are the prices obtained from a large bakery in the town of Elberfeld last December:—

Flour.

Description	Price per	
	14 lbs.	s. d.
Finest wheat flour	2	8
Wheat flour	2	5½
Best rye flour	2	1½
Ammunition flour	1	10
Coarse rye flour	1	9½

Bread.

Description	Price per	
	4 lb. loaf	d.
White bread, made with milk and wheat flour	9	3
Fine bread, made of wheat and water	8	½
Rye bread, pure	6	
Rye + wheat (½ wheat + ½ rye)	6	
Rye + wheat (⅓ wheat + ⅔ rye)	6	
Ammunition bread	5	½
Black bread	5	

From the above figures, which have never been challenged, your readers can draw their own conclusions.

Protectionists are most anxious to prove that rye bread is good, and they suggest that it is preferred to wheat bread. Free Traders never denied that rye bread was good. They stated that it was an inferior bread to wheat,

and that the chief reason for its use in Germany was its lower price in comparison with wheat bread. Rye costs less than wheat in Germany, and this is a proof that it is an inferior grain. The bread which is reckoned the finest bread is wheat bread, all the world over, and in the best hotels in Germany it is regularly served with all meals. On account of the duty the price of wheat bread is too high in Germany for working-class people, and they buy breads made from mixtures of cheaper grains, according to price. The "black bread" in Elberfeld is made from a very coarsely ground rye flour, and it is sold and spoken of as "black bread," although it is a very dark brown in colour.

FRED SMITH.

92 Halsbury Road, Fairfield, Liverpool, June 4.

It is assumed in the letter that the whole difference in price is due to the duty on wheat. But an examination of the figures given shows that the cost of the various breads is not closely proportionate to the price of the flours, and it would seem that the bakers take a much larger profit on the wheaten bread. Indeed, this must certainly be so unless the yield in bread from a given weight of rye flour is much larger than from a similar weight of wheaten flour, a point upon which no information is to hand.

THE WRITER OF THE ARTICLE.

The Recoil of Radium B from Radium A.

WHEN radium A is transformed into radium B, the process is accompanied by the expulsion of an α particle. It has been shown that in these circumstances the atom of radium B recoils from the α particle with considerable velocity, as is to be expected from a consideration of the momentum of the system.

Some experiments have recently been made to determine whether radium B is charged when it recoils, and, if so, to ascertain the sign of the charge carried by it. Measurements to determine whether the radium B was deflected when passing through an electrostatic field revealed the fact that at least some of the atoms of this product, on formation from radium A, carried with them a positive charge when projected through a high vacuum. Experiments were therefore made to measure the magnitude of the deflection suffered by the atoms of radium B when projected through an electric field at right angles to the direction of motion of the particles.

Now, since the α particles from radium A travel with a velocity of 1.77×10^9 centimetres per second, the recoiling atoms of radium B should have a velocity of 3.3×10^7 centimetres per second, on the assumption that the atomic weight of radium B is 214 and that of the α particle 4. The deflection to be expected when subjecting the recoil particles to a field of known strength can easily be calculated if it be assumed that each particle carries one atomic charge, or half that carried by an α particle. The results of the experiments to deflect the radium B in an electrostatic field were consistent with this theory of the phenomena, but the experimental difficulties were such as to prevent us, so far, from making very accurate determinations.

Before attempting to make these measurements with greater accuracy, it was thought of interest to investigate the deflection of radium B in a magnetic field. This has been done by Mr. E. J. Evans and one of us, and the results obtained show that when radium B recoils through a magnetic field the deflection suffered by the particles is of the size to be expected from theory.

Taken together, the results of the electrostatic and magnetic deflections of the atoms of radium B after recoil leave little doubt that the atomic weight of radium B is in the neighbourhood of 200, that this product carries with it on recoil a single positive atomic charge, and that the velocity of the particles is of the order of magnitude to be expected from considerations of momentum. It is, however, hoped that subsequent experiments may lead to a determination of these important quantities with accuracy.

Curve Tracing and Curve Analysis.

THE review of a book on practical curve tracing in NATURE of June 9 is tantalising to one who is not in the least interested in drawing the graph of an equation, but who is frequently plotting curves from experiment, and who would like to find formulæ, not only to fit them, but to explain them. I look through most of the reviews of mathematical books in NATURE in the hope of discovering one that deals with the practical analysis of curves, and I am continually disappointed.

Can no mathematician be induced to recognise that for some of us an equation is the end, and not the beginning, of a piece of work? In innumerable cases experimental work ends with a curve, such, for example, as a hysteresis curve, and no attempt is made to find an equation to fit it.

Half a dozen rules exist, the uses of log. and semi-log. paper can easily be explained, but nobody has gathered them together with explanation of the difference between empirical formulæ and rational equations, of interpolation, smoothing, and of the legitimacy of extrapolation.

London, June 9. *aidt* A. P. TROTTER.

A Brush for Collecting Mercury.

SINCE more or less mercury is always spilled around the laboratory, a simple and efficient mercury collector is of great use. I have found a very good one, and, since I have not seen it in use before, I will describe how it is made.

It is made like a paint-brush, with the difference that $\frac{1}{40}$ copper wire is used instead of camel's hair in the brush part. The fine copper wire is then amalgamated with mercury. Use the brush as though painting with it. It will take up large globules and go into cracks and collect the smallest particles, so that none need be lost. Use a cup when collecting, and when the brush is full shake the mercury into the cup.

LIGHT ALLOYS.

THE problem of producing an alloy which shall combine great strength with a low specific weight has been before metallurgists ever since the commercial manufacture of aluminium became an accomplished fact; more recently, however, the requirements, in the first place, of racing yachts, then of motor cars and of motor cycles, and, finally, the pressing problems of aerial navigation, have added a rapidly increasing importance to the whole question. At the present moment German manufacturers particularly are putting forth claims in regard to achievements in this direction which appear startling at first sight, and it is interesting to examine the whole state of the question.

The need for a light alloy lies in the fact that pure or nearly pure aluminium is, unfortunately, very weak mechanically. Its low specific gravity ($2\frac{7}{11}$) is more than counterbalanced by the fact that its tensile strength, even in the form of rolled bars, does not exceed 7 tons per square inch. If these figures are compared with those of the best special alloy steels suitable for structural purposes, we find that some of these show tenacities up to 64 tons per square inch, with a density of approximately 7.9. Consequently, a bar of aluminium, to bear the same ultimate load as a bar of such steel having a cross-sectional area of one inch, must have a sectional area of approximately 9 square inches, and would therefore weigh about three times as much as the steel bar. A light alloy which is to compete successfully with such special steels, therefore, must either be much lighter than pure aluminium or it must combine with the density of aluminium a tensile strength of 21 tons per square inch.

NO. 2120, VOL. 83]

So far as alloys consisting principally of aluminium are concerned, it does not appear that this tensile strength has ever been attained, except in the case of hard-drawn wires the ductility of which has been reduced to an excessively low value. It must, however, be borne in mind that the high-tension steels referred to above cannot be employed in excessively thin sections, so that in many special cases, where the scantling of structural parts cannot be reduced to minute dimensions, while the strength required is not very great, light alloys may be employed with advantage as compared with alloy steel. The same argument applies, however, to a comparison made on similar lines between light alloys and the stronger kinds of wood. These woods are all considerably weaker, per square inch of sectional area, than the light alloys now available, but when their much lower density is taken into account, as well as the advantage of larger scantlings, the result must in many cases be favourable to the employment of wood. It is for this reason that the frames of most aeroplanes are constructed of wood. When, however, an alloy of density less than 3, and possessing a tensile strength of more than 20 tons per square inch under conditions allowing of a ductility equivalent to an extension of not less than 15 per cent. on a 2-inch test-piece, becomes available, its employment will become advantageous as compared both with the best alloy steel and the best wood.

The light alloys available at the present time are somewhat numerous, and, as regards those of them which are patented or otherwise proprietary articles, it is difficult to obtain satisfactory data; it is certain, however, that extravagant claims are often advanced for such alloys, and these are not verified when samples are tried in a testing machine.

The claims of those advertising or selling such alloys must therefore be looked upon with much reserve.

Among the earlier alloys of aluminium which found a certain amount of practical application were those with iron and with nickel. One of the racing yachts engaged in one of the later races for the America Cup was built of plates rolled from one of these alloys, but the metal suffered from excessively rapid corrosion, and the presence of iron in aluminium alloys, although it undoubtedly confers considerable strength upon them, is rightly regarded as extremely undesirable. At the present time, the most completely studied of the light alloys are those in which copper is incorporated with the aluminium, either alone or with the addition of other elements, such as manganese. In the form of rolled bars and sheets, these alloys attain a tensile strength of slightly more than 17 tons per square inch, with an elongation of 15 per cent. on 2 inches; these figures apply almost equally to alloys containing about 4 per cent. of copper alone, or to those containing 3 per cent. of copper and 1 per cent. of manganese, or 2 per cent. of copper and 2 per cent. of manganese, the specific gravities of all these alloys lying close to $2\frac{8}{11}$. So far as trustworthy data are available, these figures probably represent the best available alloys of this character. Alloys of aluminium with from 15 to 20 per cent. of zinc may possibly yield somewhat higher figures, but, owing to the presence of a considerable proportion of zinc, their density is also much higher, so that they can hardly be classed among the light alloys.

The light alloys at present employed in practice are principally used in the form of more or less complicated castings, such as motor-car engine crank-cases, the corresponding parts of aerial motors, and similar purposes. When thus used the alloys cannot be compared with special alloy steels, and still less with wood, and they hold the field quite easily against cast-iron, brass or bronze of any kind. For these

purposes, hardness rather than ductility is desired, and alloys containing rather more than 4 per cent. of copper, or the corresponding amount of manganese, can be employed. The casting of these alloys presents some difficulty, but a considerable number of foundries are able to produce castings of this kind with regularity; the secret of their success lies largely in casting the alloy at a suitable temperature, and in the preparation of a mould having a hard and very dry surface. All the alloys of this class undergo a comparatively enormous amount of shrinkage in passing from the totally liquid to the totally solid condition, and unless due allowance is made for this contraction, faulty castings always result.

In the case of the aluminium-zinc alloys, a difficulty of another kind arises; while these alloys are less viscous when molten, and flow into the moulds more freely than the aluminium-copper alloys, they are very weak and brittle while hot, and castings made of these alloys are very apt to crack while cooling if their contraction is opposed to any considerable extent; it is probably on this account that these alloys have acquired the reputation of being "treacherous." They have, on the other hand, been employed with some success for the production of so-called "die castings." These castings are produced by means of metallic moulds, and can be made so accurate that no machining is required even for such objects as screw-threads and certain parts of instruments. On the other hand, these alloys are said to be weak under vibration, but this statement as yet requires confirmation by systematic investigation.

The question of the power of light alloys to resist corrosive influences is one of considerable importance; it has been generally accepted by those accustomed to deal with aluminium and its alloys that the pure metal is much more resistant to corrosion than any of its alloys, and, as regards some of these, this view is undoubtedly correct. The numerous "solders" which have been advocated for jointing aluminium and its alloys all suffer very seriously from this point of view. It must, of course, be borne in mind that aluminium itself has a powerful affinity for oxygen, and only protects itself from rapid atmospheric oxidation by the formation of a very thin coating of oxide on all exposed surfaces; if this coating is ruptured, as, for instance, by friction, continuous oxidation results, and the presence of an alloyed element in the form of a distinct constituent may cause such interruption. Again, the contact of aluminium with another metal, in the case of all those metals usually met with in engineering construction, leads to the formation of galvanic couples, and the consequent rapid corrosion of the aluminium. In this way also an alloyed element may intensify corrosion. On the other hand, it is equally possible that the presence of an alloyed metal may improve the protective coating of oxide formed on the surfaces of the metal, and there is good reason to believe that the presence of copper produces this effect to some extent, while the presence of manganese—as has recently been shown—facilitates the formation of a surface "patina" containing manganese oxide as well as alumina.

Even in the best circumstances, however, the protection of light alloys from corrosion is a most important matter, and this is accentuated by the difficulty of finding a suitable paint or varnish the constituents of which do not act upon aluminium—an action which generally takes the form of an interchange of oxygen between the pigment and the metal. Processes for coating the light alloys with a less corrodible metal, such as copper, tin, zinc, &c., have been tried, but these modes of protection are accompanied by the risk of an increased amount of local corrosion owing to galvanic action, if the metallic

coating is anywhere broken through. A more hopeful line of thought is to be found in the development of processes for coating the alloys with an adherent layer of some inert compound of aluminium, much as iron and steel are coated with a layer of phosphate of iron in the "Coslettising" process.

Finally, some reference may be made to the possibilities of the use of magnesium and its alloys for the production of light and strong materials of construction. The fact that magnesium has a specific gravity of only 1.74 at once suggests its use for such a purpose, but the fundamental objection lies in the fact that it is much more corrodible than aluminium, and that therefore the attainment of even moderate durability in its alloys must be a problem of much difficulty. That some solution of this problem may have been found is suggested by the statement recently made that the newest German Zeppelin airship is to be constructed of an alloy known as "Elektron," said to be an alloy of aluminium and magnesium. Its density is stated as being close to 1.7, so that it must clearly consist of magnesium alloyed with only 1 or 2 per cent. of aluminium. No data as to the strength of such an alloy are available, but from the known constitution of the alloys of the aluminium-magnesium system, it appears probable that the addition of aluminium to magnesium in proportions up to 7 or 8 per cent. will materially increase the strength of pure magnesium, but the actual results cannot be predicted; it is, however, probable that pure magnesium is rather weaker than pure aluminium, so that it would be surprising to find in this group an alloy having a density less than 1.8, with a tensile strength above 10 or 12 tons per square inch. Alloys of aluminium with small proportions of magnesium are, it may be mentioned, in somewhat extensive use, particularly for certain parts of scientific instruments, under the name of "magnalium," but these alloys, although somewhat lighter, are not so strong as the best of the aluminium-copper and aluminium-copper-manganese series.

From the foregoing review of the question it will be seen that the problem of light alloys is still far from a satisfactory solution, and that there is a need for further systematic study of the alloys of the lighter metals.

WALTER ROSENHAIN.

GREEK ARCHÆOLOGY.¹

THE "Annual of the British School at Athens" still remains of the somewhat unwieldy size that it has assumed of late years. A return to the more convenient bulk of, say, vol. viii. would be welcomed by the reader; yet it cannot be said of any of the articles in vol. xiv. that any part of them might profitably have been excised. Only the fourth instalment of Dr. Mackenzie's work on "Cretan Palaces" seems rather too long. Still, no doubt the various questions raised by Dr. Dörpfeld's criticism of Dr. Mackenzie's former articles, Dr. Noack's work on Cretan buildings, and the discoveries of Neolithic prototypes of the "Homeric" palace in Thessaly, needed exhaustive treatment. So we are compelled to postpone reading Dr. Mackenzie's views on the relations of the Homeric house to the Cretan palaces until next year.

The director of the school and his assistants continue their account of the discoveries at Sparta, which have conferred such lustre upon British archaeological work during the last three years. Few believed that excavations at Sparta would prove so interesting.

¹ "The Annual of the British School at Athens." Vol. xiv. (Session 1907-8.) Pp. x+468; 15 plates. (London: Macmillan and Co., Ltd., 1909.) Price 25s. net.

We assumed too hastily that the rude, countrified Lacedæmon of the prejudiced and tendentious Athenian historians whom we are taught at school to accept as infallible would yield little or nothing of interest to our spades. Yet the excavations of Messrs. Bosanquet and Dawkins and their helpers have shown that early Sparta was in no way behind other Greek cities in art and civilisation; and we remember that in Homeric days Lacedæmon was a lordly house of princes, while Athens was nothing at all. The excavations of 1909, which are not treated in this volume of the "Annual," have revealed to us the scanty remains of the old Mycenæan civilisation of Sparta, at the Menelaion, the heroön of Menelaos, on a hill some two miles distant from Sparta itself, on the opposite bank of the Eurotas. We await with interest the publication in the next "Annual" of these discoveries. The volume before us deals chiefly with the continued excavations of the temple of Artemis Orthia, which have resulted in the discovery of the most primitive shrine on the site, which dates from the eighth century B.C. Geometric pottery found beneath its floor shows that the place was sacred at an earlier date, but no Mycenæan sherds prove a history going back into the Bronze age. The geometric sherds lie on virgin soil, and the sanctuary was evidently a new one, established by the Dorians.

The great quantity of pottery found has enabled Mr. Droop to construct a scheme of the development of Laconian pottery from its first stage, immediately succeeding the Geometric, to its latest. The identity of the Laconian style with that hitherto known as "Cyrenian" is proved.

Prehistoric archaeology is represented in this volume by two articles by authors who disagree with one another. M. Vassits, the curator of the Belgrade Museum, writes a somewhat inconclusive article on "South-eastern Elements in Prehistoric Servia," in which he claims, reasonably enough, that the Ægean culture must have sent forth a stream of influence which passed up the Vardar valley into the Danubian basin, but does not bring forward much positive evidence of importance to confirm this probability. Messrs. Wace, Droop, and Thompson contribute an account of their very important excavations in Thessaly, which have put into their proper perspective the previous discoveries of Sotiriadis in Bœotia, and Tsountas in Thessaly, and have shown that in early times northern Greece possessed a peculiar art and culture of its own which was very little affected by Ægean influence. We say "very little"; the authors would say "not at all," but without much probability. Mr. Wace and his colleagues have discovered that in northern Greece a Neolithic culture continued to exist until long after the Ægean had reached the full flower of the Bronze age; and that the Thessalian contemporaries of the Minoan Cretans were stone-using barbarians. Then, brushing aside the few traces of Ægean influence on this barbaric culture (such as the rude spiral ornament in the Dimini pottery), they assume that the North-Greek and Ægean contemporary cultures had no connection with one another, and were absolutely independent, not only in origin, but until suddenly the higher culture broke down the lower in the latest Minoan age. It is obvious, however, that this is impossible. The Ægeans were active seamen, and it is incredible that Ægean influence should not have affected the Thessalians, conservative though they were, from the beginning; and, at the same time, that the Ægean influence should not have affected the north coast of the Ægean Sea and have penetrated up the Vardar valley, as M. Vassits says it did, and have greatly influenced the Danubian Bronze-Age civilisation. We believe that

the independent North-Greek Neolithic and Chalcolithic "culture" was no bar to this, and that itself it was much more affected by the Minoan culture than its discoverers believe. For us, then, M. Vassits and Mr. Wace are both right.

The great importance of the Thessalian discoveries for the history of the origin of European civilisations is evident. It has never seemed to the present writer probable that the changes from the age of Stone to that of Metal, and from the age of Bronze to that of Iron, each necessarily took place at about the same time all over the European and Mediterranean world; iron, for instance, seems certainly to have been used sporadically by the Egyptians as early as the time of the fourth and sixth dynasties, about 3000 B.C., whereas even in southern Europe it does not appear much before 1000 B.C.; and now we see the same thing in this case of the continued use of stone, for long exclusively, by a large community in northern Greece down nearly to 1300 or 1200 B.C., and contemporaneously with the existence, but two hundred miles off, of the head centre of the splendid Bronze-age civilisation of Minoan Crete. We are again reminded that, though nature *nihil facit per saltum*, human activity does progress in precisely this haphazard way. Our archaeologists, too much under the influence of the professors of natural science, have assumed that the evolution of human progress was far more even and equable than actually was the case.

The Greek sculpture of the later period takes up less space in this year's "Annual" than in that of last year; there is only one short article by Mr. Wace on an interesting Pergamene head found at Sparta.

Prof. Burrows and Mr. Ure contribute an account of their excavations in tombs at Rhitsóna (Mykalessos), which have produced large quantities of pottery of the classical period; and there are interesting articles by Mr. Hasluck on the topography of Laconia, and by Mr. Hogarth on Hierapolis Syriæ, the ancient sanctuary between Aleppo and the Euphrates, otherwise called Bambyke or Mabog, the modern Mambij. Mr. Hogarth publishes several fragmentary Greek and Latin inscriptions and graffiti of Roman days from this ancient holy place.

H. R. HALL.

GOATS AND MALTA FEVER.

A QUESTION asked in the House of Commons on June 13 illustrates the desirability of members of Parliament becoming familiar to some extent with scientific facts before concerning themselves with subjects in which such facts are involved.

The question was in regard to the part played by the goat in the spread of Malta fever, and arose out of a misreading of the evidence given before the Royal Commission on Vivisection (Q. 14,242). The question asked was to the effect that, seeing no goats had been infected by the alleged Malta-fever germ, and that it did not give rise to any ill-health or fever in these animals, why spend money on any inquiry regarding the part played by goats in Malta fever?

The evidence given before the Royal Commission was that the goats did suffer from this disease, that the micro-organism did multiply in their bodies, but that it did not give rise to any appearance of ill-health or rise in temperature. It is this that makes the goat so dangerous. If Malta fever caused high fever and the other symptoms of a severe disease in the goat, as it does in man, the goat would probably cease to be a danger. The animal would be confined to its stable, and its milk would run dry. As it is, the goat which acts as a source of the virus of Malta fever continues to accompany the herd into the town or village, appears the picture of health, and secretes quite as much milk as its harmless neighbours.

This is a matter of great practical importance, since the Maltese themselves refuse to believe that Malta fever is milk-borne, although the Commission sent out in 1904-5-6 to investigate the disease proved this up to the hilt. Since then the Maltese have been exporting their Malta-fever-carrier goats, and spreading this serious human disease far and near. That this should be permitted would seem to be beyond belief, but, looking nearer home, we must remember that our own milk supply is not quite free from the tubercle bacillus.

The American Government attempted to import Maltese goats in 1906. The drinking of the milk of these gave rise to an epidemic of Malta fever on board the vessel which conveyed them from Malta, and a woman in the quarantine station in America became infected. The sequel to this story is told in a recent report of the Board of Agriculture of America. The goats remained under strict quarantine and inspection for some two years, those showing marked infection with Malta fever being slaughtered from time to time. The result is that all the animals imported have been slaughtered—even the kids born in America—not a single animal could be saved, on account of Malta-fever infection.

This disease is becoming more widespread every year. Last year the Sleeping Sickness Commission of the Royal Society discovered an epidemic of it affecting a large part of the native population round the shores of Lake Albert Edward, in the south-west corner of Uganda, and the native goats in that out-of-the-way place were found to be the carriers, just as in Malta.

In regard to the result of forbidding the use of goats' milk to the sailors and soldiers in Malta, it cannot be too often repeated that this simple order at once led to the extinction of the fever in the garrison. This does not, of course, refer to the native population, among whom the incidence of the disease is as great as ever. In 1905, before the preventive measures came into operation, there were 643 cases in the Army alone; in 1906, 147; in 1907, 11; in 1908, 5; in 1909, 1; in 1910, 0.

THE KING AND THE ROYAL SOCIETY.

AMONG the addresses received by the King at St. James's Palace on June 9 was one from the Royal Society, which was presented by a deputation consisting of Sir Archibald Geikie (president), Sir Andrew Noble (vice-president), Mr. A. B. Kempe (treasurer and vice-president), Sir Joseph Larmor and Prof. J. R. Bradford (secretaries), and Sir William Crookes (foreign secretary), with Mr. R. Harrison (assistant secretary) bearing the mace.

In the course of the address it was stated:—

We are proud to remember that no less than forty-seven years ago King Edward was graciously pleased to enter the Fellowship of the Royal Society, and later, on his accession to the Throne, to become our Patron.

Your Majesty enters upon the duties of your high station with a wider personal knowledge of the Empire and its various peoples than was ever possessed by any previous Sovereign of this country. Your subjects have had many proofs that this extended knowledge has been accompanied by an active sympathy with every cause and movement that will promote their welfare and happiness. The interest which your Majesty has shown in the progress of discovery and invention assures us that these elements of national greatness will continue to receive your favour and protection.

His Majesty replied as follows:—

I thank you for the loyal address of condolence from the president, council, and Fellows of the Royal Society on the death of my beloved father. It is a consolation to

feel that your society, numbering amongst its fellows the most distinguished men of science of this country, sympathises with me in my terrible bereavement.

Your words of appreciation of the character of the late King are very welcome to me. He always regarded with the deepest interest those scientific discoveries, and those applications of discoveries already made, which have been of such supreme importance in the advancement of civilisation. I also have watched with close attention the work of your society, and it is my sincere hope that its prosperity will continue, and that a Fellowship of the Royal Society will always be esteemed one of the highest honours which can be earned by devotion to the cause of science.

I desire to thank you most cordially for your congratulations on my accession to the Throne, and to assure you of my sympathy and support in your beneficent efforts for the promotion of natural knowledge. I gladly accede to your request that I should inscribe my name as Patron in your charter book.

PROF. GEORGE F. BARKER.

PROF. BARKER, whose death was announced last week, was one of the most genial men of science on the other side of the Atlantic. He was a frequent visitor in London, and invariably of recent years, during the period of his stay, he was made an honorary member of the Athenæum. He was born in Charlestown, Mass., in 1835, and died on May 25 last. He was educated in the Boston public schools, finishing at Yale, where he graduated in 1858.

The American system of education is continuous and methodical, and whatever line of pursuit an American boy is prepared for, he is ultimately turned out well drilled for his future career. Barker commenced in the Albany Medical College, where he received the degree of Doctor of Medicine in 1863, and was appointed professor of chemistry at Wheaton College, Illinois. Thence he proceeded to the Western University of Pennsylvania in the same capacity, but later he became professor of physiological chemistry and toxicology. In 1872 he was appointed professor of physics at the University of Pennsylvania, in Philadelphia, and there he taught until 1900, when he retired on account of ill-health.

Prof. Barker was an admirable teacher and expounder, but he did not undertake much research, and therefore his name is not so well known in the scientific world as that of many of his countrymen. He was much engaged as an expert witness, especially in patent cases. He acted as United States Commissioner to the Paris Electrical Exhibition of 1881, to the Electrical Exhibition held in Philadelphia in 1884, and he took a very prominent part on the jury of the electrical department of the great exhibition in Chicago in 1893. He was a past president of the American Chemical Society and of the American Association for the Advancement of Science. He had served as vice-president of the American Philosophical Society, the headquarters of which are in Philadelphia, since 1899. His English friends will miss him very much when they visit America.

NOTES.

SIR JOHN GAVEY, C.B., will deliver the James Forrest lecture at the Institution of Civil Engineers on June 22. The subject will be "Recent Developments of Telegraphy and Telephony."

A CONVERSAZIONE of the Institution of Electrical Engineers will be held at the Natural History Museum, South Kensington, on Tuesday, June 28.

PROF. T. W. RICHARDS has accepted the invitation of the council of the Chemical Society to deliver the Faraday lecture of the society next session.

THE death is announced, at the age of eighty-four years, of Prof. W. P. Blake, emeritus professor of metallurgy, geology, and mining, and director of the School of Mines of the University of Arizona.

A CORRESPONDENT says he "would like to ask Messrs. Cowell and Crommelin whether it is not highly probable that the Star of Bethlehem was, after all, nothing else than Halley's comet"? We submitted the inquiry to Dr. Cowell, who has been good enough to reply that he does not consider it "highly probable" that the two objects are identical.

It is proposed to establish, under the title of the India Society, an association to promote the study and appreciation of Indian culture in its æsthetic aspects. The new society will publish, for distribution to its members, works showing the best examples of Indian architecture, sculpture, and painting, and will assist in the preservation of the traditional arts and handicrafts of the Empire. The honorary secretary is Mr. T. W. Rolleston, Ardeevin, Christ Church Road, Hampstead, N.W.

THE National Association for the Prevention of Consumption is inaugurating an educational campaign against tuberculosis. So great has been the success of the Travelling Tuberculosis Exhibition that the council is convinced that the time has come for a vigorous and widespread effort. A special appeal committee has been appointed, over which the Earl of Derby will preside, to raise funds. Its object is to raise an annual income of 5000*l.* for the purpose of spreading information on the question of the cure and prevention of consumption. This campaign is to be carried out by means of travelling tuberculosis exhibitions; caravans, with lantern-slides, for small towns and villages; popular lectures; an information bureau; and the distribution of literature. The cooperation of all persons is solicited to aid in raising the fund, which will be applied entirely to educational purposes, as the committee feels that if the country can be aroused to a comprehension of the loss in life and money occasioned by tuberculosis, and the methods by which the disease can be controlled, ultimate conquest is assured.

THE Italian earthquake of June 7, referred to last week, occurred in a district which is frequently disturbed by shocks from more or less distant centres, but in which they rarely originate. Avellino, where the recent shock was strongly felt, is thirty miles east of Naples. The epicentre of the earthquake was, however, about thirty miles still farther to the east, including the villages of Calitri and San Fele, at both of which there was much damage to property and some loss of life. The only important earthquake which is known to have occurred in the same centre is that of September 8, 1694, when more than four thousand lives were lost. Calitri was then entirely destroyed, and at least 700 persons were killed. The epicentre of both earthquakes lies only a few miles to the north-west of that of the great Neapolitan earthquake of 1857, and not far from the continuation of the isosismal lines drawn by Mallet in his well-known report.

PROF. RONALD ROSS, in an address to representatives of the missionary societies of the world meeting at Livingstone College on Commemoration Day, June 11, urged that missionaries, like the priests of old, should be healers both of the mind and of the body. He suggested that missionaries might ascertain, by the examination of the spleen, whether children in the tropics were affected by malaria, and that this would give a rough indication of the amount of malaria in the district. He suggested that

quinine might then be administered to the children in the district, and that this would tend to check the spread of the disease. He also hoped that they would be able to assist in drainage schemes, so that the breeding places of mosquitoes might be eradicated. He thought all missionaries should have such training as that given at Livingstone College, in order to be enabled to share in these sanitary precautions.

MANY meteorologists will be glad to learn that the activity of the British Rainfall Organisation, founded some fifty years ago by the late Mr. G. J. Symons, has been placed upon a permanent footing by the transfer of the management by the director, Dr. H. R. Mill, to a strong representative board of trustees interested in rainfall work. The board will consist of Dr. Mill (as chairman), Mr. F. Druce (treasurer), Mr. R. M. Barrington, Sir Alexander Binnie, Mr. C. L. Brook, Mr. C. J. P. Cave, Mr. D. W. Freshfield, Dr. H. Mellish, Sir John Murray, and Mr. J. G. Wood. The board, with the aid of other observers, will form an endowment fund for the continuance of the work, which hitherto has been dependent on the efforts of its promoters and voluntary contributions. The observers now number nearly 5000, and the accumulated records are quite unique. Dr. Mill now makes over the whole of the documents and the lease of the headquarters in Camden Square to the board of trustees as a free gift for the benefit of meteorological science.

THE fifteenth annual congress of the South-eastern Union of Scientific Societies was held at Guildford from June 8 to 11. Dr. D. H. Scott, F.R.S., was succeeded as president by Prof. Ernest Gardner, who delivered a discourse on the evolution of classical art. Some of the papers read were of much local interest, notably one by Mr. H. Bury on the relation of the River Wey to the Blackwater and the Arun—a study of river-development on the lines laid down by Prof. W. M. Davis. Another local paper dealt with the Pilgrims' Way between Farnham and Albury, in which Mr. J. G. N. Clift discussed the question whether the route was along the higher or the lower road. Mr. E. A. Martin explained his experiments on dew-ponds, made with the view of determining the way in which the supply of water was maintained. Dr. W. Martin showed in a learned paper how the bird's-eye views and maps of the sixteenth and seventeenth centuries should be interpreted. A lecture on colour in insects was given by Mr. J. W. Tutt, in which he pointed out the need of obtaining definite information respecting the changes which bring about differences of coloration. Dr. Vaughan Cornish lectured on waves in sand and snow, and Mr. A. R. Horwood, of Leicester, referred to the extinction of cryptogams. The Rev. R. Ashington Bullen is succeeded as honorary secretary of the union by Dr. William Martin, who will be assisted by Mr. Norman Gray. Next year's congress will be held at St. Albans, under Sir David Gill, K.C.B.

THE University of California, continuing the investigation of the numerous shell-mounds on the shores of San Francisco Bay, publishes in the fifth part of vol. vii. of its Proceedings a report on that at Ellis Landing, by Mr. N. C. Nelson. This is one of the largest of the series, and the period required for its accumulation is estimated at more than three thousand years. From the very beginning it was used both as a dwelling site and place of burial, and it was occupied by the Californian aborigines up to a time not long antecedent to the European discovery and occupation of the country. The earliest occupants were not savages of the lowest grade, and there is throughout the strata distinct evidence of the evolu-

tion of culture. The later inhabitants were skilled in various industries, and made journeys to, or had trade relations with, distant tribes. Even if it was from time to time occupied by migrants or enemies, these people were all essentially of the same type, and the last were Indians similar to the inhabitants of Middle California within historic times.

MESSRS. DULAU AND Co. have published part iv. of the "Treasury of Human Inheritance," the publication containing pedigrees, illustrative of the inheritance of various defects or other characters, issued by the Galton Laboratory for National Eugenics. The present part contains pedigrees of a large number of cases of hare-lip and cleft palate, with introductory explanation and bibliography by Dr. H. Rischbieth; pedigrees of hereditary deaf-mutism collected by the Eugenics Laboratory; and pedigrees of congenital cataract, collected and annotated by Mr. N. Bishop Harman. The pedigrees are given in the same general style as in previous parts, and the first and third articles are illustrated by a number of plates, which are exceedingly well reproduced.

MR. M. OSHIMA, of the Bureau of Scientific Researches at Taihoku, has been enabled to add twelve species to the twenty-nine recorded in Stejneger's "Herpetology of Japan, &c.," as indigenous to Formosa. Of these twelve additions, four species and one subspecies are regarded as new to science. Mr. Oshima's paper appears in vol. vii., part iii., of *Annotationes Zoologicae Japonensis*, which also includes four articles on as many groups of Japanese invertebrates.

To the June issue of Witherby's *British Birds* Mr. H. Wormald contributes an exquisitely illustrated article on the attitudes assumed by the mallard and certain other drakes during the period of courtship. The performance generally commences by four or five mallards swimming round a duck with their necks drawn in, and then suddenly lowering their beaks, and at the same time raising themselves nearly upright in the water and drawing the beak up the breast. For the other actions we must refer the readers to the paper itself, as they are difficult to describe.

In their thirty-eighth report (1909-10) the directors of the Zoological Society of Philadelphia state that in December last a large number of animals collected by the Smithsonian Institution expedition to East Africa, under Mr. Roosevelt, were temporarily accommodated in the gardens previous to their transport to the National Zoological Park at Washington. Specimens of Thomson's gazelle, waterbuck, Coke's hartebeest, and wart-hog became, however, the property of the society. The last-named species, we regret to see, figures in the list as *Macrocephalus* in place of *Phacochærus*. When a name fits an animal so admirably as the latter does the wart-hog, it ought in no circumstances to be changed.

We have to acknowledge the receipt of the report of the director of the Zoological Gardens at Giza, near Cairo, for 1909, in which it is stated that the season under review was unusually favourable to the animals, although the number of visitors was 26,239 less than in the previous year. To the late and present Governors of Senar the gardens were indebted for a large and representative collection of animals from the Blue Nile, while a feature of the year was the large number of species which bred in the menagerie. Jungle-cats and foxes were responsible for the deaths of several animals, while to rats, owls, &c., may probably be attributed the disappearance of many others.

In past years locusts have caused enormous losses in South Africa to the farmers, who have usually, on religious grounds, taken no steps to destroy them. Since agricultural departments have been formed, locust officers have been appointed whose duty it is to collect information about the swarms and the places where eggs are laid, and to take such destructive measures as may be necessary. The report of the chief officer for Cape Colony for the past season has recently been issued in the *Agricultural Journal of the Cape of Good Hope* (No. 2, 1910). The most successful method of destruction is to spray the veldt with a dilute solution of sodium arsenite and treacle, or, if the grass is too short, to scatter some finely chopped green vegetation, bran, or even "voetgangers" themselves, previously soaked in the solution. When the swarm comes along it is immediately attracted by the treacle, and eats with great voracity, so that the insects soon begin to sicken and die. It is even recorded that a second swarm has come up and devoured the first, two swarms thus perishing through one spraying. At an earlier stage the destruction is a simpler matter—the insects are sprayed immediately they hatch out. Wherever these methods are adopted damage from locusts becomes comparatively small, and as soon as the religious scruples of the farmers can be overcome and adequate help is rendered, the locust plague will cease to be formidable because it can be controlled.

MR. E. HERON-ALLEN, writing from Large Acres, Selsey, sends an account of the extraction of several colours by him from purple iris flowers. The petals of from twenty to thirty flowers of the deep purple iris, which were either quite withered (shrivelled, but still moist) or just beginning to wither, were put into a jar and just covered with alcohol. At the end of ten minutes, (1) a bright and typically iris reddish purple solution was produced; (2) these soaked (in alcohol) blossoms, squeezed fairly dry and steeped in plain cold water for ten minutes, gave a bright ultramarine-blue solution, with no trace of purple or red; (3) these alcohol-soaked blossoms, left in the water for an hour, gave a deep (almost indigo) blue solution, with no trace of purple or red. Another similar lot of blossoms, cut just above the seed pod, were steeped in enough alcohol to cover them, for three hours, and gave a rich crimson solution with no trace of blue or purple. Several other brilliant and distinctive colours were obtained by various treatments of blossoms and residues. Mr. Heron-Allen's interesting observations remind us that while we have in this country a wide range of blue and red, as well as of yellow flowers, there is not, with the exception of woad (*Isatis tinctoria*), a single indigenous blue, or even red, colouring matter which has ever been of any importance as a dye-stuff. Many years ago woad was used to some extent as a source of indigo, while weld (*Reseda luteola*), dyer's-broom (*Genista tinctoria*), and many other yellow dyes were also employed, but we were dependent upon foreign countries for our colouring matters even when natural dye-stuffs were used. The chemical constitution of the colouring matter of the purple iris does not appear to have been investigated, but the results obtained by Mr. Heron-Allen may probably be explained by the extraction of traces of acid and alkaline bodies by the solvents used.

MR. JOHS SCHMIDT, head of the recent Danish expedition in the *Thor* for the investigation of physical conditions in the Mediterranean, has sent us a reprint of a preliminary report on the work of the expedition, published in *La Géographie*. The *Thor* cruised in the Straits of Gibraltar and along the north coast of Africa to Sardinia, then

explored the western Italian coast, and made some observations further east in the southern Adriatic and off the coast of Greece. The results are of great value and interest. Special attention may perhaps be directed to the section of the region west of the Straits of Gibraltar made between February 20 and 28, 1909, which may be compared with a similar section based on Dr. Wolfenden's observations made in the *Silver Belle* in 1904.

IN the *Sitzungsberichte* of the Vienna Academy of Sciences of December 9, 1909, Prof. W. Trabert discusses the connection between the temperature conditions of the atmosphere and the pressure at the surface of the earth. The inquiry is based upon observations of the temperature of the upper air during 1903-8 made by the aeronautical observatory at Lindenberg, and on the simultaneous behaviour of the barometer at the ground level. For this purpose those days were selected on which the air-column over Lindenberg was colder than the previous and following days, and *vice versa*. The results show, *inter alia*, that the barometer rises during the existence of cold air-columns; the minimum of pressure occurs generally on the day before, and the maximum on the day following. With warm columns of air the reverse holds good. After an extreme of pressure a column of extreme temperature occurs as a rule on the first or second day afterwards, *viz.* a warm column follows a high pressure, and *vice versa*. There is, at all events, an intimate connection between temperature conditions in the free air and pressure at the ground level, from which fact the author agrees with the opinion generally obtaining at the present time, that "the hope of meteorology lies in the upper regions."

AN extended series of tidal observations on the Pacific coast was obtained by the Canadian Tidal Survey during the summer of 1909, under the supervision of Dr. W. Bell Dawson, the superintendent of the Survey. There were in all a series of twenty recording tide-gauges in simultaneous operation along the coast of British Columbia. One noteworthy result obtained is that the time of high and low water at the head of the long inlets on the coast is very little later than at the mouth. For instance, at the head of Bute inlet high water is only seven minutes later and low water fourteen minutes later than at Lund, sixty-six miles below. The range of the tide at the head of the other inlets is only from 2 to 12 per cent. greater than at their mouth. This rapid progress of the tidal undulation must be due to the great depth of such inlets. Where the depth is so great, the whole surface of the inlet rises and falls simultaneously, in correspondence with the impulse at its mouth given by the rise and fall of the tide in the open. It would also appear that there is little current except in the mouth of the inlet, where the pulsation takes place. The results obtained by Dr. Dawson provide valuable information upon the subject of the progress of the tide in ordinary shallow estuaries and in deep inlets. They are in no sense, therefore, of merely local interest or local application, but they illustrate the general question of the rate of progress of the tide relatively to the depth of the channel or inlet.

THE velocities of certain reactions between metals and the halogens in solution form the subject of a paper by Messrs. R. G. van Name and Graham Edgar in the current number of the *Zeitschrift für physikalische Chemie* (May 24). Solutions of iodine and bromine in potassium iodide and bromide solution respectively were allowed to react with mercury, cadmium, zinc, copper, and silver at 25° C. and 35° C., and the velocities of solution of the metal measured. With iodine the velocity of solution was

found to be practically independent of the nature of the metal. The temperature coefficient of the reaction was found to be unusually low, about 1.3 for 10° rise, instead of 2.0 generally found for reactions in homogeneous systems.

SPECIAL interest attaches to a paper by the late Dr. Ludwig Mond on "Some New Metallic Carbonyls," which appears (with an introduction by Dr. R. L. Mond) in the *Journal of the Chemical Society*. A description is given of the apparatus, by means of which the action of carbonic oxide on metals could be tested at temperatures up to 450°, and at pressures up to 500 atmospheres. An account is also given of a new black cobalt carbonyl, $\text{Co}(\text{CO})_8$, prepared by the decomposition of the red tetracarbonyl, $\text{Co}(\text{CO})_4$, recently described, of a ruthenium carbonyl, of which only a small quantity was obtained as an orange-yellow deposit, and of a molybdenum carbonyl, $\text{Mo}(\text{CO})_6$, forming highly refractive white crystals which sublime without melting in an atmosphere of hydrogen or carbon monoxide at 30° to 40°.

PROF. H. B. DIXON's presidential address to the Chemical Society, reproduced in the Society's *Journal*, deals with the "Union of Hydrogen and Oxygen in Flames." He considers that the explosion of the two gases is a direct action, (1) because well-dried mixtures of electrolytic gas always explode with a spark; (2) because the velocity of explosion in a well-dried mixture is greater than when steam is added; and (3) because the explosion-wave is propagated exactly in the same way as a pressure-wave in the gas. In the case of the combustion of the gases at moderate temperatures, he agrees with Dr. Baker that steam plays an important part in the interaction of the two gases, but suggests that if once a flame is started the presence of moisture is not necessary for its propagation. During the combustion small amounts of hydrogen peroxide are formed, which can be preserved by allowing the jet to impinge on ice or on solid carbon dioxide. It has been suggested that hydrogen peroxide is the first product of the interaction, and this view has been supported on various grounds, as, for instance, on the ground that the primary interaction in a gaseous mixture must be between two molecules only. For these views no sufficient support appears to be forthcoming, and many of the arguments used in its favour are shown to be fallacious.

THE idea first expressed by Lord Rayleigh, and afterwards by Prof. Liebenow, that the high electrical resistivity of alloys was due to thermo-electric forces set up at the points of contact of the constituents of the alloys, has been taken up by several physicists, but no attempts to establish its truth experimentally have succeeded. In the *Physikalische Zeitschrift* for May 15 there is a communication from Mr. K. P. Brooks which appears to prove definitely that the idea is untenable. Mr. Brooks has measured the resistivity at different temperatures of columns consisting of a large number of thin gold and silver discs, and of sticks of compressed gold and silver dust, and has found that their resistivity and their temperature coefficient of resistivity lie between those of their constituents, and vary with composition according to the ordinary law of mixtures. Alloys of the two have, on the contrary, higher resistivities and lower temperature coefficients than have their constituents.

IN the *Revue générale des Sciences* of April 30 Prof. E. Cohen, of the University of Utrecht, writes of what he terms the "infectious diseases of metals." Under this heading he describes systematic observations on the allo-

tropic transformation which metallic tin undergoes at moderately low temperatures. More interesting, because of far wider importance, however, are his observations and views on what he terms the "maladie d'écrouissage"; this is, in reality, simply a process of spontaneous annealing or re-crystallisation which occurs in certain circumstances in metals which have been severely hardened by plastic strain. So long ago as 1900 Ewing and Rosenhain showed that when pure lead has been freshly crushed or rolled, the minute crystals commence to grow, even at the ordinary temperature, at a rate which produces visible changes in a few weeks. Prof. Cohen's observations show that processes of this kind are not confined to lead, but occur also in harder materials, especially in hard-drawn brass, thus accounting for the spontaneous cracking of cartridge-cases which occasionally occurs in practice after a lapse of several years from the date of manufacture, on the view that the re-crystallisation process is accompanied by a change in volume. The whole process is favoured by any rise of temperature, so that the phenomena are more readily observed in hot climates. Whether such action takes place at possibly a still slower rate in iron and steel is a problem still to be investigated. An important fact brought out by Prof. Cohen's experiments, however, is that the process of re-crystallisation is initiated and accelerated by intimate contact with a piece of the same metal in the stable or "annealed" condition; it is, indeed, this phenomenon which leads Prof. Cohen to describe the whole process as an "infectious disease" of metals.

The *Engineer* for June 3 contains a description of the Drutt Halpin system of thermal storage recently installed at the King's Road works of the St. Pancras Borough Council Electricity and Public Lighting Department. Each of four water-tube boilers has been fitted with a storage vessel, and some figures regarding the performance of the plant are certified by Mr. Baynes, the borough electrical engineer. Each boiler, as originally installed, had a maximum normal evaporation of about 11,000 lb. per hour. One boiler fitted with a thermal storage drum was run for 2h. 51m., the storage drum being full at the start and empty at the finish. During this time the average evaporation per hour was found to be 17,542 lb., or an increase of 59.5 per cent. more than the normal. During this test the average working pressure was 185 lb. per square inch, the temperature in the drum 360° F., and the draught at the boiler exit 0.5 inch by water-gauge. With this system it is found that deposits from hard water are found in the storage drum rather than in the boiler, and are therefore not subjected to the heat of the furnace, which would bake them to a hard scale. Such deposits are very easily blown off from the storage drum in a soft powdery state.

MESSRS. LONGMANS, GREEN AND CO. have published a third edition of Dr. F. Mollwo Perkin's "Qualitative Chemical Analysis: Organic and Inorganic." The first edition of the work was reviewed in our issue of August 22, 1901 (vol. lxi., p. 397), and it is sufficient to point out that to the present issue has been added a short section dealing with some of the rarer elements and a new chapter on ethereal salts.

A THIRD edition of Mr. Walter B. Priest's "Scheme for the Promotion of Scientific Research" has been published by Messrs. Stevens and Sons, Ltd. We dealt with the second edition somewhat fully in our issue of January 21, 1909 (vol. lxxix., p. 345). In the present edition the administration of grants has been further explained, and the author of the book proposes terms of allocations of

grants in relation especially to electrical science. The author hopes that the advantages to be gained by legislating for the promotion of scientific research, where it affects purposes of general utility and advantage, will receive serious consideration.

OUR ASTRONOMICAL COLUMN.

THE METEOR OF JUNE 1.—Further observations of the large meteor of June 1 gh. 40m. have been received by Mr. Denning from various parts, and they are in very fair agreement with each other and with the values given by him for the height, radiant, &c., in *NATURE* for June 9.

The meteor was seen from Clapham Common passing from a few degrees below the pointers in Ursa Major to a place just north of "The Twins." The trail was a reddish-yellow colour, while the nucleus was a brilliant electric-blue. At Loughton, Essex, the meteor was viewed during a portion of its flight over the western sky. The object appeared extraordinarily brilliant, with a blue head and red tail.

As an instance of the erroneous impressions of nearness occasioned by the startling lustre of fireballs of this kind, it may be mentioned that the observer at Loughton estimated it as seventy yards distant, and thought it must have fallen behind a house near him. Search was made for fragments, but without avail. As a matter of fact, the meteor was more than 100 miles distant. The shower of Scorpids to which it owed its origin is singularly rich in fireballs in June, and they form probably the débris of some dissevered, periodic comet the materials of which are now distributed into a wide stream.

COMING TOTAL ECLIPSES OF THE SUN.—From Dr. Pio Emanuelli we have received an abstract from the *Rivista di Astronomia e Scienze affini* (April) in which he discusses in detail the conditions of the total solar eclipses of the sun on May 9, 1910, April 28-29, 1911, and April 17, 1912. The eclipse of 1911 will have a period of totality of nearly five minutes, and the line of totality will completely traverse the Pacific Ocean; commencing on the east coast of Australia, it will terminate at a short distance from the west coast of Central America. A small chart given by Dr. Emanuelli shows the path of the shadow touching the islands of Nassau, Samoa, and Tonga. Vavau Island will probably afford the best locale for observations, and at the port of Neiafu, on the south-west coast, totality will last for 3m. 36.8s. with the sun at an altitude of 43°. At Tau, in the Samoan archipelago, totality will endure for 2m. 13s., the altitude being 51°. The last island to be traversed by the shadow will be Nassau, which is practically an uninhabited desert 1280 metres long and 914 metres across; but here the duration of totality will be 4m. 10s., and the altitude of the sun 57°.

THE NEW CANALS ON MARS.—In No. 422 of the *Observatory* (p. 215) M. Jonckheere states that, from observations made at Hem, there can be no doubt as to the reality of the two new canals recently described by Prof. Lowell. Independent observations by M. Jarry Desloges and himself disclosed these features, which were carefully studied at the Hem Observatory.

THE OBJECTIVE-PRISM DETERMINATION OF STELLAR VELOCITIES.—In No. 4, vol. xxxi., of the *Astrophysical Journal* Prof. R. W. Wood reports further progress in the preparation of light-filters for use in the objective-prism, radial-velocity work recently described by Prof. E. C. Pickering. It will be remembered that by employing a neodymium-chloride filter, Prof. Pickering introduced a fine absorption line into the spectra to which the stellar lines could be referred for measurements of velocity in the line of sight. Prof. Wood now finds that the addition of erbium chloride introduces another good reference line at λ 382, whilst, with isochromatic plates, the narrow interspace between two neodymium bands at λ 5220 might be employed. With vapours he believes better results could be obtained, and he is also experimenting on the manufacture of solid screens by using a solvent which would solidify, such as styrol. The success attained so far is very promising for the final application of this method.

EXPLORATION OF THE KARAKORAM RANGE.¹

IN the communication referred to below H.R.H. the Duke of the Abruzzi gives a very interesting account of his expedition last summer to Baltistan, in Kashmir territory, undertaken with the object of ascending K₂, the highest

from this point of the gigantic peaks and spurs of the main range, of which one, now known as Mustakh Tower, is the most striking feature, is described.

Beyond this camp reference is made to, and a hypothesis ventured on, a very conspicuous feature (mentioned in my paper, "The Glaciers of the Mustakh Range," R. G. Soc., January, 1864)—the long line of white ice in masses more or less detached, and distinct in structure from that of the ice on either side. I was unable to follow this ice-flow to its source. I venture yet another hypothesis. Its position is central; it appeared to originate from the precipitous western face of Gusherbrum, and to be glacial ice quite free from any morainic matter drawn into the flow of the main northern and southern branches, but had never been subjected to the pressure and formed under the same conditions as the ice which carried and partly held it in position. This is only one of the phenomena connected with these great glaciers awaiting elucidation and calling for that closer investigation which the first explorers had not the time to solve.

On reaching the base of K₂ a close examination of the peak was made, first on the western side up the tributary glacier named Savoia, leading to the saddle at its head, 21,863 feet. It was a stiff climb; steps in the ice had to be cut all the way up to the summit. The Tibetan side presented a precipitous wall of rock; beneath was a glacier flowing west to the Oprang Valley, probably a tributary of the glacier descending from the Mustakh

peak in the N.W. Himalaya, as well as to investigate the physical features of that range, which his previous mountain work in North America and Africa would render so valuable by comparison.

The rapidity and facility of modern-day travel compared with that of fifty years ago is remarkable. From Srinagar to the foot of the Baltoro occupied only fifteen days, which in 1861 took me twenty-nine. The Duke proceeded *via* the Indus Valley and the Braldoh River, and returned by the Skoro La and the Deosai Plains, all now well known and constantly travelled over.

The Baltoro Glacier has since 1861 been made famous by the visits of no fewer than three exploring parties, commencing in 1892, who have added to the topographical detail of its furthest sources. This last expedition was large and well equipped; besides its leader, there were the Marquis F. Negrotto, Messrs. Vittorio Sella, F. De Filippi, three Italian guides, G. Petigrew and A. and E. Brocherel, four porters and an assistant photographer, and Mr. Baines, who joined the party in Kashmir to look after the transport arrangements, so that the number of porters proceeding from Askolay was about 360. On May 18 they began the ascent of the great glacier, the first camp being at Liligo, on the right bank, where the marginal ice cliff is mentioned as being 196 feet high. The next day Rdokas, on the same side, was reached, where the party were detained three days by bad weather, snow falling and covering the surface of the glacier. This was made the base-camp. The magnificence of the view to the north

Pass. As the Duke describes it, the northern flank of K₂ seen from that side must form a gigantic wall nearly 10,000 feet in height. Seen well from here, K₂ was deemed impracticable for the Alpine climber. The explorers next attacked the eastern side, and

FIG. 1.—The Peak K₂ from Windy Gap.

FIG. 2.—The Bride Peak.

reached the points attained by the Anglo-Austrian expedition. From this splendid Alpine basin, as it is described, K₂, with its precipices and snow cone, shows itself in all its splendour; the difficulties of its ascent were apparent, and they had to declare themselves conquered—that only in an aeroplane could the summit be reached. From the

¹ *Bollettino della Società Geografica Italiana*, April, 1910. *Esplorazione nei monti del Karakoram*. By S. A. R. Luigi Amedeo di Savoia, duca degli Abruzzi. Con due carte e 5 illustrazioni fuori testo.

water parting on this side they saw a precipitous slope on the Tibetan side, not vertical as at the Sella Savoia, but a very crevassed glacier. The Italian guides and porters might have descended, but returning was the difficulty. The Duke was under the impression they would see from here the Oprang Valley; however, he was surprised to find a great glacier flowing south-east, separating Windy Gap from a great mountain chain which appeared to connect with Staircase Peak on the north; this glacier received numerous tributaries from the eastern face of the Staircase and mountains south of Windy Gap. The Duke says that here are two important geographical problems to be resolved—how the chain is attached to Staircase Peak and where the glacier the travellers saw emerges. From Windy Gap and Sella Vittoria Sella the eastern peaks of Gusherbrum were seen, and the Duke suggests that the glacier from there and the Staircase was the one seen by Young-husband from the Oprang Valley. A most plucky attempt was made by the Duke and two porters to reach the top of Staircase Peak, but after a night at 21,650 feet they were baffled by a *bergschund*, which they failed to work round. From here K₂ appeared more than ever inaccessible; it is recorded, also, that its northern face is precipitous, also that towards the east chains and mountains were lost in the distance.

Rejoining his party on June 28, the Duke determined to make a final effort to ascend the Bride Peak (K₆), 25,119 feet. Ascending the main Baltoro glacier, from Footstool Camp of Conway, on July 3, he and Sella started for the Kondus Saddle; the view they obtained from this point, 20,772 feet, compensated them for all they had gone through. To the south it lay over the Kondus Glacier, embracing Peaks K₇, K₈, and K₉; he noted that this valley trends to the east, then bends to the north, coming round Golden Throne and Hidden Peak, and perhaps joins the pass at the head of the Ordoch Glacier of Young-husband.

Although the work was most severe and many camps were in exposed and trying sites, great praise is due to all, and the account is written in a most natural, unpretentious way. The value of the Italian guides on work of this nature is well exemplified, for when they were on the Chogolisa Saddle, and Sella had left for Rdokas, they prevailed on the Duke to wait for fine weather and attack the "Bride Peak," and the little party actually stayed three weeks on this exposed ridge of 21,000 feet.

The ascent was finally made, and a point 24,577 feet reached, close below the summit, when, dense mist coming on, and the remaining 500 feet being of a dangerous nature, they reluctantly had to descend, having attained the highest altitude yet reached by man. More it was impossible to do. The Duke trusts some future traveller, profiting by his labours, may some day reach the magnificent summit of the Bride Peak (Fig. 2). The future surveyor who may be sent there is taught a valuable lesson by these most capable mountaineers towards the securing of an accurate plane-table survey of the wonderful unknown country lying to the eastward. With the numerous peaks fixed by the triangulation, it is shown conclusively that the area occupied by the Terim Gangri and glacier, together with the Snowy Range from which the Remo Glacier descends, could all be mapped and dozens of peaks fixed from points already visited by the Duke of the Abruzzi and Dr. Longstaff, supplemented by a few others at the head of the Kondus Valley and those seen from the Mustakh Pass crossed by Younghusband.

H. H. GODWIN-AUSTEN.

FURTHER OBSERVATIONS OF HALLEY'S COMET.

A NUMBER of further observations of Halley's comet are recorded in Nos. 4415-8 of the *Astronomische Nachrichten*. In No. 4416 (p. 401) Prof. Max Wolf gives a sketch showing the position of the tail on May 12 at 14h. 15m. (Königstuhl M.T.). A slight curvature was noted, the convex side being towards the north, and the extremity of the tail lay on a line joining α Equulei and β Aquarii. From this observation it was deduced that the actual length of the tail was about 45 million kilometres (28 million miles), whilst that part

through which the earth would pass, if passage took place, was at least 3° broad. Observations extending from May 17 to 24 indicate that the halos observed at the Königstuhl Observatory on May 19 were more than twice as strong as those observed on the other days. Dr. Cerulli directs attention to an apparent shortening of the tail towards 15h. (M.E.T.) on May 18, which he ascribes rather to the alteration of direction, in regard to the line of vision, than to the approach of daylight.

Herr A. Miethe records that, at the photographic observatory of the Royal Technical High School, Berlin, on May 24, the nucleus of the comet was seen to occult the 8.5 magnitude star A.G. Lpz. I. 4615; for 28.1 seconds the star was lost in the brightness of the nucleus, but at 9h. om. 40.5s. (M.E.T.) it was again seen amongst the matter streaming out from the nucleus. It then appeared as an absolutely sharp, bluish point of light, and suffered no apparent alteration beyond a slight twinkling. Herr Osthoff records some cloud observations made at Cologne on May 19, but found nothing which might be ascribed to the action of the comet's tail; the 22° halo around the sun is accepted as the natural result of the presence of the cirrus clouds observed.

Observations made at Warsaw on May 26 indicated that the axis of the tail, in the plane of the comet's orbit, made an angle of 11° with the radius vector at distance 0.18 from the head. Computations by Dr. Banschewicz show that this would mean a delay of 0.6-0.7d. in the passage of the earth through the tail after the conjunction of the comet with the sun.

No. 23 of the *Comptes rendus*, for June 6, contains several further reports of observations of the comet.

MM. Luizet and Guillaume (p. 1492) give a *résumé* of their observations since early in December, 1909, directing special attention to the changes which took place in the form of the nucleus, the structure of the various parts of the head, and the extent of the tail after the beginning of March. On May 15 it was noted that the pronounced flattening of the nucleus was in a direction perpendicular to that observed on May 14.

MM. Cirera and Ubach give the results obtained at the Observatoire de l'Èbre (Spain), during the period May 11-26, from observations of terrestrial, atmospheric, magnetic, and electrical phenomena. Some disturbances were recorded on May 18 and 19, but the authors believe that they were not connected in any way with the comet, although they hesitate to pronounce definitely on the subject until the results have been more fully considered.

M. Comas Sola, of the Fabra Observatory, describes (p. 1496) a very brilliant projection of gas from the nucleus on May 31. A photograph, exposed for eighty-three minutes, showed that this projection extended some million kilometres from the nucleus, in the direction opposed to that of the sun. A condensation in this projection gave the appearance of a second nucleus, which, on June 2, was about 40' from the primary nucleus, and was some three magnitudes fainter. Between these two nuclei there appeared to be an alignment of very feeble stellar points, but these were so faint as to be doubtfully seen. A photograph taken, with ninety minutes' exposure, on this date showed, among other interesting details, a long aigrette emerging from the nucleus and forming a medial line in the tail. On June 4 the secondary nucleus was invisible, but the primary was accompanied by four condensations, which travelled rapidly away from it. In 110 minutes the principal one of these was displaced 5.9", in regard to the primary, in the direction of the tail.

M. Giacobini also directs attention (p. 1496) to the breaking up of the nucleus on June 2. To him it appeared that the comet had split into two nebulosities, each having a nucleus, the only difference between their aspects being that one was considerably fainter than the other. He also remarks on the rapid alteration of the form of the nucleus since May 24. Prior to that date it had been distinctly nebulous and elliptical, but since then it has appeared as a sharply defined point.

As mentioned previously in NATURE, M. Jean Mascart travelled to Tenerife to observe the comet, and set up his instruments on the spot occupied by Piazzi Smith in 1858. He now describes (p. 1497) the instruments and the observing conditions during his two months' sojourn at the station. At an altitude of 2715 metres he was well above

the usual clouds, and only on one night was the sky obscured. Further, he gives a detailed account of his observations of the sky on the night of May 18-19, but beyond an exceptionally fine display of the zodiacal light no special phenomena were remarked.

Photographs of the comet taken at Helwân, Kodaikanal, Johannesburg, &c., were shown at the meeting of the Royal Astronomical Society on Friday last, and all of them show plainly what a striking object the comet was in more favourable latitudes and in clearer skies. The long straight tail is seen to have a very complicated structure of fine filaments and waves.

Several observers have forwarded to us accounts of recent observations of the comet. Mr. Leach, of Malta University, states, on June 8, that the comet had been seen every evening since May 20, and, although fainter, the tail still extended some 20° or 30° . It was best seen on June 1, when the tail extended nearly to Jupiter. He also remarks on the change in the appearance of the nucleus, which, latterly, was quite stellar in character and of about the second magnitude.

Mr. J. W. Scholes, of Grimsar, Huddersfield, sends an account of observations made at Morecambe Bay. A sketch, made at 11.10 p.m. on May 31, in a clear, cloudless sky, shows three plumes, or tails, two shorter ones lying beneath, and separate from, the main tail. The lowest, and shortest, is quite near to Castor and Pollux, and nearly parallel to a line joining them. No simple, definite explanation of this apparition is yet forthcoming.

PAPERS ON INVERTEBRATES.

IN the May number of the *Entomologist's Monthly Magazine*, Dr. D. Sharp records the history of the discovery in the New Forest of a new species of arboreal beetle of the genus *Corticaria*. One species of this genus, *C. similata*, was for thirty-seven years known as British only by a single specimen. In 1908 beetles of this genus were taken on an oak-tree in the New Forest and identified with that species, which they seemed to indicate to be sexually dimorphic. Other specimens procured, both in the Forest and at Woking, demonstrated, however, that not only was *C. similata* re-discovered in Britain, but that the former area is the home of a new species, for which the name *C. lambiana* is proposed. *C. similata* has been subsequently taken in Scotland.

To the Proceedings of the Academy of Philadelphia for December, 1909, Mr. T. H. Montgomery contributes the second part of his observations on the habits of spiders. Particular interest attaches to his account of the breeding habits of *Pisaurina*, the species of which closely resemble the *Lycosidae* in structure, but differ by being arboreal instead of terrestrial during the cocooning season, and in carrying the cocoons by means of the chelicera instead of suspended from the spinnerets. The large white cocoons of one species are usually found on poison-ivy (*Rhus toxicodendron*); and from observations on specimens kept in confinement it appears that the female carries the cocoon about with her until a few days before the young are ready to hatch. As they emerge, she commences to enclose them with a network of lines, she herself remaining on the outside of the nest thus formed. In this manner the old cocoon and the young spiders are eventually enclosed in a complete nest, which may take as much as three days to construct.

The January and February issues of the same serial for the current year are occupied by papers on molluscs—for the most part American land and fresh-water forms—among which the longest is one by Messrs. Pilsbry and Ferriss, on the land-snails of the south-western States. As the result of their study of Arizona snails, the authors have been led to doubt the power of environment as a main factor in the differentiation of species, and to regard this as capable of explanation only on the hypothesis of variations in the egg, leading to modifications of the organism, for the most part not affecting the well-being of the race. Such adaptation as exists is probably due to selection, and the isolation of colonies would favour the perpetuation of mutations.

Fresh-water gastropods of the genera *Limnea* and *Physa* progress, it is well known, by crawling, back-downwards, on the surface-film of the water. On p. 42 of the serial

just cited Mr. H. S. Cotton shows that the same mode of progression occurs in the case of a marine bivalve of the genus *Modiolaria*, the remarkable feature in this instance being the small size of the area of adherence.

To the May number of the *American Naturalist* Dr. H. A. Pilsbry communicates a note on a new type of barnacle (*Stomatolepas praegustator*) inhabiting the mucous membrane of the throat of the loggerhead turtle. Although sessile barnacles are well known to infest the external surface of turtles and whales, while certain parasitic forms penetrate the integument of their crustacean hosts, no commensural thoracic type appears to have been previously described. *Stomatolepas* belongs to the subfamily *Coronulinae*, and is nearly related to *Tubicinella*, which lives on the skin of whales, and *Stephanolepas*, a barnacle found imbedded in the horny plates of the shell of the hawksbill turtle.

SOME BIOLOGICAL SERIALS.

THE frequency with which the successive numbers of the *Quarterly Journal of Microscopical Science* make their appearance may be taken as an index of the activity in research—of a particular kind—on the part of British biologists, and the editor is to be congratulated on the issue of seven parts of what used to be literally a quarterly journal during the last twelve months. The April number (vol. lv., part i.) maintains the usual high standard of this publication. It opens with a detailed description, by Prof. G. C. Bourne, of the anatomy of a remarkable New Zealand mollusc, *Incisura (Scissurella) lytteltonensis*, illustrated by five carefully drawn plates. Mr. W. J. Dakin gives a very full description and discussion of the eye of the scallop—*Pecten*—an organ which, on account of a certain resemblance to the vertebrate type of eye, has for a long time past attracted a large share of attention from biologists, and which lately, we believe, has played a not unimportant part in the theories of philosophers. Mr. Dakin concludes that "there is no ground whatever for placing the *Pecten* eye in the same class as the vertebrate eye, for the resemblance is very superficial, and though the retina is inverted in both cases, this has been produced in very different ways." Prof. E. A. Minchin and Dr. H. M. Woodcock have a paper on the blood-parasites of certain fishes, accompanied by three of those remarkably beautiful plates which we have learnt to expect from protozoologists. A special welcome should be extended to another protozoological paper, the first, we believe, from the pen of Mr. Julian S. Huxley, grandson of Prof. T. H. Huxley, which deals in a very thorough manner with a new genus and species of gregarine from the digestive tract of that remarkable crustacean *Anaspides tasmaniae*. Both this memoir and that by Prof. Bourne, already referred to, are based on material obtained by Mr. Geoffrey Smith on his recent trip to Australasia. The number concludes with a reprint of Prof. Hubrecht's address to the Boston meeting of the International Zoological Congress on the foetal membranes of the vertebrates, in which the author elaborates his remarkable views on the interpretation of mammalian development.

In the second volume of the *Zeitschrift für induktive Abstammungs- und Vererbungslehre* Prof. G. Steinmann further elaborates his theory of the extreme polygenetic origin of the Mammalia. This is a new and somewhat startling hypothesis which does not seem, as yet, to have attracted much attention in this country; its acceptance would involve a far-reaching modification of generally adopted views as to the phylogeny of the Vertebrata. The reptiles, which are themselves supposed by Prof. Steinmann to have arisen polyphyletically from the Amphibia, are divided into two groups, the Orthoreptilia, which include the existing crocodiles, chelonians, lizards, and snakes, and the Metareptilia, which include extinct forms which have no reptilian representatives at the present day. The Metareptilia are again divided into Avireptilia, which are supposed to be the ancestors of the birds, and Mammoreptilia, from different groups of which the various lines of mammalian descent are traced. Thus the Ichthyosauria are regarded as the ancestors of the Delphinoidea, the Plesiosauria of the Phytetereoida, the Thalattosauria of the Mystacocœti, the Pterosauria of the Chiroptera (the

Theriodontia of the Carnivora, and so on. The author bases his theory mainly upon palæontological evidence, but the ordinary zoologist will find it difficult to believe that such highly specialised mammalian features as the development of hair, the allantoic placenta, and the habit of suckling the young have been evolved many times over, and yet always in conjunction with one another.

The third part of the second volume of Dr. J. W. Spengel's "Ergebnisse und Fortschritte der Zoologie" contains two useful summaries. The first, by Mr. H. F. Nierstrasz, deals with recent additions to our knowledge of the Chitons, which has enormously increased during recent years. The second, on the physiology of the faceted eye, by Mr. Reinhard Demoll, is based almost entirely on Exner's classical, but no longer very recent, work on the compound eyes of crustaceans and insects. The problem presented by these eyes is an extremely complex one, and really lies in the domain of the student of physical optics rather than that of the zoologist. On the whole, it appears that the Müllerian theory as to their mode of action still holds the field, but that this theory is not equally applicable to all cases.

REPORTS ON ICE IN SEAS AND OCEANS.

THE report on the state of the ice in the Arctic seas during 1909, published by the Danish Meteorological Institute, possesses more than usual interest on account of Admiral Peary's remarkable sledge journeys in the spring of that year. It summarises the conditions for each month, so far as known from reports supplied by traders to those parts, with maps for April–August inclusive. The state of the ice was unfavourable in Barents Sea and round Spitsbergen, while in the Greenland Sea and Denmark Strait the ice boundary was much more westerly than usual. The coasts of Iceland were almost free of ice, but much was observed off Newfoundland and on the Transatlantic steamer routes. On the south-east of Greenland and in the North American archipelago conditions were very favourable; in the Bering Sea they were about normal, and in the Beaufort Sea rather favourable, especially towards the middle of the summer. It is inferred that the amount of ice along the south-east of Greenland will be somewhat small in 1910, and that favourable conditions along the south-west coast of Greenland may result during the summer of this year.

From statements made on the useful monthly meteorological charts for the North Atlantic and Indian Oceans for April last, issued by authority of the Meteorological Committee, it appears that ice was scarce in the Southern Ocean during 1909. Up to about the middle of March last reports of only forty bergs passed in that year were received by the Meteorological Office; half these related to a position midway between New Zealand and Cape Horn. A later chart, however, states that from December, 1909, they commenced to be rather frequently reported. Tables referring to the bergs met with in previous years show that lengths of six to thirty miles are not uncommon, while some thirty of those sighted in that ocean in the last quarter of a century were 800 feet or above in height. Up to the present time, the report states, the birthplace of the largest of the bergs (1000 to 1500 feet in height) has not been definitely settled.

THE INTERNATIONAL HORTICULTURAL CONGRESS.

THE International Horticultural Congress at Brussels, April 30 to May 3, was attended by a large number of representatives, including delegates from the important horticultural societies. The meetings took place in the Salle des Fêtes in the grounds of the Great Exposition, at that time in a very incomplete state. Among the various subjects discussed was that of horticultural nomenclature. While there has been a general desire on the part of the more scientific horticulturists to conform to the rules of botanical nomenclature agreed upon at the International Botanical Congress at Vienna in 1905, it was felt that certain details which were not discussed at Vienna, but which were of special interest to horticulturists, should be definitely settled. The congress was unanimous in agreeing to adopt the Vienna rules of nomenclature, with neces-

sary additions in the case of horticultural varieties and hybrids. It was agreed that the names of horticultural varieties, expressed, in accordance with the rules, in the vulgar tongue, must remain fixed when used in other languages than the one in which they were originally employed. When possible, the name should consist of a single word, and never of more than two, or at most three, words. To ensure valid publication a description of the variety must be drawn up in Latin, English, French, German, or Italian.

As regards garden hybrids, it was agreed that the specific name may be expressed in Latin, or in a vulgar tongue and written in Roman characters; if possible it should be a single word, but, at any rate, not more than three words. Various suggestions had been made as to the system of nomenclature for artificial hybrids in which two, three, or more genera are involved. In the case of bi-generic hybrids, the general custom was confirmed of forming a Latin generic name by the combination of the names of the parents; the specific name, also in Latin form, is to be separated from the generic by the sign of hybridity, thus, *Laeliocattleya* × *Smithii*. For plurigeneric hybrids the recommendation of the Royal Horticultural Society of London was adopted, namely, the use of a conventional generic name, derived from that of some person of distinction, with the termination *ara*, e.g. *Lawrenceara*.

The programme of the congress also included a visit to the Royal park and conservatories at Laeken, and to the new colonial gardens and plant-houses. The latter contain many plants of interest from the Congo.

LOWELL OBSERVATORY PHOTOGRAPHS OF THE PLANETS.¹

THE pictures which I have the honour of showing to-night represent the results of the new planetary photography originated at Flagstaff in 1903–5, and now beginning to be successfully copied elsewhere, notably this last summer by M. le Comte de la Baume Pluvinel and M. Baldet in France, who from the summit of the Pic du Midi de Bigorre succeeded themselves in getting imprints of the canals of Mars. Although the method was originally designed to exhibit the markings of what is practically our nearest neighbour in space, it has since been applied to the other planets with an outcome as surprising as it is satisfactory. Little details which one would not have supposed could still long enough for their pictures to be taken stand out unmistakably on the plates, the faint equatorial wisps of Jupiter offering a good example of such tractability, though by no means the most remarkable.

That the canals of Mars should be made to write their own signatures on a photographic plate was the occasion of the invention of the process, which, after long and patient study by my assistant, Mr. Lampland, they were finally induced to do. To his marvellous feat the best tribute was that of Schiaparelli, who, after recognising the canals on the print sent him, wrote me in wonder that photography could be made to do such work, "I would never have believed it possible." Since then further improvement has been reached, to which almost every member of the staff has contributed. The process is based upon what our visual study of the planets has taught us to be the crux in the matter—the all-importance of definition. For this reason the older celestial photography, which furnishes such beautiful pictures of the stars and nebulae, was here impotent. This will be realised when one considers that the whole disc of a planet could be put inside the image of a single star. For a like cause reflectors cannot be employed, for with them all faults, instrumental or atmospheric, are magnified three-fold over those of a lens. They may give imposing-looking pictures, but the finer detail is lost, a fact which is evident at once to an expert. Now it is in the registration of this finer detail that the accomplishment lies, and which from a scientific point of view marks its importance.

Study of the conditions leading to definition has made these photographs possible, just as lack of such study alone makes possible the scepticism one sometimes hears.

¹ A discourse delivered at the Royal Institution on April 8 by Prof. Percival Lowell.

Thus it is a well-known fact with us that the main markings of a disc may come out sharp, while the delicate ones are obliterated by a blur which otherwise eludes detection. This applies as much to photographic as to visual results, and it is this defect that a reflector introduces. Another optical mistake, which has latterly been hailed as showing that the lines are not lines, but a series of dots, was made the other day in France. The observer saw perfectly correctly, but one with knowledge of the optics of a telescope in our air should have known that the effect observed was the inevitable result of using an aperture which the seeing did not warrant, as he could easily have assured himself by looking at the shattered rings in the synchronous image of a star. Even in our far better Flagstaff atmosphere the best results are got by diaphragming the aperture down.

In photography we cannot diaphragm down to advantage because we need the light, and this is one reason why photographs cannot rival an expert eye. Visual observations conducted by an eye fitted by nature, and trained by experience, must always surpass the best the camera can do.

One reason for this resides in the fact that the eye registers its impression in the twentieth of a second, while the plate takes forty times as long. The result is that the planet's presentments in its bad moments are superposed upon its good ones to a composite photograph of the whole, not unlike that got from a similarly merged company of doctors where all individuality is lost in one inane smile. As such well-meaning imbecility does not do justice to the planet, its exposure-time must be shortened to the limit of effect.

For a like reason the out-of-focus images of what by courtesy is called the achromatic telescope must be suppressed. So what the new process does is to monochromatise the light as nearly as possible. This is accomplished by a colour-screen, and a plate sensitised in accord with it. Then at the moment of exposure every precaution is taken that all movement shall be as nearly nil as can be secured within the instrument itself, and in the air without it. Lastly, he who would photograph the canals must successfully must first have seen them, that he may know when his opportunity arrives.

Planetary photography is not intended, nor is it destined, to supersede visual observation. Research on the planets must rest in future, as in the past, on the ultimate power of the eye and of the brain behind it, a useful adjunct in such investigation, whether this take the form of telescopic, spectroscopic, or other perhaps new line of inquiry. But in certain ways the sensitive plate may supplement the retina. Position is one of these, contrast another. For the eye to place in their proper posts all the markings of a multi-featured disc in the short time at its disposal is a well-nigh impossible task. The film registers them at once *in situ*. Values are another thing the photographs bring out clearly. They exaggerate contrast, it is true, as compared with the eye; but this is no detriment. Rather the reverse, for it furnishes a greater scale for measurement.

In looking at the photographs two things must be borne in mind. One is that the irregularities due to the grain of the plate must not be attributed to the images. Thus, within the limits set by the grain, the lines on Mars show as lines, not as a patchwork. This is perfectly apparent when they are carefully scanned. When we consider that the original images are only 5 mm. in diameter we realise the strain of lantern exhibition. Even so they are magnified 200 times in the taking. They are then further enlarged on the slide, and lastly thrown greatly increased upon the screen. The wonder is that they stand this lime-light publicity at all.

The second point is that we are not dependent on them for our minute knowledge of the planet. A good eye trained to the subject sees at least ten times as delicately as the film; but it must be an eye suited to planetary work, which is quite a different eye from that good at faint satellite or nebula detection. It is very important to remember this, for not only is there a physiologic reason for it, but mistake of it is often made in high quarters. When an observer records a polar flattening as twice and four times what hydrodynamics permit, his forte lies elsewhere than in planetary research.

Three planets will now show you their presentments, Mars, Jupiter, and Saturn. I was minded at first to omit Mars, passing by this old acquaintance with a nod, but so great have I found the interest in him here as elsewhere that he has been put beside the others.

As an example of the delicacy of the detail to be described on him, not only by the eye, but in the photographs, may be instanced the sight of one of the many vicissitudes of his changeable year, which suddenly appeared one day when least expected. The event was the first frost of the season in the Antarctic regions of Mars, detected visually at Flagstaff on November 16. The patch was at once photographed, and is plainly apparent on the plate. To chronicle thus the very weather on our neighbour will convince anyone that interplanetary communication has already begun, and that, too, after the usual conventional manner of ordinary mundane greetings.

My next mention shall show you the pitch of precision to which measurements of these little prints can attain. It is well known that the south polar cap of Mars is not centred on the pole, but lies some 6° off it, in longitude 20° or thereabouts. When the images showing the cap at two different longitudes were measured, the measures revealed distinctly the excentring of the cap, and even registered with some accuracy its amount and position. When we reflect what this means, it looks as if Mr. Crommelin's belief that areology would stand indebted to the photographs for help in its geodetic survey is in a fair way to be realised.

It would be possible in these photographs to take you on many a journey to that other world, but one such interplanetary voyage must suffice. This shall give you sight of the great new canals that appeared last September in a region of the planet where no canals had ever showed before. To begin with, you should know that the lines you will see are certainties, not matters admitting of the slightest question for all their strange regularity, and so seen by all those who, from the most prolonged and careful study, are qualified to speak. Schiaparelli described them as looking as if they had been laid down with rule and compass, and not only I, but all of my assistants, have seen them thousands of times the same. Nor are they near the limit of vision in our air, which sometimes sets the planet against the sky as if etched in a steel engraving.

In the second place, the technical word "canals" does not mean ditches dug, but artificially fertilised strips of country to which the water from the polar cap is led by some mechanical means. We have proof of their artificiality from the fact that they develop latitudinally down the disc from pole to equator after the cap begins to melt, for on a body the surface of which is in equilibrium, as with Mars, neither water nor any other substance could take this equatorward course unless it were intelligently conducted. What the conduits that lead it may be like we ignore, for all we see is their effect on vegetation.

Lastly, the organisms of Mars can hardly resemble men, which opens up for them unknown possibilities of intelligence and renders them really interesting.

On September 30 last, when the region to the east of the Syrtis Major came round into view again after its periodic hiding of six weeks, due to the unequal days of the earth and Mars, two imposing canals were seen leading up from the Syrtis to the south-east, which had not been there at the preceding presentation. Research showed that not only had they never previously been seen, but that they could never have existed as such before. The long and full records of the observatory, extending over fifteen years, made it possible to be absolutely sure of this. Yet these canals, with several subsidiary ones, fitted into the general canal system as if they had always made part of it.

Not only was their coming into existence established by the drawings, but the photographs of previous years testified to the same unheralded advent. By comparing the drawings and photographs made at the same epoch the oneness of the two becomes evident, while the change of both with the Martian seasons is clearly portrayed. Thus we have actually witnessed a "canal" called into being by the life existent at this moment on the surface of Mars.

Turning now to Jupiter, we find a completely different

set of features registered on the plates, no less corroborative of the drawings made of him at Flagstaff, but utterly unlike those of Mars. Their symmetry is immediately striking, and then no less is its purely latitudinal character. They are belts, bright and dark, banding the disc half-way to the poles. Their behaviour, however, indicates in them no regard for the sun, as they are quite oblivious both to the planet's day and to his year. They last indifferently through both, and disappear at their own good time. That the brighter are clouds and the darker the gaps between seems inferable; but they are not as our clouds. With us the heat that causes cloud comes from without, with Jupiter from within. Sun-occasioned the one, self-evolved the other. We have visual evidence of this internal heat of Jupiter in the cherry-red that tinges his darker belts, as if we there looked down into the seething cauldron below. We have theoretic proof of it, too, in the oblateness the disc presents taken in connection with what we know to be the planet's mean density. In two articles shortly to appear in the *Philosophical Magazine*, those who care for mathematics will find that his own fire alone enables Jupiter to keep his youthful figure, and, furthermore, that his shape shows him to consist of a comparatively small kernel wrapped in a huge husk of cloud. Even those who do not care for the oldest of the sciences must admit a certain grandeur in it when theory can thus plumb depths experiment may never fathom.

These belts have another peculiarity. Their several parts are travelling at idiosyncratic rates. With them it is a go-as-you-please race, in which each outruns or falls behind its neighbour. On this interesting subject we owe most to your fellow countryman, Mr. Stanley Williams, who for some years has acted as timekeeper and referee of this Jovian family contest. In future he will have no mean rival in the photographic plate. Not that it sees as well, but that it may be measured at leisure by any investigator who likes.

There is one feature in the photographs which has had a long and eventful history. I refer to the Great Red Spot. Detected in 1879, it lasted as such to within a few years. Rather a long life for a hole in the clouds! Now, properly speaking, we see only the grave in which it lies buried, the oval shell it once occupied; but these same photographs were, in a sense, the means of bringing its cradle also to light. Sixty years ago, a cycle of Cathay, Sir William Huggins made a fine series of drawings of the planet, and on receiving the present pictures was struck by the resemblance of the two. In consequence he sent me prints of his. On scanning them my eye was caught by an oval placed as the present one lies. Clearly it was the cradle prepared already for the Great Red Spot twenty years in advance. He had been present before its birth, as he is still, happily, present after its demise.

In the next set of images we envisage a Jovian event of some interest, in spite of the frequency with which it occurs—the transit both of a satellite and of its shadow across the planet's disc. For this means to Jupiter the occasion of a total eclipse of the sun, an impressive phenomenon were there anyone there to see. In the left-hand images the satellite itself may be described just passing off the disc, while in their complete procession the shadow, which is the eclipse, may successively be followed in its travels from one side toward the other of the planet's face. The swiftness of its traverse may be marked in the displacement it undergoes, not only directly, but with regard to the Jovian cloud-belts, which are themselves whirling round at the rate of 25,000 miles an hour. To witness thus the progress of a total solar eclipse on the great planet gives one, perhaps, his most vivid experience of Jovian affairs.

The third point we may mention in these photographs is their revelation of the equatorial wisps. Some years ago Mr. Scriven Bolton detected a most curious set of markings lacing Jupiter's bright equatorial belt. His discovery met with the usual approved disapprobation which has been the orthodox reception of astronomical advance since Galileo's time. Were a discovery to be hospitably hailed it would prove disconcerting to the discoverer, who would instantly suspect something wrong. Eventually the subject was referred to us for corroboration. This we were able, fortunately, to secure. A singular phenomenon

they proved to be, criss-cross filaments of shading traversing the belt from triangular spots at its edges, for all the world like the lacings of a sail that hold the bolt-rope to its spar. Though perfectly evident to the eye, we hardly hoped to catch them on a plate. Nevertheless, Mr. E. C. Slipher did, and innumerable other images of them have since been got by us; their pictures you will presently see for yourselves upon the screen. Why such peculiar rents should be torn in the planet's great cloud envelope we cannot yet explain, but further news about them has still more lately come to us from the planet to which we now pass in our journey outward from the sun, the great ringed planet Saturn.

In some respects Saturn is the most difficult of the three planets to photograph, certainly the most tiring. So faintly is it illuminated that what takes but two seconds for Mars takes twenty or more for Saturn. To keep the image of the planet upon its guiding cross-wires for that length of time, with the nervous knowledge that any slip will be

Reproduction of a photograph of the planet Saturn taken on November 4, 1909, by Prof. Lowell.

fatal, seems an eternity. Since sensations measure existence, it may be commended as a sure, though not happy, way to prolong one's life.

On the resultant images may be seen abundant detail. Cassini's division is there as large as life, and somewhat broader, due to the difficulty of keeping it still; so also is the shading of the inner side of ring B, and the tones of the several portions of ring A. The ball appears finely, its belts standing out even more than to the eye, and the duskiness of its polar hoods being peculiarly pronounced. The shadow of the ball upon the rings is, of course, salient, and so is the shadow of the rings upon the ball. This much is evident at a glance, but there is more to be made out by him who examines closely.

If we consider the images of November 4, which happen to be mine, we shall notice a dark band below the rings where they cross the ball, and one which is but dusky above them. Now at this date both the sun and the earth were above the plane of the rings, as we see the image, the sun the higher, the sun's relative latitude being $-12^{\circ} 18'$, that of earth $-11^{\circ} 4'$.

We saw, in consequence, the shadow of the rings A and B underneath the rings themselves. This accounts for the dark band below. What, then, was the dusky band above? It could not be the shadow of these rings, for the shadow could not fall on both sides of them at once, nor could it be seen above. A little consideration will reveal to us what this band was. Inside of ring B toward the planet lies the crêpe-ring C. It is a semi-transparent ring, because its particles are widely scattered, instead of seeming solid like the outer rings, where the particles lie closer together. Their constitution we owe to perhaps the greatest mind of the last century, your own Clerk-Maxwell. This, then, was the explanation: in the dusky band we were looking through the crêpe-ring on to its own shadow thrown upon the ball. Thus the crêpe-ring revealed its presence unmistakably, not by being seen, but by being seen through.

When we compare these images of November 4 with those taken by Mr. E. C. Slipher on September 9, we note

a marked contrast in the two fringes of shadow. This corroborates what we have just deduced, for at this time the relative positions of the sun and earth were reversed.

In the case of Saturn we have, as another interesting detail, the excellent instance it affords of contrast. From the bright equatorial belt, the most brilliant part of the whole picture, we notice a regular gradation of tints down to the faintest parts of the rings, for it is noteworthy that the dark belts of the planet are not so dark as these. This grading is particularly serviceable for being practically that of the eye, for the colour screen and plate used were such as to give us the light from that portion of the spectrum of which the eye takes greatest cognisance. The relative effect, therefore, on the plate is the same as on the retina.

Lastly, we come to what is one of the greatest triumphs of the whole process, the self-recording of the wisps of Saturn. It was in September that these wisps were first detected visually, independently, by my assistant, Mr. E. C. Slipher, and myself. Curiously enough, they were suspected synchronously on the photographic images, and on later ones were definitely seen. They counterpart almost precisely those of Jupiter, though, of course, in very faint replica. Here comes in the beauty of the photographic method. Instead of taking but a single image, twenty or more are taken one after the other on a single plate. Meanwhile, the colour-screen is moved. Thus any detail in the image due to defect on the plate proclaims its origin by its singularity, and in the same manner the colour-screen betrays its self-written markings. If a detail is repeated on several images in place it must be real, however faint.

As we take our leave of Saturn let me point out the beautiful elliptical figures of the rings thus shown, a symmetrical correctness wonderfully pleasing to the eye, and which the best of drawings fails to reproduce.

From the detail these photographs have thus proved themselves able to depict, they mark a new departure in planetary research. While, on the one hand, they exhibit to the world at large something of the advance recently achieved in our knowledge of the solar system, on the other they constitute in themselves the beginning of a set of records in which the future of the planets may be confronted with its archived past, and which shall endure after those who first conceived such registry shall have long since passed away. They can never take the place of first-rate visual observation, but they will form a firm foundation for whatever shall subsequently be seen, and will enable such changes as must inevitably ensue to be the better collated and compared. They are the histories of the planets written by themselves, their autobiographies penned by light; and in their grand historical portrait gallery, where the planets' pasts live on for ever in immortal youth, astronomers yet to come may see the earlier stages of the great cosmic drama which is slowly but surely working itself out.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Mr. E. M. Holmes, whose magnificent collection of seaweeds and algae was purchased for the University some time ago, has now presented to the botanical department another series of about 2000 beautifully preserved specimens, together with a number of valuable books on algology. The possession of this collection, the finest of the kind in the world, places the University in a unique position for the study of this branch of botany.

Prof. Sidney S. Dawson has resigned the chair of accounting.

An official degree of M.Sc. is to be conferred on Prof. F. W. Gamble.

Dr. Arthur Francis Bashford, director of the Imperial Cancer Research, has been appointed to deliver the Ingleby lectures for 1911.

Prof. Charles Lapworth, F.R.S., has been appointed to represent the University at the International Geological Congress at Stockholm in August next.

CAMBRIDGE.—The general board of studies has appointed the following university lecturers:—Dr. Marr, geology;

Dr. Shore, physiology; Dr. Baker and Mr. J. H. Grace, mathematics; Mr. G. F. C. Searle and Mr. C. T. R. Wilson, experimental physics; and Mr. H. O. Meredith, economics.

The special board for biology and geology has nominated Prof. I. Ikeda to occupy the university table at the laboratory of the Marine Biological Association at Plymouth for three weeks between July 15 and August 30.

GLASGOW.—Among the recipients of the honorary degree of Doctor of Laws on Thursday, June 9, were Dr. H. Dyer, C.E., first principal of the Imperial College of Engineering, Tokyo, now honorary principal of the college, and emeritus professor of the University of Tokyo; and Prof. G. O. A. Montelius, royal antiquary of Sweden and professor at the National Archæological Museum, Stockholm.

LEEDS.—On Saturday, June 11, the University held a Congregation for the purpose of installing the Duke of Devonshire as Chancellor in succession to the late Marquis of Ripon. The gathering, which included the Mayor and Corporation of the City, a large representation of Yorkshire civic and educational authorities, as well as the Court, Senate, and Convocation of the University, was held in the Town Hall. After the ceremony of installation a band of one hundred and fifty students sang a chorus from Bach's "Dramma per Musica." The Chancellor delivered a short address, in which he alluded to the hereditary interest of his family in the fortunes of the Yorkshire College and the Leeds University, and expressed himself anxious to maintain the tradition to the utmost of his power. He commended the work of tutorial university extension, and the prosecution of research, especially in connection with the prevention of disease. In connection with the ceremony, honorary degrees were conferred on a number of distinguished public men, including the Prime Minister (who was born near Leeds), the Earl of Crewe, Lord Lansdowne, and the Speaker. The degree of D.Sc. was conferred on Lord Rayleigh, Sir Clements Markham, K.C.B., and Prof. Osler. Sir Hugh Bell, Bart., received the degree of LL.D. On behalf of the honorary graduates, Mr. Asquith congratulated the University upon the installation of its new Chancellor. He expressed the opinion that the new universities had justified the faith and fulfilled the high hopes of their founders, and he passed a warm eulogium upon the work of the University of Leeds. The ceremonial of the proceedings, which was picturesque without being archaic, excited great interest, and the part taken by the students met with general approbation.

On Thursday, June 23, Dr. H. A. Miers, F.R.S., principal of the University of London, will present the prizes at the London (Royal Free Hospital) School of Medicine for Women. Mrs. Garrett-Anderson, president of the school, will occupy the chair.

We learn from *Science* that an announcement has been made of the receipt by Western Reserve University of a gift of 50,000l. by Mr. H. M. Hanna, as an addition to the endowment of the medical department, and that Mr. J. Ogden Armour has made a gift of 14,000l. to the Armour Institute of Technology.

ACCORDING to a Reuter message from Peking, the Throne of China, approving a recommendation of its Board of Education, decrees that English shall be the official language for scientific and technical education. The study of English is made compulsory in all provincial scientific and technical high schools.

THE annual conference of the Association of Teachers in Technical Institutions, which was postponed on account of the death of King Edward VII., will be held at Birmingham on Friday and Saturday, June 17 and 18. Mr. J. Wilson, president of the association, will deliver his address on the latter day, and a paper will be read by Dr. T. Slater Price on the relations of technical institutions to the universities.

THE late Prof. J. Campbell Brown, professor of chemistry for thirty-two years in Liverpool University, left estate of the gross value of 43,101l., of which the net personalty has been sworn at 42,740l. We learn from the *Times* that he bequeathed to the professor's of chemistry of the University

of Liverpool and their successors. his collection of old alchemical and similar books, to be kept together as the nucleus of a collection for the professors' private room. He left a sum sufficient to produce an annual income of 50*l.* to Liverpool University to found an advanced chemical scholarship to be called "The Campbell Brown Scholarship," and a sum sufficient to produce an annual income of 800*l.* to the University of Liverpool upon trust for the endowment of a chair of chemistry in addition to existing chairs, to be called the Campbell Brown chair, or if a chair shall have been endowed, then either for a chair for the teaching of agricultural chemistry or a chair of some other branch of industrial chemistry. He also left 5000*l.* to the University upon trust to place the income at the disposal of the Campbell Brown professor for the time being towards the cost of his apparatus and material. If the University of Liverpool shall not accept the bequest for the endowment of the chair on these conditions, the whole sums are to be given to the University of Manchester to endow a Campbell Brown chair of music. The residue of his property he left upon trust to found a series of entrance scholarships each of the value of 60*l.* per annum, to be held at the University of Liverpool, tenable for three years and renewable for a fourth. The value of the bequest for the proposed professorship is from 25,000*l.* to 28,000*l.*, of that for the advanced chemical scholarship 1500*l.*, and for the entrance scholarships 5000*l.* to 8000*l.*

At one of the meetings of the Women's Congress held at the Japan-British Exhibition on June 8, the question of a university standard in home science was discussed. Mrs. St. Loe Strachey read a paper on the ideals of home science, and defined a university standard as meaning the attainment by a student of such a standard of knowledge as could be rewarded by the grant of a degree if it had been attained in a subject in which our universities examine for a degree. In the special courses in home science being held at King's College for Women, the teaching claims to attain to a university standard. The students are not allowed to be content with merely acquiring a knowledge of the technical processes carried on in the practice of domestic science, but are required to study at first hand the various scientific principles which underlie the proper conduct of a house or institution and the bringing up of the young. It is true, she said, that women in our universities have for many years past studied physics, chemistry, biology, bacteriology, and, indeed, the whole list of sciences mentioned in the King's College syllabus, but the point is that these subjects should be studied in a definite, coordinated course, having for its object "to provide a scientific education in the principles which underlie the whole organisation of home life." Miss Oakley, warden of King's College Women's Department, said the new movement met the spirit of the age in its insistence that science should be everywhere, that reason should occupy all spheres, that there should be no dark corners left. The meeting seemed hardly to realise that to be thoroughly effective in improving the conditions of home-life the science teaching received by women must be begun in the school, and that many women will have few opportunities for further study after school days are over. The conditions in the schools must be improved. First, a course of practical work in science suitable for girls, and having the needs of the home before it at every stage, must be forthcoming; and, secondly, there must be a supply of well-educated mistresses who, in addition to their laboratory practice and general knowledge of science, have gained a first-hand acquaintance with household needs and difficulties, and have become experts in such arts as are required in the kitchen and laundry.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 9.—Sir Archibald Geikie, K.C.B., president, in the chair.—J. A. Gray: The distribution of velocity in the β rays from a radio-active substance. The β rays from some radio-active substances have been deflected in a magnetic field, and the detection of sets of homogeneous β rays attempted by the photographic method. Radium emanation was the substance first used. It was placed in a very narrow thin-walled tube, drawn out from

capillary tubing, so thin that the α rays from the emanation escaped. Enough black paper was placed over the tube to absorb the α rays and to protect the photographic film from phosphorescence caused by the α rays. The β rays from the active deposit had thus to pass through very little absorbing material. If the β rays from a simple radio-active substance are emitted at an identical speed, we should therefore expect to find evidence of such, even if β rays do change slightly in velocity in passing through matter. Although several photographs were taken, no sign was found of sets of homogeneous β rays from RaB and RaC. Experiments were then tried with RaE as radiating substance. Here we have β rays which are very nearly absorbed according to an exponential law, and if, as many writers have assumed, absorption according to an exponential law signifies homogeneous β rays, these rays should be practically homogeneous. It was found, however, that the velocities of the rays were distributed over a wide range. The results of the experiments may be summarised as follows:—(1) β rays which are absorbed according to an exponential law are not homogeneous; (2) β rays must fall in velocity in passing through matter, for, if not, the absorption coefficient of any mixture of rays must decrease as the rays pass through matter.—W. Wilson: The decrease of velocity of the β particles on passing through matter. In a previous paper it was shown that the velocity of β particles suffers an appreciable decrease on passing through matter. The present experiments were undertaken with the view of directly confirming this result. Homogeneous beams of rays were separated by means of a magnetic field from a heterogeneous beam given out by the active deposit from radium. These homogeneous rays passed into another magnetic field, where their velocity was measured. Sheets of aluminium were then placed in the path of the rays between the two fields, and the velocity of the emergent rays was found to have decreased by an appreciable amount. From considerations of the law of absorption found to hold for homogeneous rays, the decrease of velocity of the rays as they pass through matter could be calculated, and was found to agree with the results obtained experimentally. The results obtained are in agreement with the equations $E = k(a - x)$ and $E^2 = k'(a' - x)$, where E is the energy of the rays, x the thickness of matter traversed, and k and a constants. The agreement is rather better in the former case than in the latter, but the range of velocities considered was not sufficient to differentiate sharply between them. Although the change in velocity observed was only from 2.85×10^{10} to 2.25×10^{10} cm. per sec., yet the change of the properties of the rays with respect to absorption is very large, the absorption coefficient of the former being 4.9 cm.⁻¹, while that of the latter is 35.2 cm.⁻¹.—J. N. Brown: The rate of emission of α particles from uranium and its products. The object of the experiments was to estimate the number of α particles emitted per second per gram of uranium in equilibrium with all its products (i.e. as it occurs in pitchblende). The pitchblende was prepared as a thin film, over which was placed a zinc sulphide screen. The scintillations produced on the screen by the α particles were observed through a microscope. Each scintillation corresponded to the emission of one α particle from the pitchblende. The weight of pitchblende sending particles to the portion of screen viewed by the microscope was readily obtained, and since the screen was very close to the film the number observed could be taken as half the total quantity emitted by this weight of pitchblende so long as the thickness of the film was less than the distance of penetration of α rays into pitchblende. This point was ensured by making observations on films of various thicknesses and plotting a curve between number of scintillations per minute and weight of film, the result being calculated from a film for which the curve showed the rate of production of scintillations to be proportional to the thickness. The percentage of uranium in the pitchblende was estimated, and the result finally expressed as number of α particles per second per gram of uranium in equilibrium with its products, the figure obtained being 7.36×10^4 . From Rutherford's result for radium the value for uranium can be obtained through a series of calculations, each of which may involve a 5 per cent. error. The value obtained in this way is 9.1×10^4 .—Hon. R. J. Strutt: The accumulation of helium in geological time, iv

s paper gives further determinations of the ratio of um to radio-active matter in minerals, chiefly those urring in Archæan rocks. Very large relative quanti- of helium are found, in one instance (a sphene from afrew Co., Ontario) indicating an antiquity of at least million years, even if no helium has escaped. The que case of beryl, which, as shown in a former paper, tains much helium with hardly any radio-active matter, discussed. An explanation, suggested by Dr. Boltwood, put forward. It is supposed that beryl, in crystallising, e separated from the parent magma one of the longer- ed products of the uranium or thorium series, such, for mple, as radium, ionium, or radio-thorium, without the ent element. This product would decay, leaving no e of its presence except the helium generated. Reasons given for believing that nothing of this kind has opened in the cases relied on for measuring time.—

T. Lattey : The effect of small traces of moisture on e velocities of ions generated by Röntgen rays in air. e experiments of Prof. J. S. Townsend (Proc. Roy. e., vol. lxxxi., A, 1908, 464) on lateral diffusion of a row stream of ions moving in an electric field led to e conclusion that negative ions are much smaller in per- tly dry air than in air containing a small quantity of isture. It was consequently to be expected that com- e removal of water vapour would cause an increase in e velocity with which negative ions move under the luence of an electric field of force. At his suggestion an estigation of the velocities of ions in air at low pressures is undertaken, and it was found that, while the complete oval of water vapour had only a small effect on the ocities of positive ions, yet the same cause increased e velocities of negative ions by a factor rising to as uch as thirty for some of the forces that were used, and is factor appeared to be much larger for larger forces. e velocities of positive ions are known to vary directly th the potential gradient (X) and inversely with the essure (p) of the gas in which they are travelling; in her words, v/pX is a constant where v is the velocity. etween 14 and 29 mm. pressure the following values of X were obtained:—dry air, $v/pX=1121$; moist air, $v/pX=780$. In the case of negative ions it is known that en air is moist v is not a linear function of X/p , but at v/pX increases slightly as X/p increases. The ocity is, however, a function of X/p , and is independent actual values of either X or p. In dry air it was found at while v is still a function of X/p , yet the rate of ecrease of v with increase of X/p is considerably more id than in moist air. This is illustrated by the follow- g table:—

Velocities of Negative Ions in Dry Air in Centimetres per Second.

(mm.)	X/p=0.04	0.05	0.06	0.07	0.08	0.09	0.10
14.3	107	175.5	310	580	1126	2200	4210
18.4	103	163	279	514.5	1006	2050	4120
24.5	119.5	172.5	286	509	936.5	1799	3480
28.8	116	180	268.5	519.5	926	1652	—
Mean	112.5	173.2	287.8	510.5	953.5	1845	3635

us when pressure remains constant at 14.3 mm. and e varies from 0.56 volt per centimetre to 1.43 volts r centimetre, velocity increases from 107 centimetres per econd to about 4000 centimetres per second. When the s is slightly moist the corresponding velocities would be out 32 centimetres per second and 90 centimetres per econd. Thus in air containing about 11.5 per cent. (by easure) of water vapour the velocities observed were:—

(mm.)	X/p=0.04	0.10
18.0	80	89
19.3	83	92
Mean	81.6	91.7

-Dr. A. O. Rankine : The variation with temperature of e viscosities of the gases of the argon group. The ratio f the viscosity at the temperature of steam to that at atmospheric temperature has been determined for each of e five gases. Taking Sutherland's equation $\eta = \frac{KT^b}{1+C/T}$ he values of C have been calculated, and are shown in he following table. C is least in the case of neon; in act, this is the lowest value yet recorded for any gas.

This suggests that neon is the most nearly perfect gas known. A further interesting point is that C is, in the cases of argon, krypton, and xenon, proportional to the critical temperature:—

	He	Ne	A	Kr	X
C	70	56	142	188	252
Tc	—	[63]	155.6	210.5	288
Tc/C	—	[1.12]	1.10	1.12	1.14

The critical temperatures of helium and neon are not definitely known, but it is certain that Tc for helium is much too low to conform with the above rule. With regard to neon, however, Tc is known to be less than 68° absolute, and this does not exclude the value 63° absolute calculated by means of this rule. It has also been noticed that, with the exception of hydrogen, the same rule holds good for all other gases the data for which are available.

-Dr. W. G. Duffield : The effect of pressure upon arc spectra. Part ii. No. 4.—Gold.—Prof. B. Hopkinson : Radiation in a gaseous explosion. The pressures produced by the explosion of a mixture of coal-gas and air in a vessel plated with silver on the inside have been recorded, first with the walls highly polished, and second when the walls are blackened. The mixture contained 15 per cent. coal-gas, and was at atmospheric pressure and temperature before firing. The maximum pressure reached in the explosion was about 110 lb. per square inch above atmosphere, corresponding to a temperature of about 2200° C. It was found that when the walls were polished the maximum pressure was about 3 per cent. higher, and the rate of cooling for the first half-second about 35 per cent. less, than when the walls were blackened. The state of polish of the walls had a great effect on the rate of cooling, differences hardly appreciable to the eye making a marked difference in the rate of fall of pressure. The heat received by polished and blackened surfaces, respectively, was determined by means of a bolometer of silver strip fixed to the walls, the remainder of which was black. The change of resistance of this strip during explosion and cooling was recorded by means of a reflecting galvanometer on a moving film simultaneously with the pressure. From the rise of temperature of the strip and its capacity for heat the heat-flow into it could be deduced. It was found that when the strip was polished the heat received during the first quarter of a second after firing was three-fourths of that received by blackened strip in the same period, the pressure records being the same. Relative rates of heat loss to completely blackened and completely polished walls deduced from pressure records, during 0.25 second, varied from 0.6 to 0.7. Direct measurement of radiation from the gas was made by means of a recording bolometer placed outside the vessel, and exposed to the radiation through a fluorite window. At the end of half a second after ignition the total quantity of heat radiated and recorded by the bolometer amounted to 22 per cent. of the heat of combustion of the gas. At this period the gas was still radiating heat to a perceptible amount, its temperature being then 1000° C. At the moment of maximum pressure (1/20 second after ignition) 3 per cent. of the heat of combustion had been radiated away. The radiation recorded by the external bolometer exceeds by about 50 per cent. the difference between the heat absorptions by the blackened and polished silver respectively. The estimate of the latter difference is, however, subject to a good deal of uncertainty on account of the large correction for heat lost to the backing to which the bolometer strip is fixed. Moreover, there are reasons for supposing that it does not represent the whole of the radiated heat.

Royal Microscopical Society, May 25.—Mr. A. N. Disney, vice-president, in the chair.—Dr. M. D. Ewell : Comparative micrometric measurements.—E. Heron-Allen and A. Earland : The recent and fossil Foraminifera of the shore sands of Selsey Bill, Sussex, part v., the Cretaceous Foraminifera.

Physical Society, May 27.—Prof. H. L. Callendar, F.R.S., president, in the chair.—Dr. W. H. Eccles : An oscillation detector actuated solely by resistance-temperature variations. Experiments are offered as additional support for the hypothesis of the mode of action of certain types of electrical oscillation detectors. This hypothesis suggests that in detectors constituted of a loose contact, the

energy of the oscillatory current through the contact is transformed into heat at the contact and warms the matter there sufficiently to change its electrical resistance, and, consequently, the steady current through the indicating instrument. The experiments are on a detector of the so-called "crystal rectifier" type, from which, however, the possibility of thermoelectric effects has been eliminated.—

S. W. J. Smith: The limitations of the Weston cell as a standard of electromotive force. The experiments of Mr. F. E. Smith on cadmium amalgams are discussed. Theory and experiment suggest that there is no range at any temperature over which the E.M.F. of a Weston cell is absolutely independent of the percentage of Cd in the amalgam. Even if the materials are pure, the existence of surface energy must cause some variation. Within the range over which the E.M.F. is usually taken as constant the E.M.F. appears to rise, very slowly, with increase in the cadmium content. The rate varies, but is never more than a few millionths of a volt for 1 per cent. Cd. From the data it seems possible also to discover the precise way in which the use of the richer two-phase amalgams may lead to variability of the E.M.F. of the Weston cell. The interpretation advocated is that the irregularities are due to electrolytic skin effects arising out of want of uniformity of composition of the surface grains. The probable reason why the temperature coefficient of E.M.F. of a Weston cell, always small, actually vanishes near 0° C. is indicated.

Geological Society, May 25.—Prof. W. W. Watts F.R.S., president, in the chair.—Dr. F. H. Hatch and R. H. Raftall: Dedolomitisation in the marble of Port Shepstone (Natal). The Port Shepstone marble is shown by chemical analysis to be a dolomite. It owes its marmorisation to thermal metamorphism by an intrusion of granite, which surrounds it and penetrates it in broad dykes. This intrusion took place at some time prior to the deposition of the Table Mountain or Waterberg Sandstone, and is therefore pre-Devonian. The metamorphism of the dolomite under normal conditions produced a saccharoidal marble of coarse texture, consisting of carbonates; and the fact that neither periclase nor brucite has been produced in the normal marble is taken to indicate that the high-pressure conditions obtaining during the metamorphism precluded dedolomitisation.—E. B. Bailey: Recumbent folds in the Highland schists. A description is presented of the stratigraphy and structure of a portion of the Inverness-shire and Argyllshire Highlands. The district considered lies south-east of Loch Linnhe, and extends from the River Spean in the north to Loch Creran in the south. The following conclusions are arrived at:—(1) The schists of the district are disposed in a succession of recumbent folds of enormous amplitude—proved in one case to be more than twelve miles in extent. (2) The limbs of these recumbent folds are frequently replaced by fold-faults, or "slips," which have given freedom of development to the folds themselves. (3) The slipping is not confined to the lower limbs of recumbent anticlines, and is due to something more than mere overthrusting. It is a complex accommodation phenomenon. The cores of some of the recumbent folds have been squeezed forward, so that they have virtually reacted as intrusive masses. (4) In the growth of these structures many of the earlier formed cores and slips have suffered extensive secondary corrugation of isoclinal type.

Linnean Society, June 2.—Dr. D. H. Scott, F.R.S., president, in the chair.—Dr. A. B. Rendle and others: A contribution to our knowledge of the flora of Gazaland: an account of collections made by Mr. Swynnerton, by members of the Department of Botany, British Museum, with notes by Mr. Swynnerton. The collections which form the subject of this paper were made by Mr. C. F. M. Swynnerton chiefly in the high country which forms the boundary between eastern Rhodesia and Portuguese territory. It consists of a number of detached masses of highland separated by river valleys which ultimately unite to form the Buzi, an important river running eastwards through the lower-lying Portuguese territory to enter the Indian Ocean near Beira. Mr. Swynnerton has supplied an interesting account of the phyto-geographical character of the district. There is evidence that it was once covered with dense forest, which has, however, been largely

destroyed by the annual forest fires during some form of dense population. At present the forest occupies the more protected uplands, forming great patches; such are the great forests in the Chimanimani mountains in the north, a rugged range reaching a height of 8000 feet, and the Chirinda and Chipete forest patches closely adjoin each other in the south. Chirinda is described as a virgin forest of enormous, and mostly evergreen, trees, covering about 12,000 acres of the higher portions of the hill. The larger trees range from 80 to 170 feet in height, and the undergrowth, with mosses, ferns, epiphytes, and lianas, is of a thoroughly tropical character. As was to be expected from the geographical position, the botany of these highlands shows a strong South African affinity, and several of the genera and a considerable number of the species have not been hitherto recorded beyond South Africa. A large proportion of the plants are identical with those previously known from Nyasaland. There is also a well-marked Angolan element. An interesting novelty, *Pseudocalyx africanus*; *Pseudocalyx* is a Malagasy genus not hitherto known from tropical Africa.

Mathematical Society, June 9.—Sir Wm. Nive, president, in the chair.—G. T. Bennett: The composition of finite screw displacements.—Prof. M. J. M. Hill: Differential equations with fixed branch points.—Miss Long: Geiser's method of generating a plane quartic curve.—W. P. Milne: The generation of cubic curves by apolar pencils of lines.—E. Cunningham: The constitutive equations of material media in electrodynamics.—Dr. W. H. Young: (1) A new method in the theory of integration; (2) semi-integrals and oscillating succession of functions.—H. R. Hassé: The transformation of the equations of the theory of electrons for quasi-stationary motion.

EDINBURGH.

Royal Society, May 2.—Prof. Hudson Beare, vice-president, in the chair.—Sir Joseph Larmor: Address on the dynamics of molecular diffusion, with extension to suspended particles. After referring to the remarkable parallelism between the phenomena of a free gas, of small molecules constituting a dilute solution in water or other fluid, and of the Brownian movements, Sir Joseph proceeded to emphasise the distinction between osmotic pressure and gas pressure. The former depended on the frictional pull of moving particles, and the latter on the momentum of the free motion. The zigzag paths of particles suspended in water, photographs of which were projected on the screen, suggested that here also, as with gases, there was an average free path and an average speed to which the power of diffusion stood in definite relations. In this discussion the unexpected result emerged that, at the same temperature, the mean speed was proportional to the number of particles in suspension. Recent observations under the ultra-microscope, by which we can detect particles of a size more minute than can be seen by direct optical methods, have not contradicted this conclusion. The analogy between free gases and dilute solutions must not therefore be pressed too far. There was ground for thinking that we were approaching a great advance in the interpretation of phenomena of this kind, namely, the average phenomenon of a great crowd of molecules as they affect *en masse* our senses of perception. The main interest and fascination of science lay in the growing points where new knowledge was gaining ground on the unknown; and to consider some of the recent achievements and the outstanding problems in a field now rapidly undergoing development seemed more suitable for such an audience as the Royal Society of Edinburgh than to pass under review once more some harvest already definitely won and safely garnered in the stores of human knowledge.

May 16.—Prof. Crum Brown, F.R.S., in the chair. J. W. M'David: Equilibrium in the ternary system, water, potassium carbonate, potassium ethyl di-propylmalonate. Crichton had observed that when a concentrated aqueous solution of this last-named salt was shaken up with a concentrated solution of potassium carbonate, two distinct layers were formed. The object of the present paper was to show how the miscibility of the two solutions depended on their concentration, temperature, &c. Various solutions

the two salts in approximately equal proportions were mixed together and left to settle, and one mixture was made with quite different weights. Analysis showed that there was always a considerable quantity of potassium carbonate in the upper layer; but that the amount of potassium ethyl di-propyl-malonate present in the lower layer was scarcely appreciable until the solutions were comparatively dilute. When water was added drop by drop, the liquid being kept well stirred, the two layers ultimately disappeared, and one homogeneous solution was left. This disappearance of the two layers was quite well marked, and was due to the potassium carbonate passing to the other layer.—Prof. Alex. Smith and A. W. C. Lenzie: A method for determining boiling points under constant conditions. The apparatus consisted of a small bulb with a bent capillary, the whole being attached to a thermometer suspended in a beaker which contained water, sulphuric acid, melted paraffin, &c., according to the temperature to be measured. The method was especially useful when only small quantities of the material could be used. The apparatus was also found to be very serviceable in measuring vapour pressures. The authors gave illustrations of its adaptability in a second paper, entitled "A Simple Dynamical Method for determining Vapour Pressures." In a third communication by the same authors attention was directed to a common thermometric error in the determination of boiling points under reduced pressure. It was found that appreciable corrections had to be applied when the bulb of the thermometer was enclosed in an evacuated vessel. This was due to the dilatation or deformation of the bulb. The error might be as much as one-fifth of a degree.—Dr. J. Brownlee: The mathematical theory of random migration, and epidemic distribution; and the inheritance of complex forms, such as stature, on Mendel's theory. In the former paper, which was a continuation of an earlier communication, equations were formed which represented closely epidemic distribution, and the distribution which small animals, such as small crustaceans, took up experimentally. The theory led to the exponential curve as an approximate solution, and the facts were in good accord with the theory. Experiments were made with *Daphnia*, *Pulex*, *Littorina*, &c. In the second paper it was shown that the distribution of such a complex as stature when the dominant elements are equally derived from both sides may be represented by the terms of the trinomial $(1+n+1)^n$. In the case of random mating and of equal fertility, $n=3.3$. This point number was in Pearson's terminology leptokurtic, that is, the apex had a smaller radius of curvature than the normal curve fitted to the same sets of figures.—Prof. R. J. A. Orry, Dr. A. W. D. Robertson, and K. S. Cross: (1) Craniological observations on the lengths, breadths, and heights of 100 Australian aboriginal crania; (2) a biometrical study of the relative degree of purity of race of the Tasmanian, Australian, and Papuan; (3) the place in stature of the Tasmanian aboriginal as deduced from a study of his cranium. These three papers formed a connected series of anthropomorphic investigations, leading to the determination of the Tasmanian race affinities. The statistics throughout were treated in the recognised modern method, in which variability about the mean, correlation between pairs of dimensions, and the estimation of deviations were discussed by rigorous mathematical analysis. Dr. Robertson in the first paper concluded that the difficulty of separating the skulls into sexes rendered it advisable to have resulting values obtained for cranial races without reference to sex, and that the Australians, though less heterogeneous than some other races, were not as homogeneous or pure as some series which were regarded as homogeneous, and that the relationship of their cranial measurements, as indicated by the coefficient of correlation, was low, but was higher than most modern, though lower than primitive, races. In the second paper, after a general account of the many conflicting views expressed by various writers, an elaborate comparison was instituted between the cranial characteristics of 86 Tasmanian, 191 Papuan, and the hundred Australian skulls of the first paper. The coefficients of correlation for length-breadth, breadth-height, and height-length showed that, as readily recognised by other investigators, the greatest stress must be laid on the length-breadth coefficient and the

least on the breadth-height. The whole investigation proved that, of the three types considered, the Tasmanian was the purest and the Papuan the least pure. The result supplied a link in the chain of evidence concerning the heterogeneity of the Australian as contrasted with the homogeneity of the Tasmanian. Of the third paper, part i. only had been presented. In this, on the basis of a large number of cranial measurements, the relations of the Tasmanian to the anthropoid apes, *Pithecanthropus*, *Homo primigenius*, *H. fossilis*, and *H. sapiens* were considered. In part ii. the relations to the Australian aboriginals will be discussed in similar fashion. Twenty distinct measurements of the skulls of fourteen groups were made and tabulated side by side, and from the comparison among these important conclusions were drawn as to the relative evolutionary value of certain measurements. The general results were that, of recent man, the Tasmanian stood nearest to *Homo fossilis* (Brux and Galley Hill remains), but morphologically had progressed a very long way from *Homo primigenius* (Spy and Neanderthal skulls) and the anthropoid apes, and that *Pithecanthropus* stood nearer to the anthropoid apes than to *Homo primigenius*.

PARIS.

Academy of Sciences, June 6.—M. Émile Picard in the chair.—H. Poincaré: Time signals intended for ships. An account of the system adopted for sending wireless time signals from the installation at the Eiffel Tower. A simple form of receiving apparatus has been designed for the ship, the cost of which is less than that of a chronometer. Signals are sent at midnight and at two and four minutes past midnight, each signal being preceded by an introductory signal.—A. Haller and Ed. Bauer: The preparation and properties of the β -alkyl- α -hydrindones or the 22-dialkyl-1-indanones. The chloride of the dialkyl-benzylacetic acid is obtained from the acid by the use of thionyl chloride. Benzyl-dimethylacetyl chloride in suspension in petroleum ether is treated with aluminium chloride; the dimethylindanone is readily isolated in good yield from the reaction product. Indanone can be methylated directly by the sodium amide reaction previously described by the authors.—A. Chauveau and M. Contejean: The formation and elimination of nitrogenous waste in subjects in the state of youth.—Pierre Termier and Jacques de Lapparent: The monzonite of Fontaine-du-Genie, near Cherchel, Algeria, and on the micromonzonites of the neighbouring region.—R. Zeiller: Some Wealdian plants of Peru.—M. Luixet and J. Guillaume: The appearances of Halley's comet. A detailed account of the varying aspects of the comet from March 1 to May 26.—P. Cirera and M. Urbach: Observations on the passage of Halley's comet made at the Observatory of Ebra, Spain (see p. 470).—J. Comas Solà: Halley's comet. Photographs taken on May 31 and June 1 showed a double nucleus.—M. Giacobini: Halley's comet. On June 2 the comet appeared doubled, with two nuclei. Before its passage over the sun the nucleus was sensibly elliptical; after the passage the nucleus became reduced to a point.—Jean Mascart: Photograph of Halley's comet. An account of work done at Tenerife at a height of 2715 metres.—Joseph Marty: Singular values of an equation of Fredholm.—A. Chatelet: The classification of a system of tables equivalent among themselves.—L. Zorotti: The properties of Cantorian lines.—M. Saltykow: The generalisation of the theorem of S. Lie.—E. Barre: A series of solutions of Lamé's equations of elasticity in a homogeneous and isotropic medium.—Th. Rosset: A new sound-recording instrument. A record on a wax cylinder is copied directly on to another wax cylinder by a system of levers. Mirrors are fixed to the levers, and a photographic enlargement of the phonograph trace thus obtained. If the second wax cylinder gives sounds identical with the first, then the photographed record is necessarily a true one.—P. Pascal: The accuracy of the methods of measuring magnetic susceptibilities. The methods which have been proposed by the author have about double the accuracy of methods utilising a torsion balance.—A. Perot: The mercury arc in a vacuum. The effects produced by varying the conditions of working are described.—Daniel Berthelot and Henri Gaudechon: The oxidising effects of the ultraviolet rays on gaseous bodies. The peroxidation of the

oxygen compounds of nitrogen and of sulphur. All experiments to cause the combination of oxygen and nitrogen by the action of the ultra-violet rays gave negative results. Nitrous oxide under these conditions gave nitrogen and some of the higher oxides, and nitric oxide behaved similarly. Sulphur dioxide in the presence of mercury gave sulphate of mercury and sulphur, a considerable proportion of the sulphur dioxide remaining unchanged. Sulphur is produced in this reaction even if oxygen is added in excess.—**J. O. Serpek**: The nitrides and oxides extracted from aluminium heated in air. Commenting on a recent note by M. Kohn-Abrest, the author points out that the fact of the production of oxide and nitride of aluminium simultaneously by the combustion of aluminium in air has been known for a long time.—**P. Mahler**: The action of air on coal. Data are given for the amounts of carbon monoxide and dioxide produced by the action of air on coal maintained at temperatures varying between 25° C. and 105° C. This action takes place slowly at the ordinary temperature, and from this it follows that the traces of carbon monoxide which have been found in the air of mines are not accidental, but normal.—**Georges Dupont**: The oxidation of the acetylene γ -glycols. Synthesis of the α -acid alcohols.—**A. Arnaud** and **S. Posternak**: The isomerisation of oleic acid by the displacement of the double linkage. A repetition of the work of Saytzeff on the addition of hydriodic acid to oleic acid, and the subsequent removal of this acid by the action of alcoholic potash, has shown that a very complicated mixture of isomeric acids is obtained. The *iso*-oleic acid of Saytzeff is not a single substance.—**Léon Brunel**: The passage of some aromatic hydroalcohols to the corresponding phenols. The best of the methods examined was found to be that of Sabatier and Senderens, the catalytic dehydrogenation of the aromatic hydroalcohols by passing over hot reduced copper.—**MM. Stœcklin** and **Crochetelle**: The accidental presence of sulphocyanides in milk and their origin. Sulphocyanides may be introduced into milk when certain Cruciferae enter into the food of the cow.—**Raoul Combes**: The simultaneous production of oxygen and carbon dioxide in the course of the disappearance of the anthocyanic pigments in plants. It is shown that the simultaneous evolution of oxygen and carbon dioxide is more general than has been hitherto supposed, and always occurs when the acid pigments are disappearing.—**H. Jacob de Cordemoy**: The influence of the medium on the variations of the secreting apparatus of the Clusiaceae.—**A. Contamin**: The resorption of experimental tumours of mice under the influence of the X-rays. The results of a histological study of the resorption of a glandular epithelioma under the influence of the X-rays.—**Mlle. Bolesława Stawska**: Studies on cobra venom and the anti-venom serum.—**M. Fougerat**: The homologies of the muscles of the posterior member of reptiles.—**M. Rose**: Some tropisms.—**G. Seliber**: The symbiosis of the butyric bacillus in culture with other anaërobic micro-organisms.—**Jean Bielecki**: The variability of the proteolytic power of anthrax bacteria.—**V. Roussanof**: The Palaeozoic strata of Nova Zembla.—**A. Doby**: A fossil-bearing horizon in the *Muschelkalk* of Bourbonne-les-Bains (Haute-Marne).—**Jean Boussac**: The Helvetian Nummulitic and the pre-Alpine Nummulitic in central and eastern Switzerland.—**M. Roman**: The Rhinoceri of the European Oligocene, and their connection.—**M. Fournier**: The nodules (*Septaria*) of the Triassic ammonites of Madagascar, and on the development of *Ammonea*.

THURSDAY, JUNE 23, 1910.

INDIAN ENTOMOLOGY.

Indian Insect Life; a Manual of the Insects of the Plains (Tropical India). By H. Maxwell-Lefroy, assisted by F. M. Howlett. Pp. xii+786. (Calcutta and Simla: Thacker, Spink and Co.; London: W. Thacker and Co., 1909.)

THIS handsome volume reflects great credit upon its authors, who occupy the posts of entomologists to the Imperial Department of Agriculture in India; and also upon the staff of the Agricultural research Institute at Pusa, under the auspices of which the observations and specimens have been collected on which the present work is based.

In some prefatory remarks Mr. Maxwell-Lefroy informs us that the book is largely a product of his spare time and scanty holidays, adding that "such a volume has been so much required that he has felt that even an imperfect one was better than none." His estimate of his own work is modest—

"It may be," he says, "that a better volume will be built up on this basis, when the study of Indian entomology is further advanced. I may also emphasise the fact that where little is said, little is known, and the blanks in the book are designedly prominent to emphasise the enormous scope there is for work. I trust also that the volume may be a real stepping-stone to better things, and may help those who are advancing their knowledge of the insect life of India."

Keeping in mind the limitations thus indicated by the author himself, we cannot but congratulate him and his collaborators on the amount of useful information they have contrived to embody in their work, and on the result which has evidently been expended on its get-up and general appearance. So sumptuous indeed is the book in these latter respects that the title of "Manual" seems to be somewhat of a misnomer.

A marked feature of the book is its admirable series of illustrations. These have mostly been prepared by the artist staff of the Pusa Institute. Both the half-tone blocks and the line engravings show good workmanship; while the colour-plates, carried out by the Calcutta Phototype Company, "under very trying artistic conditions and for the first time in India," bear comparison with the best of their class. Many of the artists engaged on these illustrations are, we are informed, natives of India, trained in art schools of their own country. Their work is highly creditable to all concerned.

The plan of the book is simple. It opens with an introduction of about forty pages, in which are briefly discussed the structural characters of the class Insecta, its position in the zoological scale, the instincts and habits of insects, their classification, and the principles of nomenclature as applied to the group. The methods of identification of specimens and the existing appliances for the study of entomology in India are also noticed, and a section is devoted to a careful exposition of Indian zoogeography. The food and habitat of insects are dealt with in a practical manner, and the introduction closes with a reference

to the beneficial and other activities of insects in relation to man.

Following the introduction comes a systematic account, profusely illustrated, of each of the nine orders into which for present purposes the authors divide the class of insects. There is, of course, much divergence of opinion, and more of practice, among entomologists on the subject of classification; and the authors do wisely in warning the student against "getting to attach too much importance to any classification systems except as working conventions which have as much regard to truth as circumstances will allow." The characteristics of each order, and those of its subdivisions, are carefully given, and the most noteworthy specific forms under each head are more or less fully dealt with, sometimes, especially those of economic importance, in considerable detail. Many valuable observations on habits and life-histories are incorporated in this portion of the work, which covers the ground in as satisfactory a manner as could be expected from the limited space at the authors' disposal.

Finally, we have, somewhat after the manner of the excursions in Scudder's well-known work on the butterflies of the eastern United States, a number of brief treatises of a general kind, dealing with such subjects as cosmopolitan insects, gregarious habits, attraction to light, insects and flowers, migration, deceptive colouring with other means of protection, galls, silk, the size of insects, and insect noises. These essays, which are interspersed among the systematic sections of the book, include observations many of which are of great interest and value. As an example of a good field observation, which many travellers will be in a position to confirm, we may cite the following:—

"If one goes into a grass field, intent on observing large grasshoppers, one will suddenly see a brightly coloured insect jump up, fly a little distance, and disappear. . . . The eye has followed the bright colours and loses the insect as these disappear with the closing of the wings at the completion of the flight. One's eye is not seeking the cryptically-coloured grasshopper, which thus escapes attention, even if one could easily see the motionless insect."

The modesty of the claims put forward by the authors tends to disarm criticism; nevertheless, it may perhaps be suggested that some of the topics, especially those dealt with in the introduction, might with advantage have been treated more fully. It is unfortunate, too, that the authors allow themselves to be influenced by the somewhat silly outcry that has been raised in some quarters against bionomic conclusions "drawn from museum specimens." No naturalist ought to undervalue either museum study or field observation. Each is an essential factor in unravelling the problems of evolution, and each has furnished the other with important suggestions for further research. Field work on mimicry, in especial, owes much to the stimulus afforded by the careful study of material preserved in collections.

We do not agree (p. 419) that there is much difficulty in distinguishing *Terias hecabe* in all its forms from other species of *Terias*, nor that the colouring

of the upper surface of *Coletis* (or *Teracolus*) *amata* is well described as "orange." "Thaxter" on p. 405 is a misprint for Thayer. These, and a few similar slips, are but slight blemishes on a thoroughly useful book.

F. A. D.

THEORETICAL STUDIES IN RELATION TO NAUTICAL SURVEYING.

Hydrographic Surveying: Elementary—for Beginners: Seamen and Others. A Practical Handbook. By Commander Stuart V. S. C. Messum. Pp. xiv+504. (London: C. Griffin and Co., Ltd., 1910.) Price 12s. net.

THEORETICAL considerations dealing with the effect of errors of observation constitute one of the distinctive features of this book. It may be doubted whether such investigations are appropriate to a practical handbook intended for beginners; and in some instances, where they are merely of academic interest, their introduction is unnecessary. The dissertations on the manipulation of the station pointer, for example, are diffuse and of little practical utility. The chapter on the principles governing the selection of objects for fixing positions contains certain theorems which will be of interest to those already familiar with the subject; but beginners would find concise directions as to what goes to make a good fix more helpful to them. The discussions bearing on the "circle of equivalents" bring out a useful fact in a form somewhat different from that in which it has usually been presented. The principle involved is an important one, but it is possible to strain unduly its practical application. So much stress has been laid on it that beginners might easily be misled; the author himself appears to have misapplied the principle on more than one occasion.

This is notable in the example of plotting given on p. 197, where it is suggested to accept an intersection of two lines cutting each other at an angle of a little more than 30° , in preference to an intersection of about 90° . In this case primary points are alone concerned, and the considerations indicated by the author are not applicable. A similar misapprehension is noticeable on p. 201, in the paragraph relating to the projection of check lines from the best lines of reference. It is here implied that in the case of primary points, one of the lines on which they are plotted might have been laid off with a length of radius so short as to vitiate any lines laid off from it subsequently.

The question is discussed at some length as to the best zero to select for shooting up other objects when the position of the observer is not accurately determined. The problem is one of frequent occurrence, and is of great importance, but the treatment it receives is not satisfactory, and is liable to misapprehension. In this, as in some other cases, the broad practical rule of choosing a zero situated at about the same distance as the object to be shot up and making as small an angle with it as possible is not stated; whilst the investigation rests on assumptions not realisable when drifting in a boat or the ship in

an unknown direction, as always happens in practice. In the paragraph on measuring a base by chained portions, the rule of sines is used for solving triangles having one very obtuse angle and two acute angles. The proper method of solving such triangles might have suggested to the author the fact that since cosine of small angles change very slowly, small errors of observation are practically of no account, and consequently that the measurement of the off-set is unnecessary and less accurate than using each separate section of the base as measured.

Other instances of misapplication of theory to practice might be quoted, but those mentioned suffice to indicate a want of appreciation of practical requirements, and suggest the possibility that the author is more familiar with the theoretical study of the subject than with the conduct of a survey.

In discussing the question of false station, there is no reference to the simple method of eliminating all errors from that source by the expedient of observing at equal distances on opposite sides of the true station. There is, moreover, an easier method than that given by the author for calculating the correction for false station.

The use that might be made of a distant peak in connection with the angle of elevation of the masthead when sounding a shoal has also escaped attention; neither is there any reference to the use of angles of elevation in making a running survey of an island when circumstances admit.

The investigation of the error of parallax in connection with sextant angles, due to the use of the long telescope when reflecting objects close to the observer is of some theoretical interest, and is worthy of mention. As a matter of fact, the error from this source is not nearly so great as the author assumes, since it only exists in a minor degree with the short telescope which in practice is always used, being most convenient.

The various instruments and the methods of using them are fully described, and the ordinary operation connected with surveys of small extent are given in detail, together with a number of examples of such surveys, besides a useful chapter on amending the details of a chart.

A. M. F.

PRODUCTION OF SEED-OILS.

Linseed Oil and other Seed Oils: An Industrial Manual. By Prof. W. D. Ennis. Pp. xiv+312. (London: Constable and Co., Ltd., 1909.) Price 16s. net.

IN this work the author aims at the production of a manual which will serve as a fairly complete guide for the manufacturer of certain seed oils, more particularly linseed oil. He notes that, with one or two exceptions, the principal publications dealing with this subject hitherto have discussed it chiefly from the chemical standpoint. Accordingly in this volume the chemistry—which, after all, is relatively simple—is subordinated to the manufacturing and commercial aspects of the industry.

The work is written from the American point

view, and this no doubt detracts somewhat from its value to the English manufacturer. On the other hand, the latter will probably find some compensation in seeing how his problems are regarded by other eyes.

After a short historical description, the first eight chapters deal with the standard forms of equipment used in extracting oil from seed by the pressure process. Such matters as the location and planning of the mill, the selection of the best type of apparatus, the handling of the seed, the treatment of the oil, and the moulding of the oil-cake are discussed in ample detail. Economical production is kept in view throughout.

In the second and some later chapters we come across pages of algebraical formulæ which at first sight look like extracts from a mathematical textbook. They are the author's method of analysing in general terms various problems of manufacture, in order to show definitely the effect of adopting certain processes or courses of treatment. For example, the question is discussed algebraically whether in given circumstances it pays best to separate the "screenings" from the seed and sell them, or to pass them through the mill with the seed, or, thirdly, to separate them and grind them up with "cake." When all the factors have been combined into a formula, the man with an eye for an equation can readily see what effect an alteration in any factor will tend to produce. The man not endowed with such an eye can readily puzzle the matter out, and be all the better for the exercise. In such a way an intelligent control over the operations can be maintained.

In the subsequent chapters the method of extracting oil from seeds by percolation with a volatile solvent is described and discussed. Only about 10 per cent., however, of the oil produced in the United States is obtained in this manner.

Questions of output, shrinkage, and cost of production are dealt with at some length; and there are chapters on refining, on boiled oil, and on miscellaneous seed oils. The author contrasts the great development of the cottonseed oil industry in the United States with the comparative neglect shown in regard to other oils—linseed excepted. Rapeseed oil is the most conspicuous failure; but more olive oil should be produced, he thinks, in California, more cocoa-nut oil on the Pacific coast, and more pea-nut oil in the eastern States.

A section on the chemical characteristics of linseed oil gives briefly the chief items which the oil-works chemist requires to know. Information on various technical points, collected from scattered trade journals, has also been included, and certain official rules and regulations, such as those of the New York Produce Exchange and the Minnesota Grain Commission, have been laid under contribution in respect of the commercial aspects of the industry.

Many illustrations of apparatus are given, and the treatment is throughout of eminently practical character. Probably there are few intelligent oil manufacturers who would not be able to get at least some useful hints from the book.

C. S.

ZOOLOGY OF THE INDIAN OCEAN.

An Account of the Alcyonarians collected by the Royal Indian Marine Survey Ship "Investigator" in the Indian Ocean. By Prof. J. Arthur Thomson and J. J. Simpson. Part ii., The Alcyonarians of the Littoral Area. With a Report on the Species of *Dendronephthya* by Dr. W. D. Henderson. Pp. xviii+319+ix plates. (Calcutta: Indian Museum, 1909.)

THE first part of the memoir of the Alcyonarians of the Indian Ocean was published in 1906, and reviewed in NATURE of May 2, 1907. The second part deals with the shallow-water species, and fully maintains the high standard set by the first in wealth of detail and sumptuous illustration.

The authors of this volume have set themselves a task which is far more difficult than that of naming and describing the deep-sea species, and they have faced it boldly and, on the whole, satisfactorily. In the order Alcyonaria there are certain genera of wide distribution in tropical shallow waters which exhibit an infinite variety of form, of mode of branching, of colour, and of detail in skeletal characters, and the zoologist to whom the task is assigned of naming the spirit specimens sent to him by the collectors has to form an opinion as best he can on the vexed question of what characters or groups of characters in combination are sufficiently important to constitute a specific difference. In the absence of any knowledge of the development of the colonies, or of the relation of the different forms of growth to their surroundings on the reef, or of the transmission by heredity of the different characters he uses for purposes of classification, his opinion is rarely one of very great scientific value. Nevertheless, if his task is conscientiously performed, his descriptions accurate, and his illustrations adequate, our science is enriched by a number of recorded facts which may be of considerable value when the solution of the underlying biological problems is seriously taken in hand.

No better illustration of this difficulty could be found than that of the genus *Spongodes*, so excellently treated in this volume by Dr. W. D. Henderson. Following the example of Prof. Kükenthal, in whose laboratory he worked for some months, Dr. Henderson has distributed the specimens in the collection among no fewer than sixty-one species, of which fifty-three are described as new to science. But the question must occur to anyone who has seen *Spongodes* in abundance in its natural surroundings whether these numerous species could be maintained, even by the author himself, if another consignment of the same or greater dimensions were sent to him from the same locality. There is an advantage and a disadvantage in creating a large number of specific names for a common genus like *Spongodes*. It enlarges our knowledge by giving us detailed descriptions and illustrations, and in so far as it does that it is a gain; but, on the other hand, it tends to underestimate the importance of what may be a very definite character of all these common shallow-water genera, the power of adaptability to their immediate

surroundings. An animal that is able to move about can, within certain limits, choose its own immediate surroundings, and is not, therefore, so much in need of adaptability, but a sedentary animal or colony of animals must either adapt itself to the surroundings of the spot to which the larva happened to become fixed or it must perish. The evidence that there is really more than one variable species of Spongodes does not appear to be at all conclusive, but it is at any rate satisfactory to feel, when we contemplate the results of Dr. Henderson's labours, that we have some further knowledge of the varieties of form it may assume.

One word of protest may be said about the use of the generic name *Dendronephthya* for Spongodes. Whether the application of the strict rules of priority justifies the change or not, and those who study the literature of the genus may fairly claim that it does not, the inconvenience and confusion which the change of such an old and well-known generic name as Spongodes introduces are quite sufficient justification for our refusal to accept it.

As might be expected in the description of a shallow-water fauna, the number of new genera (four) is very small. Of these the curious cup-like genus *Studeriotis*, with its retractile polyparium, is the most interesting. The new nephthyid *Cactogorgia*, with its dense armour-plated walls of large spicules, is a remarkable example of the extreme limits to which spiculation in the Alcyonaria may be carried.

The suggestion made by the authors that the genus *Chironephthya* should be fused with *Siphonogorgia* is clearly a move in the right direction.

Among the many useful and valuable features of the volume, attention may be specially directed to the summary of the characters of the pennatulid genus *Pteroides*. A hope may be expressed that before long a similar summary of the genera and species of the *Juncellidæ* may be published. This family is evidently under the consideration of the authors, but in the present volume they have only given a tabular statement of the specimens in the collection, without assigning them to specific groups. The excellent coloured plates and numerous illustrations in the text add very materially to the volume, which is a very noteworthy addition to our knowledge of the Alcyonaria.

S. J. H.

certain views which have not as yet obtained complete adherence. On the whole, however, he gives an impartial view of the state of each problem so far as the kaleidoscopic nature of the case allows.

With regard to the question of protoplasmic structure, von Prowazek concludes that Bütschli's alveolar theory does not account for all the facts. He holds that protoplasm may be absolutely structureless, and must, therefore, be regarded as polymorphic. Each protozoan cell is, according to him, at least binuclear. This view, though well known to be shared by Hartmann, is not generally accepted, and it would have been advisable for more and better figures of the nuclei of such common forms as those of *amœba* to have accompanied the statement, which, as it stands, is not rendered quite convincing, though we are aware of the evidence in its support. The functions of the nucleus are dealt with at some length, and their discussion involves the consideration of much experimental evidence; in fact, it would be difficult to name any function of the organism which is not assigned by some writer to the activity of the nucleus. Form, motion, enzymes, or at least proenzymes, respiration, division, reproduction, heredity, regeneration, are all more or less confidently assigned to this versatile structure. Not only are its functional activities increasingly stressed, but the importance of the nucleus in originating structures hitherto supposed to be cytoplasmic is also fully considered. An interesting exception that is noted in this discussion is the fact that *amœbæ* can live for at least a month without a nucleus, and a portion of a *Stentor* deprived of its nucleus may regenerate the lost parts of its body.

Attention is directed to the importance of the membrane that encloses the protozoan cell, and to the mode whereby osmosis or absorption is performed. The suggestion of Overton that the membrane contains "lipoids" (e.g. lecithin and cholesterin), and that these take an active part in the absorption of substances into the cell, is somewhat over-emphasised, since it is by no means certain how far these "lipoids" contribute to the formation of the ectoplasmic structures. At the same time, so much attention is now being paid to this aspect of biochemistry that the discussion is a very timely one and should lead to further research.

The latter half of the book is occupied by summaries of what is known as to the functions and "tropisms" of protozoa. With regard to respiration, attention is directed to the natural or induced anærobic character of many ciliates as well as to the behaviour of other infusoria when supplied with excess of oxygen. Loeb's view that the presence of a nucleus is essential to the oxidation of the cell is not upheld. An interesting account is given of the nutrition and movements of protozoa, but the behaviour of forms such as *amœba*, which contain chlorophyll corpuscles, is almost entirely neglected, in spite of the work of Grube and Doflein, and there is room for direct observation on the supposed ingestion of bacteria in the case of many infusoria. With regard to the significance of fertilisation, the author concludes very much in the sense of Doflein as given in his recent

THE PHYSIOLOGY OF THE PROTOZOA.

Einführung in die Physiologie der Einzelligen (Protozoen). By Dr. S. von Prowazek. Pp. v+172. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 6 marks.

THIS work differs from all other treatises on the growing subject of protozoology in being largely devoted to the problems of function. It is a condensed account of our present knowledge of this highly important and difficult subject, and consists of summaries of physiological results, often too short to be easily intelligible, but of considerable value to that increasing number of investigators who are interested in recent advances in this field. The author is a well-known and active worker, and does not hesitate to press

large work, reviewed in this journal on March 3. The act is regarded as one of harmonising the discrepancies that arise through specialisation of chromatic and motor organs in the male, and of assimilative structures in the female.

In conclusion, we have to regret the absence of an index or of a list of references, but we may recommend the work as an extremely useful and compact summary of recent work on the physiology of the protozoa.

AMATEUR ASTRONOMY.

An Easy and Concise Guide to the Starry Heavens, arranged as a Companion to the Umbrella Star Map and Revolving Star Dome for Instruction in Astronomy. By D. McEwan. Pp. 137. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1910.) Price 5s.

THE idea of using the concave surface of an umbrella as a star map is excellent, but, of course, not new. The portability and convenience of manipulation of such a stellar guide are obvious advantages, while the aspect in which the constellations are seen, unlike the view in a celestial globe, corresponds to the reality. The actual construction of such a chart of the sky might quite well form part of the practical work of every elementary course of astronomy.

A simple guide to the heavens, to be used in conjunction with, and in explanation of, such an adapted umbrella should be worthy of notice. It is to be regretted that the present book, while pretending and seeming at the first glance to fulfil just such a function, cannot be recommended. Somewhat scrappy and not always trustworthy, it gives the impression of being the work of an amateur.

After a preface and an introduction, chapter i. devotes a page and a half to astronomical magnitudes and units, and also describes a chart of the north circumpolar stars, which is reproduced. The stars contained in the various "segments" of the "Umbrella Star Map" are dealt with in chapter ii. The persistently misnamed "segments" are really the sectors formed by the ribs and circumference of the umbrella. In the text a certain amount of information is given about the constellations and the principal stars as they occur in each "segment," while charts show their relative positions and make a very rough attempt to indicate stellar magnitudes. The scheme to represent magnitude described for the actual umbrella is not in use, apparently, in the companion book. A separate key-map in each case is used to indicate names. A table, giving for each star a serial number, the Greek letter, constellation, magnitude, right ascension, and declination, completes the information for a typical "segment." General astronomical information is introduced relative to special objects as they are encountered, so that, without reference to the index, it is difficult to find the treatment of any particular subject.

The information given is often amateurish and sometimes in error, while plausible misstatements which would trouble a beginner are to be found. The solar spectrum, for example, is "well known to consist of the seven colours," while by observations

made through a long tunnel, or from the bottom of a well, "any star coming into the field of view would be seen even in daylight." Under the title "Major Planets" are described Jupiter, Saturn, Uranus, and Neptune, while the "Minor Planets" are Mercury, Venus, and Mars. To Jupiter is ascribed only five moons, the date of discovery of the fifth being given.

Chapter iv. describes a folding key to the "Umbrella Star Map," and the next chapter deals with the solar system in a bald way. In the pages devoted to time, the sun is described as being due east at six o'clock, while amplitude is misdefined in the following chapter.

A section devoted to scouting and an index to constellations bring to a conclusion a book which needs a thorough revision if it is to be of service.

ELEMENTS OF PHYSICS.

(1) *A First Book of Physics.* By Dr. L. Lownds. Pp. vii + 145. (London: Macmillan and Co., Ltd., 1910.) Price 1s. 6d.

(2) *An Elementary Text-book of Physics.* Part IV., Heat. By Dr. R. W. Stewart. Pp. iv + 246. (London: C. Griffin and Co., Ltd., 1910.) Price 3s. 6d. net.

(3) *Matriculation Magnetism and Electricity. A Text-book for Use in Schools and Colleges arranged for Modern Methods of Teaching.* By Dr. R. H. Jude and J. Satterly. Pp. vii + 415. (Cambridge: University Tutorial Press, Ltd., 1910.) Price 4s. 6d.

(1) THIS book is intended for those beginning the study of physics. The contents do not cover the whole ground usually dealt with, but are confined to the principles of measurement, mechanics, and heat. The reason given for this is that it is now customary in secondary schools to limit the courses of study to these subjects for the first two years. Students reading this book are expected to be acquainted with the elements of mathematics, and to be able to perform for themselves the numerous experiments described in the text. Descriptive and numerical test questions form the conclusion of each chapter.

There is no doubt it will be found a very useful book. The most pleasing feature is the exactness with which statements are made, at the same time preserving great simplicity of language. Added to this, the printing and diagrams are good, and advantageous use is made of heavy type for the more important statements of principles.

(2) Dr. Stewart's fourth volume is written in much the same style as the three preceding ones. It is suitable for those possessing no previous exact knowledge of the subject of heat. Attention is paid to all the elementary thermal phenomena, the order of treatment being the usual one. What has been said above in reference to Dr. Lownds's book applies also here. Few difficulties should present themselves to an earnest reader of the subject. Here also many experiments are described, but, with the exception of a few worked in the text, examples are absent.

There is rather a surprising omission, however, in the chapter on the transference of heat by radiation.

Although the essential similarity of light and radiant heat is insisted upon, and the distinction between heat and radiant heat clearly drawn, no experiments to illustrate the application of the laws of reflection to the latter are given. The experiment with two concave mirrors in which heat is transferred by radiation from one focus to the other is surely one of the best for impressing on students the connection between the various radiations.

(3) This much longer volume is not nearly so good as those just commented upon. It is written specifically for the London matriculation examination, and it may be said at once that it is much too difficult. It would have been better if less material had been treated more fully. As it is, the book is overcrowded with statements which it would be impossible for the elementary student to deduce for himself—he must merely commit them to memory. He is told, for instance, that the “dyne” is the weight of one gram divided by 981, a statement which is not only incorrect, but conveys no impression of the importance of the absolute unit of force. A long discussion is entered upon as to the relative merits of the two-fluid and one-fluid theories of electricity. The matriculation student is advised in the text to accept the one-fluid theory, and then a footnote tells him that probably he will have to revert to the two-fluid theory because recent experiments point to the existence of positive electricity. Controversies of this kind are altogether out of place in elementary text-books; they only confuse the student.

There is a profusion of examples at the end of each chapter. These are, as a whole, good; but it is doubtful whether the pupil would be in a position to answer them intelligently if left to himself.

OUR BOOK SHELF.

Studien über die Bestimmung des weiblichen Geschlechtes. By Prof. Achille Russo. Pp. v+105. (Jena: Gustav Fischer, 1909.) Price 3 marks.

PROF. Russo has published a general account of very interesting experiments which he has made on the determination of the female sex in rabbits. His method was to dose the animals with lecithin—a well-known constituent of yolk of egg—administering it in various ways. He injected it into the peritoneal cavity or subcutaneously; he even introduced it through the mouth. From control experiments it seemed clear that one of the results of introducing the lecithin in considerable quantity into the system, where it normally occurs in many different tissues, was the accumulation of deutoplasmic material in the ovarian follicles and in the oocytes; and Russo found that rabbits treated in this way, and subsequently mated, had more female than male offspring. Sometimes all the offspring were female. The security of the conclusion that the lecithin treatment was the condition of this disproportionate number of female offspring depends on the number of cases investigated and on the avoidance of selected stocks. Russo is well aware of this, and he does not betray any dogmatism.

In the normal ovary, or in what he believes to be the normal ovary, Prof. Russo distinguishes two kinds of ova, one kind rich in nutritive material deposited in the zona pellucida and in the vitellus, the other kind with little or none. The lecithin

treatment increases the number of the richly equipped, highly anabolic ova, and they are (if the correlation has been adequately substantiated) the female-producing ova.

In young rabbits of five or six months the ova show little vitelline material, no chromidial corpuscles, and a clear zona pellucida. This is a sign of deficient nutrition, and there is some evidence that these very young ova tend to be male-producing. As the nutrition of the ovary improves with age, the ova become better equipped with “embryoplasmic” material, and tend to be female-producing. The general result of Prof. Russo’s interesting experiments is to show that the ovary is a very plastic organ, responding to the lecithin treatment by an increase in the number of female-producing ova. He suggests that the lecithin treatment of males may affect the spermatozoa in an analogous way—in their mitochondrial apparatus. In developing his thesis, the author communicates many valuable observations on the germinal epithelium, the granulosa, the zona pellucida, and the various chromatic substances which appear in the ooplasm. Statistics of the experiments and details as to methods employed are duly submitted, and the whole discussion is conducted in an admirable scientific temper.

Report on the Mines and Mineral Resources of Natal (other than Coal). By Dr. F. H. Hatch. Pp. xii+155+vii plates. Published by order of the Natal Government. (London: Printed by R. Clay and Sons, Ltd., 1910.)

THIS little volume, which contains the results of an eight months’ prospecting trip in the colony of Natal, undertaken by Dr. Hatch on behalf of the Natal Government, is extremely disappointing, as the only conclusion that can be drawn from it is that Natal possesses no mineral, other than coal, that is deserving of any serious attention. Dr. Hatch sums up his impression in the words, “no large well-developed metal mines, either of the precious or of base metals, exist in Natal.” To which may be added that the report indicates that no deposit has yet been met with which promises to be worth developing or to be likely to be mined with any measure of success, and the same is true of the non-metallic deposits—coal, of course, being always excepted. Deposits of gold, copper, tin, iron, manganese, chromium, lead and silver, molybdenum, of limestone, phosphate, graphite, asbestos, gypsum, salt, nitrate, oilshale and petroleum, building stone, slate, clay, &c., are known to exist and have here been reported on, but nothing of commercial value seems to have been met with anywhere. The value of the mineral output of Natal for 1908 is given as 741,158*l.*, out of which the value of the coal is 737,169*l.* Further comment is needless.

Modelling from Nature. A New and Original Method of Clay Modelling. By Lilian Carter. Pp. 32; and 16 plates of models copied from nature. (London: Cassell and Co., Ltd., n.d.) Price 1*s.* 6*d.* net.

THOUGH we are sceptical as to the newness and originality of Miss Carter’s method of teaching clay modelling, there is no doubt that work of the kind she describes interests young children, and assists in making them accurate and alert in examining natural objects, as well as deft with their fingers.

The Time of the Singing of Birds. Pp. 126. (London: Henry Frowde, 1910.) Price 3*s.* 6*d.* net.

THIS anthology of verse will appeal to all bird-lovers. Three compilers have been able, with the cooperation of authors and publishers, to bring together a charming collection of modern poems, as well as the better known older verses dealing with bird life.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Tail of Halley's Comet on May 18-19.

PERHAPS the following observations I made of Halley's comet on the night of May 18, when it crossed the sun's disc, may be of interest as a record.

On that evening I crossed by steamer from Palermo to Naples, as I wished to have a clear horizon all round to see what would happen. The vessel leaves Palermo at 7 p.m. and arrives at Naples at 7 the following morning, and it seemed the best place for a view.

I may say that I had been watching the comet every night from May 7, and was quite familiar with its appearance. I say this because it was quite different from that of any other comet I can remember. The first time I saw the tail was when I came on deck on May 7 about 4 a.m.; the nucleus was not visible, but right across the sky was a long white streak just like a cloud, quite as opaque as a cloud, and I could not believe it was the tail of the comet at all; but on coming on deck the next morning at 2.15 I saw the same white streak, but this time with the nucleus, also of a very white colour.

I had no instrument with me to measure the length of the tail, but I got the quartermaster to lay it off on the ship's compass; he put it down on paper; it was E. $\frac{1}{2}$ N., and the end of the tail was E. by S. $\frac{1}{2}$ S., which is about 22 $\frac{1}{2}$ ° horizontal measurement; the real length of the tail itself I could only estimate as "about half-way across the sky."

On the night of May 18, as soon as it got sufficiently dark, the tail was plainly visible; there was a ten-days' old moon which rather interfered with the view, but about 2 a.m. it had got sufficiently low and behind a thin but convenient bank of cloud, so that it did no further harm to my observation. Of course there was no nucleus to be seen; that was down below with the sun, but the tail was quite different in character from that which I had seen on the previous nights. It was not a long streak of white, but a confused mass of pinkish light extending along the horizon for 40° or 50°, and then stretching right across the sky, coming gradually to a point at the wide naked-eye double star (α and β Capricorni) below Altair, in line with the three stars. The tail narrowed in on its course upwards, and passed just below the Great Square of Pegasus, γ Pegasi being well in the tail, but α Pegasi was clear of it.

I continued watching the tail for shooting stars in its neighbourhood, but I only saw three or four; there was nothing particular about them, except that they seemed to start from the edge of the tail, which was well defined, and only travelled 4° or 5° from it.

But there still remains a curious sight to describe which I saw on the other side of the ship.

About 2.15 a.m. I went aft to get the time from the chart-room clock, and, happening to look over the port side of the ship to the west, I saw a pillar of light on the opposite side of the earth to that from which the comet's tail came up; it was about 45° (roughly) high and 50° or 60° broad at the horizon; it was straight up and down, and was much brighter in the middle than at the sides, and the bright part seemed like a pillar of light, but the lighter and more transparent sides came up and formed a large cone. The setting moon was a good deal to the right of the cone, and was somewhat clouded out, and had no connection with it. At the time I took the cone to be the Gegenshein, and did not pay much more attention to it, beyond looking now and then to see that it was still there.

Both the cone and the tail were visible from 2.15 to 3.5 a.m. It is quite possible that at this time the earth may have been passing through some of the tail, and had divided it in two.

I was up at Monte Casino the next night; unfortunately a fog came down on the mountain, but I heard that at the observatory they had seen an arch of light over the

part of the horizon from which the tail came. I did not see this; but I was at sea-level, and the observatory is up some 1500 feet.

HOWARD PAYN.

20 Hyde Park Place, London, W., June 17.

AN observing party was organised at this college for the purpose of taking note of any physical disturbances which might occur during the passage of the earth through the comet's tail, particulars of which will be published later. Our object in now writing is to put on record a remarkable appearance which presented itself at about 3.30 on the morning of May 19.

The comet has been visible here to the *unaided eye* since April 12, and up to the morning of May 18 the tail presented what may be termed a normal appearance, i.e. smaller at the nucleus than at the extremity, but on the morning of May 19 the character had altogether changed. At about 3.30 a luminous patch was seen at an altitude of about 20° from the horizon, and in the place where the tail formerly appeared. There were some clouds near the horizon, and as these cleared away the whole of the tail became visible, extending at 4.30 right up to the zenith, and there being lost in the Milky Way.

When there were no clouds the sky was remarkably clear, the Milky Way shining most brilliantly. The light from the tail of the comet was polarised, but not so distinctly as was the case with the normal tail on previous mornings. The tail persisted until daylight. It, to some extent as regards shape, simulated the Zodiacal Light, but at the same time was essentially different, and did not appear in the usual situation of the light, as it was many degrees to the north of the sun. It was much longer, narrower at the base, and ten times brighter. There is no question but that it was the comet's tail.

At 4.30 the upper half of the tail was quite free from cloud, and the gradual narrowing towards the upper end was most marked. It seemed from the curvature of the edges that a portion was missing from the under side of the tail. The conviction was borne in upon us that we saw a portion of the tail blotted out or cut off in some way, and this was certainly not done by cloud. Was it done by the earth's atmosphere? The following morning was cloudy, and nothing was seen at 3.30, but the comet appeared in the western sky at 5.40 in the evening.

Observations were not taken on succeeding mornings, which perhaps was a mistake, as something may have been left behind after contact with the earth, if contact really happened.

W. A. DOUGLAS RUDGE.

University College, Bloemfontein.

The Colour of Pure Water.

HAVING noticed the colour of the sky, of air, and of water under different conditions, I was reminded on reading the report of Lord Rayleigh's lecture (NATURE, March 10) of a few notes I had made from time to time, and now think they may prove of interest.

First, optically pure water cannot be obtained by distillation. Prof. Tyndall asked me to prepare some pure water for him, which I attempted, first by distillation with acid permanganate, and then re-distilling this from a copper vessel and collecting the liquid in a bottle placed in a large bell-jar of hydrogen, a gas which is known to provide an optically pure atmosphere. The resulting water was not optically pure. Pure water was prepared by Tyndall by melting clear block-ice in a vacuum. Its colour was blue when seen through a tube 3 feet long.

The colour of a hard water which has been softened by Clark's process may be seen at the Colne Valley water-works, visible from the train on the up line just south of Watford Station, and at Joynson's paper works at St. Mary Cray, in Kent. When the members of the Society of Chemical Industry visited these works some years ago, they were much struck by the very beautiful blue of the water. It was even suggested that it had been purposely coloured with a very pure blue dye. Water of similar purity, containing very little mineral matter, being remarkable for its softness, comes from the Greensand below the London Clay. Such blue water I have noticed

in the bed-rooms and bath-rooms of the Euston Hotel, the supply coming from an artesian well.

There are two natural sources of extremely pure water with which I am acquainted, and I cannot believe that the water from the second source receives any colour or appearance of blue through the reflection of light by fine particles in suspension. The first is in the Fairy Loch beside Loch Lomond, situated on a little promontory south of Tarbert. It is difficult to see that there is any colour in the water except at a point where it wells up from a fissure in the rock and passes over a vein of milk-white quartzite which crosses the bottom; here it exhibits a beautiful blue colour.

The second source is the Wells of Dee, situated in the Larig (Learg Gruamach) at the foot of Ben Macdhui, and between it and Braeriach, about half-way between Deeside and Speyside. It is a small tarn or pool with a bottom like that of three miles of the pass—nothing but large pieces of splintered red granitic rock. It stands about 2700 feet above the sea. The water, according to my recollection, passes down underneath broken rocks in a narrow rift in the mountain side, and is derived from the melting of snow on its northern slope near the summit, which is 1598 feet (1500 feet by my aneroid) higher and above all vegetation. The pool is too small to be shown, but the stream which runs out of it appears on the Ordnance map (Sheet 64, 1-inch scale), springing from the highest point of the pass. Some small lochs on the opposite side of the pass, about $1\frac{1}{2}$ miles further south, are also called Wells of Dee, and are the principal source of the river of that name. The bottom of the small pool is visible everywhere, and its apparent colour varies in proportion to its depth, being dull red near the sides, to a brownish-purple where it is apparently deepest. The pure blue colour of the water was only seen on putting a white object, such as a piece of porcelain, into it. The effect of the blue colour of the water on the light reflected from the red rock at the bottom is to give it a purple tint.

It is evident that the blue is wholly due to the absorption of rays of complementary colour, because if it were not the reflection of blue rays by suspended fine particles would be seen against a dark ground on looking into the water. As a matter of fact, the water when undisturbed on the surface was not visible; it was very difficult to form any idea of its depth, everything on the bottom being sharply defined. These observations were made under a diffused and subdued light in a very clear atmosphere, the light being of uniform intensity over the whole sky, which was entirely covered with small greyish clouds, no direct sunlight or blue sky being anywhere visible. A fact adverse to the view that the blue could be reflected light is that the light which escapes reflection has a reddish-golden colour. In a hazy atmosphere when the sun is low and we look towards it, we see the golden colour; in the opposite direction we see the blue opalescence. The white light from the sky traversed the water in two directions to the bottom, and then, by reflection, back again, and it is safe to say that these two opposite colours would neutralise each other.

W. N. HARTLEY.

Royal College of Science, Dublin.

The Temperature Conditions in Clouds.

As one of those who expressed doubt as to the possibility of the existence of the temperature conditions in a cloud described by Prof. Rotch at Winnipeg, I have been greatly interested by the letters of Dr. Aitken and Mr. Palmer (*NATURE*, November 18, 1909; June 2, 1910), but the examples which they quote do not present the same difficulty as Rotch's result, nor do they explain it.

The increase of temperature at or above the upper surface of clouds, which Dr. Aitken mentions, has been frequently observed in kite ascents at various places, while the two examples given by Palmer are (1) alto-cumulus, a wave cloud of the Helmholtz type formed at a surface of discontinuity: the temperature decreases upwards in the cloud itself; (2) alto-stratus, a shallow cloud formed also at a surface of discontinuity; here, too, the temperature decreases upwards in the actual cloud. In neither case do we attribute the temperature peculiarity to the clouds, but regard the clouds rather as the result of the temperature conditions.

Rotch, however, found that in a cumulus cloud, 2 km. thick, the temperature increased from the base upwards by more than 5° C., and the increase was most rapid in the lower part of the cloud.

Dr. Aitken suggests that the sun, shining on the upper part of a cloud already formed and warming it, would account for the phenomenon, or at least for inversions near the upper surface of a cloud; but if the sun raised the temperature of the upper part of the cloud, that part would be no longer in equilibrium with its surroundings and would rise upwards. Its temperature would, in consequence, fall under ordinary conditions until equilibrium with the surrounding atmosphere again supervened. The sunshine could only result in an actual increase of temperature if there existed already above the cloud an atmospheric layer of higher temperature than that in the cloud itself.

Now if Rotch's cloud were formed by convection currents according to the generally accepted ideas, the summit would be initially at least 10° C. colder than the base, and consequently its temperature must have been raised 15° C. to bring about the observed state of affairs. It is not easy to imagine how this could be done without dissipating the cloud, because it is unlikely that a cloud 2 km. high would be formed by convection currents without the upper parts losing some of the water-vapour which they originally contained, and in the present instance evaporation would begin before the temperature had risen 10° C. Moreover, the ascent took place about 9 a.m. in May; while assuming that 35 per cent. of the incident sunshine is absorbed by the cloud (Abbott and Fowle found 65 per cent. reflected) and that no loss of heat by radiation occurred, it would take a twelve-hour day near the equator to raise the mean temperature of a hemispherical cloud 2 km. high by 9° C. It appears certain, therefore, that solar radiation incident on the cloud cannot account for the phenomenon.

The only reasonable explanation I can put forward is that air below and above an inversion surface is lifted bodily upwards sufficiently far for condensation to take place on both sides. The balloon ascent must have been made in a region of convergence, and the mechanism by which the conditions were produced appears to have consisted of a cold, damp easterly wind penetrating beneath a warm upper current from a more southerly point.

Cambridge, June 6.

E. GOLD.

The Fertilising Influence of Sunlight.

WITH reference to Dr. Russell's remarks on this subject in *NATURE* of April 28, I should like to remark (1) that my point was not so much that toluene removed toxic material from the soil as that it rendered it insoluble. The question of washing out material from the soil was not raised by me. (2) and (3) Dr. Russell seems to beg the question by taking "fertility" and "bacterial activity" as synonymous. He has not, so far as I can find, proved that the addition to partially sterilised soil of an aqueous extract—or of a portion of an untreated soil—increases crop production (in contradistinction to soil fertility as indicated by bacterial activity and ammonia-production). If such is found to be the case, it would certainly require further experiment before it could be explained on the toxic theory.

With regard to water cultures, in one experiment the water was boiled every two days in some of the cultures, while in others it was not boiled. At the termination of the experiment—two days after the last boiling—the bacterial contents were found to be (per c.c.) :—

In unboiled cultures ...	... { 2500 2100 }	Mean = 2300
In boiled cultures ...	... { 350 400 }	Mean = 375

The quantity of material precipitated by potassium sulphate from the two solutions was (per million) :—

Unboiled solution ...	... 30
Boiled solution ...	... 30

It would appear that if this substance had been produced by the bacteria there ought to have been at least several times as much produced in the unboiled as in the boiled solution, since the bacterial content of the latter was never more than one-seventh of the former, and must have been for most of the time almost nil.

I have now completed an experiment in which the following results (among others) were obtained with the "great millet" (*Sorghum*), single plants of which were grown from germinated seeds for ten days in soil (1) unheated; (2) heated to 97°; and (3) heated to 170°:—

Treatment of soil	Green weight of plants (in grams)			
Unheated ...	145.5	...	Mean of 8; max. 314, min. 0	
Heated to 97°	151.7	...	" " 353, " 36	
" 170°	1055.6	...	" " 1470, " 835	

At 170° the soil was obviously sterilised completely, but the yield was four times that from the partially sterilised soil.

F. FLETCHER.

School of Agriculture, Giza, May 14.

For experiments are carried out by Dr. Hutchinson and myself to run parallel with the chemical and bacteriological examinations of the soils. Productivity is not regarded as synonymous with bacterial activity, although in general the two are intimately related. An exception occurs when the soil has been heated sufficiently to decompose some of the organic matter present with formation of plant food. As stated in my letter, the addition to tuluened soil of an aqueous extract of untreated soil increases crop productivity.

E. J. RUSSELL.

Rothamsted Experiment Station, Harpenden.

Ooze and Irrigat on.

THE interest which my former letter has aroused (*NATURE*, June 9) induces me to offer a few further remarks. For a hundred years it was usually thought that all our earthworms were of one kind, and the term *Lumbricus terrestris* was glibly used. Thanks to the help I have received from curators, gardeners, and nature-lovers at Kew, Chelsea, Oxford, Cambridge, Edinburgh, and elsewhere, my list of British *Lumbrici* now stands at nearly forty species, belonging to upwards of half-a-dozen genera.

In like manner, nearly all fresh-water worms have, until recent times, been relegated to one species, and *Tubifex rivulorum* was the magic name. Our knowledge of these wonderful ooze-workers is still deplorably limited, but a little progress is being made in their study. We now know that the so-called *Tubifex* is not a tube-maker, and that it includes such genera as *Limnodrilus*, *Stylodrilus*, *Trichodrilus*, and others, which represent more than one family, with upwards of twenty known British species. Every year is bringing new forms to light, and each new discovery supplies a missing link.

But, in addition to the ooze-makers belonging to the *Tubifex* group, I now find that certain species of white worms, which are destitute of red blood, and are usually grouped together as Enchytræids, frequently find employment in this capacity, and often get introduced among valuable plants in garden and field, to the great loss of the horticulturist. Hence the need of a fuller and more systematic study of this branch of science. Here is a subject worthy of Earl Carrington's new committee.

One correspondent remarks that the subject is "very suggestive." He adds a query which needs attention. "I suppose the worms cannot take nitrogen directly from the air like the legumes? If they could assimilate it, of course a very important point would be settled by establishing that fact, though the probabilities are that they cannot." I should like to know what biologists have to say.

Great Malvern.

HILDERIC FRIEND.

New Development in Library Work.

WITH the permission of the council of this society, I have recently instituted a departure in library practice, which I have been asked to describe to you, in the belief that other learned societies may think it worth while to try the experiment.

Fellows of medical and other scientific societies living abroad suffer many disadvantages as compared with their resident brethren, and none so great or so much felt as the deprivation of the use of their libraries. To all our fellows living abroad we now offer to prepare for them, gratis, short abstracts of papers, and even of books, upon

any medical subject, and to search for or check references to medical literature.

The innovation has been most warmly welcomed, and from remote parts of the world we have received many grateful letters. Men living in the Chitral Valley, in the Sudan, in Christmas Island, and equatorial Africa, who for years have had their work hindered by lack of library conveniences, say that what we now do for them is even better than they could have done for themselves had they been in London, for even here they would probably not be able to devote the many hours requisite for the research required to produce the results which our machinery can procure for them with a minimum of time and labour.

J. Y. W. MACALISTER.

(Secretary.)

The Royal Society of Medicine, 15 Cavendish Square, W., June 16.

Altruism in Animal Life.

YOUR Deal correspondent, Mr. Christopher Morse, has told you (p. 437) of an ablutinary caterpillar; let me tell you of life-saving "eels" in vinegar. I was examining the creatures with a microscope when one of them became stranded, owing to its having strayed into the shallower portion of the vinegar-drop, and there it wriggled the while the fluid grew shallower still. Just as it seemed on the point of giving its last expiring wriggle, what was my amazement to see three or four other "eels" make a dash from the deeper vinegar, and force themselves across the shallow to where lay their stranded comrade.

Then occurred the most singular thing it has ever been my lot to witness in the world of minute life. These tiny life-savers rushed with all the energy of desperation at their now quiescent comrade, and worked it slowly towards the deeper part of the fluid, and they reached it, too, in time to save their own and the other's life.

J. H. ELGIE.

Colours of Plasmodia of some Mycetozoa.

FROM my experience in this part, I here note the colours of plasmodia of a few Mycetozoa to supply the desiderata in the late Mr. Lister's "Monograph," London, 1894:—

<i>Physarum melleum</i> , Mass.	Yellow, then orange-yellow
<i>P. tenerum</i> , Rex.	Bright primrose-yellow
<i>P. crateriforme</i> , Petch, in litt. (Ceylon and Japan)	Dull ochreous
<i>P. gyrosium</i> , Rost.	Dingy ochrey-yellow, then dirty pink
<i>Arcyria insignis</i> , Kalchbr. and Cke.	Colourless, then milky-white
<i>Perichaena variabilis</i> , Rost.	Watery cinnamon

The following species have their plasmodia mostly of the colours as recorded by Mr. Lister, but at times of the subjoined colours:—

	Normally coloured	Occasionally coloured
<i>Physarum incurvum</i> , Pers.	Watery-white	Pale yellow
<i>Stemonitis splendens</i> , Rost., B. Webber.	Creamy-white	Sulphur-yellow
<i>Lycogala minutum</i> , Pers.	Rose-red	Bright yolk-yellow or milky-white

As regards the last-named species, Miss Gulielma Lister writes to me:—"Since my father's 'Monograph' was written we have several times had instances of the athalia arising from a white or cream-coloured plasmodium."

Now a few words on the number of species of the Japanese Mycetozoa. In the *Journal of Botany*, April, 1904, pp. 97-9, Mr. and Miss Lister noticed eighteen species collected by Mr. S. Kusano in Tokio, eleven of which had been enumerated in Prof. Matsumura's "Index Plantarum Japonicarum," published a few months previously in the same year. Since my return home from England in 1900, in order to keep my promise to Mr. George Murray, then keeper of the Botanical Department, Natural History Museum, I have sent for determination to Mr. and Miss Lister every characteristic specimen I could find in this province, which has resulted in the Japanese species of Mycetozoa actually reaching a total number of eighty-six, including the two new species *Arcyria glauca*, Lister, and *Hemitrichia minor*, G. Lister, not to mention several new varieties and forms.

KUMAGUSU MISAKATA.

Tanabe, Kii, Japan, May 21.

KOREAN GEOLOGY.¹

BEFORE the year 1883, when treaties were made by which Europeans were admitted to the country, Korea was a *terra incognita* to geologists. Captain Basil Hall had, indeed, made a few observations upon rocks examined by him on the coast dur-

The work deals mainly with the southern part of the peninsula, and describes three traverses made by the author; the important discoveries made by Mr. Yabé of fossil plants and foraminifera have been of great service in determining the geological age of some of the rock-masses.

Overlying a great mass of gneiss, mica-schist, and phyllite rocks, which may be Archæan in age, though Dr. Kotô inclines to the view that they are metamorphosed Mesozoic deposits, there are great masses of granitic rocks, including some very interesting types. Above these granites are found a series of strata, which are shown by the plants they contain to be of Jurassic age. With these deposits are found evidences of contemporaneous volcanic action, while quartz-veins, with gold also occur in them. In Japan these Jurassic strata appear to be underlain by Fusulina limestones of Carboniferous age, and anthracite beds containing Rhætic plants. Rocks of this age appear to occur in other parts of the peninsula, but not in the district examined by Dr. Kotô.

Of younger age than the Jurassic appear to be the series of eruptive rocks which our author classes as "Neogranites." These consist of quartz-porphyry (quartz-tsingtauite) and orthoclase-porphyry (tsingtauite), with a variety of granite-

porphyry for which the author proposes the term "Masanite"—the name being derived from the port of Ma-san-pho—and an aplite-granite ("Granomasanite"). Dr. Kotô regards his masanite as worthy of receiving a distinct name, from the peculiar mode of the intergrowth of quartz and plagioclase

FIG. 1.—Whirlpool of Myōng-yang ferry showing special topography with narrows and indentations which probably cause the eddy produced in the shore current by the reflex motion.

ing his voyage in 1818, and casual references may be found in other authors concerning what could be seen from the sea. In 1883 and 1884, however, a German geologist, Dr. Gottsche, made a rapid geological reconnaissance of the country, and the rock specimens he obtained were described by Prof. Justus Roth. Almost simultaneously with Dr. Gottsche, Prof. Gowland, then head of Imperial Mint of Japan, made a journey through the country for the purpose of archæological investigation, and the numerous specimens which he collected were described by Mr. (now Sir Thomas) Holland in the Geological Society's Journal for 1891. In the accounts of his explorations in China (1900-3), the late Baron F. von Richt-hofen was able to give additional particulars concerning the geological structure of the country. Dr. Bundjirô Kotô, the author of the work before us, published his account of the orography of the peninsula in 1903, a memoir which has given rise to a considerable amount of controversy.

As the result of the Russo-Japanese war, however, the country has been much more fully opened up, and the Japanese Government has sent out a number of expeditions for the purpose of inquiring into the natural resources of the country. Unfortunately, most of the reports of these explorations are written in Japanese, but Dr. Kotô has rendered a great service to geologists by embodying the most important results of these recent researches in his memoir.

FIG. 2.—Remarkable erosion-form, viewed from the south. It is a double-peak, formed of Mesozoic conglomerate resting upon a gneiss-granite.

felspar of which it is mainly composed. These plutonic rocks pass into a series of effusives classed by the author as different types of "felsophyres."

Lying unconformably upon the greatly disturbed Mesozoic strata, are found sandy strata with seams of poor lignite, while more recent deposits are only

represented by lava sheets of basalt and hornblende-andesite.

The author indicates many points in the geology of Korea on which conflicting opinions have been maintained by different authors, and it is evident that much work remains to be done in the country before some of these problems can be regarded as settled. But, in the meanwhile, this work may be accepted as giving a first sketch, clear and accurate, of what is known on the subject, with full references to the works of other authors.

The plates accompanying this memoir are by no means the least valuable part of the production. From Dr. Kotô's own photographs a hundred small but admirably executed views of Korean scenery have been prepared, two of which are here reproduced.

J. W. J.

IN THE TORRID SUDAN.¹

ONE feature about this and all other recent books dealing with the Egyptian Sudan which arrests the attention is the singular lack of picturesque scenery characteristic of this vast region away from the frontiers of Abyssinia or the temples and rocks of Dongola. Apparently one has to reach almost to the verge of the Congo Basin on the south-west, or to enter the Uganda Protectorate on the south, before the eye is gratified by remarkable landscapes. Even the river-courses outside desert influence are poor and unimpressive in their vegetation as compared with Equatorial, West, and South Central Africa. The branching düm palms, with their half-circle fronds, an occasional monstrous baobab or banyan-like fig-tree—perchance a clump of tall acacias in the gracious aspect of the rainy season—alone relieve the monotony of grassy plain and stony, sun-smitten wastes; while, of course, a considerable portion of the area of the Anglo-Egyptian Sudan is swamp, and swamp which is singularly unprepossessing, for it offers an unbroken horizon of dull bluish-green, unmarked by a single palm-tree or other noteworthy object.

The swamps of Central and Western Africa provide some of the most striking pictures to be obtained by the painter or the photographer in all Africa; immense *Raphia* palms, tall and exquisitely beautiful *Phoenix* palms, and gigantic trees two hundred feet in height rise above the stagnant water and the masses of papyrus, arums, terrestrial orchids, and amarantaceous plants. Mr. Tangye is conscious himself of the lack of picturesqueness in the Eastern Sudan (as compared with other parts of Africa). "The country, as a rule, is either too dry during a great portion of the year, or, farther south in the great swampy regions, too wet. It is annually devastated by destructive grass fires, which scorch and stunt the trees, leaving the deep-seated grass-roots unharmed and manured by the salts of the burnt ash." The trees are "small, straggly specimens" of acacias for the most part, with a few *Borassus* and *Hyphæne* palms.

As to these palms, it is interesting to learn that the elephants apparently feed on the fruit of the

Borassus (afterwards ejecting its stone). This fact was mentioned by the writer of this review some years ago, but was denied by other "Africans," who alleged that it was only on *Hyphæne* fruits that the elephant regaled himself.

The author has some interesting remarks to make on pp. 56 and 57 as to the "painted forests" of acacia, the appearance being due to the irregular peeling of the bark, together with the exudations of red gum. In these acacia woods the guinea-fowl are present in thousands.

There are interesting notes on the baboons (p. 78) and on the giraffe (pp. 79-80). The manners and customs of elephants are well described, together with their apparent, if often misplaced, sense of humour (they will pass through native villages demolishing the huts, but refraining from injuring the people; they will also come and stamp out native gardens, or in attacking native caravans will merely scatter their luggage right and left).

There is a good deal of information about the Nilotic negroes, much of which is original. The author mentions that an average of height taken by

FIG. 1.—Nuer Paddling Canoe From "In the Torrid Sudan."

the late Dr. Pirrie gave 5 ft. 11 in. for the men, while heights of more than 6 ft. were quite common. He also directs attention to certain points of similarity between the Nilotic negroes and the Melanesians which are not unworthy of notice, considering that they are here and there backed up by evidence of physiological affinity, though, of course, the gap between these two manifestations of the negro type is enormous both in millenniums and miles. Quite recently Dr. A. Keith has pointed out the craniological affinities between certain tribes of the Congo Basin and the Andamanese. The present writer has noted also certain similarities in weapons and body adornments between the Australoids and the people living on the north-eastern verge of the Congo Basin.

The awful ravages of the bush-fires in the Sudan have been already alluded to. This, no doubt, is the principal cause of ancient and modern deforestation, which has done so much to affect the surface and climate of this part of Africa.

A determined effort out of somewhat needless concern for the feelings of the French (who had nothing to be ashamed of about over Marchand's marvellous

¹ "In the Torrid Sudan." By H. Lincoln Tangye. Pp. xii + 300. (London: J. Murray, 1910.) Price 12s. net.

journey) is being made by the Anglo-Egyptian authorities to erase the name of Fashoda from the map and to call it instead Kodok. But the earlier and more picturesque name seems likely to survive, and the place itself (according to the author) is distinctly going ahead in spite of its evil reputation for malaria. On p. 286 the author gives an interesting account of a tame lion belonging apparently to a British officer resident in Omdurman at one time. When a small cub he had been soundly thumped by his master's fist to reduce him to order. As he grew into a large beast he remained mortally afraid of a thump, though its actual meaning to him then was nothing. He was perfectly good-humoured and kindly, but too playful, and delighted in jumping out on people in order to startle them, or leaping on to them in order to bear them to the ground. He would also climb the telegraph-poles (for, despite current belief to the contrary, lions are able to climb, as the present writer can bear witness). On one such occasion, from the top of the pole on which he was resting his chin to get a good look out, he descried his master coming

frequently saw a mass of white, translucent jelly lying on the turf, as if it had been dropped there. These masses were about as large as a man's fist. It was very like a mass of frog's spawn without the eggs in it. I thought it might have been the gelatinous portion of the food disgorged by the great fish-eating birds, of which there were plenty about, as kingfishers eject pellets made up of the bones of the fish they eat, or that possibly there might be some pathological explanation connecting it with the sheep, large flocks of which grazed the short herbage. But the shepherds and owners of the sheep would have known if such an explanation were admissible. They called it "pwdre ser," the rot of the stars.

Years afterwards I was in Westmorland, on the Geological Survey, and again not unfrequently saw the "pwdre ser." But I now got an addition to my story. Isaac Hindson, of Kirkby Lonsdale, a man whose scientific knowledge and genial personality made him a welcome companion to those who had to carry on geological research in his district, told me that he had once seen a luminous body fall, and, on going up to the place, found only a mass of white jelly. He did not say that it was luminous. I have never seen it luminous, but that may be because when it was light enough to see the lump of jelly, it would probably be too light to detect luminosity in it.

Then, in my novel reading, I found that the same thing was known in Scotland, and the same origin assigned to it, for Walter Scott, in "The Talisman,"¹ puts these words in the mouth of the hermit:—"Seek a fallen star and thou shalt only light on some foul jelly, which in shooting through the horizon, has assumed for a moment an appearance of splendour." I think that I remember seeing it used elsewhere as an illustration of disappointed hopes, which were "as when a man seeing a meteor fall, runs up and finds but a mass of putrid jelly," but I have lost the reference to this passage.

Thus it appeared that in Wales, in the Lake District, and in Scotland, there existed a belief that something which fell from the sky as a

luminous body lay on the ground as a lump of white jelly.

I asked Huxley what it could be, and he said that the only thing like it that he knew was a nostoc. I turned to Sachs² for the description of a nostoc, and found that it "consists, when mature, of a large number of moniliform threads interwoven among one another and imbedded in a glutinous jelly, and thus united into colonies of a specifically defined form. . . . The gelatinous envelope of the new filament is developed, and the originally microscopic substance attains or even exceeds the size of a walnut by continuous increase of the jelly and divisions of the cells."

All the nostocs, however, that I have had pointed out to me have been of a green or purplish or brown-green colour, whereas the "pwdre ser" was always white, translucent in the upper part, and transparent

FIG. 2.—Gebel Kordi: a typical Hill 350 feet high. From "In the Torrid Sudan."

from a distance, and, fearful of punishment, slid down the pole on to the ground with a bump which sobered him for days.

This book is not an easy one to review, for its information is put together in a scattered and unpretentious form, but it is very readable, and gives one as a reward for its perusal a remarkably vivid picture of the general aspect and conditions of the Sudan between Khartum and the Bahr al Zeraf, the White Nile, the Blue Nile, and the river Dinder.

H. H. JOHNSTON.

PWDRE SER.

IN my boyhood I often lived on the coast of Pembrokeshire. Wandering about with my gun I was familiar with most natural objects which occurred there. One, however, which I often came across there, and have seen elsewhere since, greatly roused my curiosity, but I have not yet met with a satisfactory explanation of it.

On the short, close grass of the hilly ground, I

¹ "Waverley Novels," Border edition, chapter xviii., p. 278.

² Sachs, "Text-book of Botany, Morphological and Physiological." Translated and annotated by Alfred W. Bennett and W. T. Thiselton-Dyer. (1875.)

In the lower part, which appeared to occur among the roots of the grass, as if it grew there. Moreover, the mass was much larger than a walnut, in fact, would generally about fill a half-pint mug.

The only reference I can find from which it would appear that the writer was describing a *nostoc* is the passage in Dryden and Lee¹ (1678).

"The shooting stars end all in purple jellies." In the following note, appended to this passage, it is clear that the writer thought that the jelly-like matter found where shooting-stars had seemed to fall, was white.

Note.—"It is a common idea that falling stars, as they are called, are converted into a sort of jelly. Among the rest, I had often the opportunity to see the seeming shooting of the stars from place to place, and sometimes they appeared as if falling to the ground, where I once or twice found a white jelly-like matter among the grass, which I imagined to be distilled from them; and thence foolishly conjectured that the stars themselves must certainly consist of a like substance."

Poets and divines carry the record of this curious belief far back into the seventeenth century.

Suckling² (1541) says:—

"As he whose quicker eye doth trace
A false star shot to a mark't place
Do's run apace,
And, thinking it to catch,
A jelly up do snatch."

Jeremy Taylor³ (1649):—

"It is weakness of the organ that makes us hold our hand between the sun and us, and yet stand staring upon a meteor or an inflamed jelly."

Henry More⁴ (1656):—

"That the Starres eat . . . that those falling Starres, as some call them, which are found on the earth in the form of a trembling jelly, are their excrement."

Dryden⁵ (1679):—

"When I had taken up what I supposed a fallen star I find I had been cozened with a jelly."

William Somerville⁶ (1740):—

"Swift as the Shooting Star that gilds the night
With rapid transient Blaze, she runs, she flies;
Sudden she stops nor longer can endure
The painful course, but drooping sinks away,
And like that falling Meteor, there she lyes
A jelly cold on earth."

Several old writers, however, while agreeing as to the mode of occurrence of the "poudre ser," and recognising the widespread belief that it was something which fell from the sky and was somehow connected with falling stars, have tried to find some more commonplace and probable explanation of the phenomenon, and most of them refer it to the stuff disgorged by birds that had fed on frogs or worms.

Merrett⁷ (1667), for instance, in his work on meteors and wandering lights, says:—

"Sequuntur Meteora, ignita, viz. Ignis fatuus, the Walking fire, or Jack of the Lantern, Castor and Pollux, Helena, Ignis lambens. Draco, Stella cadens: Est substantia quaedam alba et glutinosa plurimis in locis conspicua quam nostrates 'Star-faln' nuncupant, creduntque

multi originem suam debere stellae cadenti hujusq; materiam esse. Sed Regiae Societati palam ostendi solummodo oriri ex intestinis ranarum a corvis in unum locum congestis, quod aliis etiam ejusdem societatis viri praestantissimi postea confirmarunt."

The Rev. John Morton,¹ of Emmanuel College (1712), is, however, the only one who, so far as I can ascertain, ever tried any experiments with the view of finding out what it really was. He set some of it on the fire, and when he had driven off all the watery part, there was left a film like isinglass, and something like the skins and vessels of animal bodies. He records many observations as to its time and mode of occurrence; for instance, he says that "in 1699-1700 there was no star-gelly to be found about Oxenden till a wet week in the end of February, when the shepherds brought me above thirty several lumps." This and other observations suggest that it is a growth dependent upon the weather, &c. On the other hand, he says that he saw a wounded gull disgorge a heap of half-digested earth-worms much resembling star-jelly, and that Sir William Craven saw a bittern do the same in similar circumstances.

The Hon. Robert Boyle,² 1744, explaining how clammy and viscous bodies, such as white of egg, are reduced to a thin and fluid substance, says:—

"And I remember, I have seen a good quantity of that jelly, that is sometimes found on the ground, and by the vulgar called a star-shoot, as if it remained upon the extinction of a falling star, which being brought to an eminent physician of my acquaintance, he lightly digested it in a well-stopt glass for a long time, and by that alone resolved it into a permanent liquor, which he extols as a specifick to be outwardly applied against Wens."

Pennant³ seems to have supposed that its origin was that suggested by Morton, for in his description of the winter mew he says:—"This kind (i.e. the Cuddy Moddy or Winter Mew) frequents, during winter, the moist meadows in the inland parts of England remote from the Sea. The gelatinous substance, known by the name of star shot, or star gelly, owes its origin to this bird or some of the kind, being nothing but the half digested remains of earth-worms, on which these birds feed and often discharge from their stomachs."

I have found it commonly near the sea, but have never seen any trace of earth-worms or other similar food in it.

Here, then, we have a well-known substance which may be of different origin in different cases, respecting the general appearance of which, however, almost all accounts agree. The variety of names under which it is known point to its common and widespread occurrence, e.g. poudre ser, star-slough, star shoot, star shot, star-gelly or jelly, star-fall'n.

We have in every name, and in every notice in literature, a recognition of the universal belief that it has something to do with meteors, yet there does not appear to be any evidence that anybody ever saw any luminosity in the jelly. Nor has anybody seen it disgorged by birds, except in the case of those two wounded birds where some half-digested gelatinous mass was thrown up. Nor has anyone watched its growth like *nostoc* from the ground.

In 1908 I was with my wife and one of my boys on Ingleborough, where we found the "poudre ser" lying on the short grass, close to the stream a little way above Gaping Ghyl Hole. For the first time I felt grateful to the inconsiderate tourist who left

¹ "The Natural History of Northamptonshire, with some Account of the Antiquities, &c." By John Morton, M.A., F.R.S., Emanuel College, Cambridge, Rector of Oxenden. (London, 1712, p. 352.)

³ "Zoology Folio," 1766, p. 142.

broken bottles about, for I was able to pack the jelly in the bottom of one, tie a cover on, and carry it down from the fell. I sent it, with the sod on which it appeared to have grown, to my colleague, Mr. E. A. Newell Arber, with a brief sketch of my story and the reason why I thought it of interest. Mr. Arber reported that it was no nostoc, and said that he had sent it over to Mr. Brookes, in the Botany School, who reported that it was a mass of bacteria.

That is the end of my story, but I confess I am not satisfied. The jelly seemed to me to grow out from among the roots of the grass, and the part still tangled in the grass was not only translucent but quite transparent.

What is it, and what is the cause of its having a meteoric origin assigned to it? Has anyone ever seen it luminous?

Should anyone come upon it I should be very grateful if they would send it, and the sod on which it is found, to the Botany School at Cambridge, with a label indicating what the parcel contains, so that it may be attended to before decay has perhaps obscured important features.

T. McKENNY HUGHES.

THE TOTAL SOLAR ECLIPSE OF MAY 9, 1910.

UP to the time of writing (May 28) no account has been received from Mr. F. K. McClean with regard to the erection and adjustments of the various

two specimens of the work which had to be undertaken. The first (Fig. 2) shows the avenue which had to be made from the camp to the instrument site. The figure standing up is Mr. Young, the bending figure Mr. Dowsett. In Fig. 3 is shown the method adopted for carrying the loaded packing-cases from the water's edge to the site; the figures from right to left are Messrs. McClean, Young, Brooks, Dowsett, and the last one, on the extreme left, unknown, probably one of the miners who was in the locality, and who assisted the members of the expedition.

The communication to which reference above has been made was dated April 17, and was dispatched from Port Davey by the steamer *Wainui*. The contents are as follows:—

"On April 5 Mr. Hughes, of the Union S.S. Co., supplied us with a time-table of the *Wainui*, and informed us that the steamer would call in when passing in each direction if weather permitted, but at the absolute discretion of Captain Livingstone.

"News arrived the following day that the 6-inch Cooke O.G. of 30 feet focus would arrive by the *Athenic* on April 14, and arrangements were made for its dispatch to Port Davey.

"A telegram was also received from Mr. J. Short, of Sydney Observatory, in answer to an invitation to set up his instrument alongside of ours, in which he said that he was awaiting Government sanction, and would be glad to join us.

Finally, on April 9, the *Wainui* arrived from Melbourne, and all our instruments, tents, timber, ironmongery, food, drink, clothing, and a whale-boat were put on board,

FIG. 1.—The Country about Hixson Point, the site of the Eclipse Camp.

instruments he took out with him for the solar eclipse. It will be remembered that the observing station he chose was near Port Davey, and he selected a small island, called Hixson Point, for the actual site of the camp. The accompanying illustration (Fig. 1) indicates the position of this island in relation to the neighbouring country, and is from a photograph taken towards the east from Morning Hill.

Mr. McClean has, however, sent an intermediate letter, which will, no doubt, be read with considerable interest, describing the first week's operations from the time of the arrival of his entire party by the *Wainui* on April 7, with their whole kit and instruments. This account shows vividly the strenuous life which the party had continually to undergo during the initial stages of their settlement, and in a letter Mr. McClean states that so far "this trip is a triumph of matter over mind, as the latter has not had a look in yet, and never would have if it were not for the muscles of the party."

The accompanying illustrations, from photographs taken by Mr. H. Winkelman, will serve best to show

altogether about 140 cases and packages, and we left Hobart at 9 p.m.

"The following morning we entered Port Davey in a strong south-west wind and a heavy swell, but as soon as we passed the Breaksea Islands the sea became calm, and the landing was effected without trouble. One of the ship's boats took the instruments and cement to the foot of Hixson Point, where they were hauled up the low bluff on planks by block and tackle, and left in a pile covered with a large tarpaulin until they could be carried to the observatory site. Our whale-boat took the camp equipment up the cove to where a small stream ran through a clump of bush, and here we set up our tents after the steamer left. The landing was done between 9.30 a.m. and 2.0 p.m. with the help of some of the officers and crew of the *Wainui* and two miners who were hunting in the neighbourhood. The weather all the time was fine, but rain started in the evening after we had set up three tents, in which we spent the first night.

"The following day we completed the camp and cut a path some 100 yards long through the bush with the help of the two miners, who later continued it on through the 2-foot scrub to the observatory site. We then set up the instrument tent close to the site of the observatory, but

on Thursday, April 14, we had to remove it, as the strength of the wind was so great that even with additional guys the whole thing threatened to collapse, and we cut

FIG. 2.—Cutting a path to reach the Eclipse Camp from the shore.

a rectangular space in the middle of some low bush where there was very fair shelter. Our camp consists of a dining tent 12 feet square, a dark-room tent 6 by 9 feet with red lining, three sleeping tents 9 by 12 feet and two of 8 by 10 feet, situated on both sides of a small stream on a site cut out of the bush, and at the head of a small bay.

"Then it was necessary to cut a path from the top of the hill to the instrument cases—some 200 yards of very bad ground—and carry the cases up. This was done mostly by four persons on two timbers 2 inches square, but some of the siderostat parts proved too heavy, and had to be left until they could be unpacked and placed directly in position. Also the case containing the large dark-slide for the spectrograph had to be unpacked *in situ*, and the dark-slide alone required two persons to carry it.

"During the whole of the week there was bad weather, nearly always cloudy—night and day—always wind, and frequently rain, so that the foundations for the siderostat and cœlostat had to be oriented by compass only. All the sand and water for the concrete had to be carried up from the stream by hand—a quarter of a mile uphill—which was a big additional labour, but stone was quarried on the hill. Finally, on the Sunday morning (April 17), the foundation of the siderostat was completed, and all but seven cases were on the top of the hill, and, after the severe physical work of the last seven days, we proposed taking a half-holiday for fishing and washing clothes, or anything

that the members of the expedition chose to do. But this was not to be, for on finishing lunch we saw an ominous smoke cloud across the sky, and from the top of the bush found that the scrub was ablaze close to the instrument tent. As we came up the flag-pole collapsed, but by much beating we kept the flames from the tent. Within 6 feet of it Worthington's cases—happily empty—were burning furiously, and the large case for the dark-slide of the spectrograph was a mass of flames, as into it had been put all the straw packing from three other cases.

"Having got the fire under control near the instrument tent, half the party were drafted off to prevent it reaching the camp, and later all but two, who were required to watch the smouldering remains on the top of the hill and the line of fire in the neighbourhood of the cases still at the landing place. In spite, however, of the efforts of these six, the fire reached the bush within 60 yards of camp, and it was only due to the constant wet weather of the previous week that it stopped there, as the trees were so saturated that nothing could burn them. Most of the camp equipment was quickly moved to the shore to be covered with a wet tent-fly, and food was placed in the whale-boat, but happily these precautions were not necessary. A constant inspection was kept of the still smouldering hillside, and at 6.30 a fresh blaze started on the edge of the bush close to the bay. This was temporarily overcome by beating and by buckets of water; but the soil was red-hot, being peat, and only constant attention and lengthy rain can put it out. In addition to this there has been a small peat fire the whole time in the bush within 50 feet of the dining tent, which has been watched, but not considered dangerous until now.

"The result of the fire is that two of Worthington's cases have been burnt and one of mine, and the legs of Worthington's equatorial have been singed. The fire was round more than two sides of the instrument tent, and within 4 feet of it at one point.

"The spectrograph dark-slide had already had one narrow escape, as, soon after it left Watson's workshop, the building was burnt to the ground, and now its case is destroyed by fire the day after it was unpacked. It was a near thing, and as we came up the hill we expected to

FIG. 3.—Carrying the instrument cases from the shore to the camp on the hill.

leave by the *Wainui* the following day without instruments or kit."

WILLIAM J. S. LOCKYER.

NOTES.

UPON the recommendation of the National Academy of Sciences of the United States, the trustees of Columbia College, New York, have awarded the Barnard medal for meritorious service to science, for the five-year period ending with the year 1909, to Prof. Ernest Rutherford, F.R.S., Langworthy professor of physics and director of the physical laboratory in the University of Manchester; for meritorious service to science resulting especially from his investigations of the phenomena of radio-active materials. The medal is "of gold, nine-tenths fine, of the bullion value of not less than two hundred dollars." Previous awards of the medal are:—1895, Lord Rayleigh and Sir William Ramsay; 1900, Prof. W. C. von Röntgen; 1905, M. Henri Becquerel.

THE death is announced of Prof. Louis Raffy, who for twenty-six years was on the staff of the University of Paris. Since 1904 Prof. Raffy occupied the chair of analysis and geometry. At the funeral, orations were delivered by Prof. Paul Appell, dean of the faculty of sciences in the University of Paris, and by Prof. Bricard, president of the Paris Mathematical Society.

AN International Hygiene Exhibition is to be held at Dresden from May to October, 1911. The exhibition will include five sections: the scientific, the historical, the popular, sports, and industry. The scientific section will aim to present as completely as possible a picture of the science of hygiene. The general secretary for the scientific department is Dr. Weber, member of the Imperial Board of Health, Berlin.

WE regret to announce the death, at College Place, Camden Town, on June 19, in his one hundredth year, of Mr. E. Gerrard, formerly on the staff of the British Museum, and founder of the well-known firm of taxidermists in College Place, Camden Town. Mr. Gerrard, who was born on October 20, 1810, joined the British Museum as special attendant to Dr. J. E. Gray in 1841, and for many years had charge of the osteological collections. He was the author of the "Catalogue of the Bones of Mammalia in the British Museum," published in 1862. After fifty years' service in the museum Mr. Gerrard retired in 1896.

LORD CREWE, Secretary of State for the Colonies, has appointed a committee, formed of representatives of the Colonial Office and of the Natural History Branch of the British Museum, to consider the protection of plumage-birds. The main object in view is to consider to what extent it may be practicable to prevent, either by legislation or by departmental control, the indiscriminate slaughter of such birds now prevalent in certain parts of the Empire. Action of this nature can be effectual only by the cooperation of the Governments of all the countries included in the British Empire, and it is hoped that this may be obtained. The names of the committee will be published in due course. A provisional meeting of the members has been held already.

THE ninety-third annual meeting of the Swiss Society of Natural Sciences is to be held this year at Bâle on September 4-7. During the meeting lectures will be delivered by Prof. W. Ostwald, of Leipzig; Prof. E. von Drygalski, of Munich; Prof. P. Guye, of Geneva; Dr. L. Rollier, of Zürich; Prof. A. Ernst, of Zürich; Dr. Paul Sarasin, of Bâle; and Dr. H. G. Stehlin, of Bâle. The Swiss Societies of Botany, Chemistry, Geology, Physics, Zoology, and Mathematics will

meet at Bâle at the same time. The secretary for the meeting is Dr. H. G. Stehlin, Museum of Natural History, Augustinergasse, Bâle, from whom all information may be obtained.

ON Monday last, June 20, at the invitation of the Lord Mayor of Birmingham, a meeting of the most prominent naturalists of the city was held in the Council House to consider the establishment of a Natural History Museum. The Lord Mayor, in opening the meeting, stated that the City Council is willing to allot considerable space for a natural history museum, but cannot undertake to provide the collections. Sir Oliver Lodge moved "that this meeting heartily approves of the establishment of a natural history museum worthy of the city." In the course of an interesting speech he remarked that the study of natural history is of special value to town citizens, and it has become more difficult to carry on the study save by such means as the meeting had assembled to promote. Birmingham is a great city, and can well afford a natural history as well as an art museum. Sir George H. Kenrick seconded the motion. He emphasised the responsibility that rests on individual effort to make the museum a success. He laid particular stress on the value of a library attached to the museum, and well stocked with books dealing with the subjects illustrated only perhaps partially in the galleries. Alderman Beale, chairman of the Art Gallery Committee, and other speakers, including Prof. Carlier, strongly advocated the formation of a museum. If the City Council carries out its intention of allotting the space, there will apparently be no difficulty in filling it, to the great advantage of all branches of the community. An influential committee was formed, and the motion was carried unanimously.

THE council of the Association des Ingénieurs électriciens sortis de l'Institut électrotechnique Montefiore, Liège, has issued the conditions which will govern the triennial award of the prize—the "Fondation George Montefiore"—which is to be awarded for the first time in 1911. The prize will be the accumulated interest on 150,000 francs in Belgian three per cent. funds, and is to be given for the best original work in French or English on the scientific advance and the progress in the technical applications of electricity. The last date for the reception of works to be submitted to the committee of award is March 31, 1911. Competitors should address M. le Secrétaire-archiviste de la Fondation George Montefiore, à l'Hôtel de l'Association, rue St. Gilles, 31, Liège.

THE annual report, dated May 13, of the Society for the Astronomical Study of Ancient Stone Monuments, Cornwall Branch, shows increasing interest in the work undertaken. The "most important excursion the society has ever had" was made on July 16, 1909, to the Wendron Circles. The leading object kept in mind is to follow up some preliminary observations of monuments with a more detailed examination, with the sure result of discovering features which at the first visit escaped attention. A striking feature of the kind is reported from Tregaseal and Wendron. The summer meeting this year was held at Boskednan Circle, Madron, on June 17. The treasurer's report shows an increasing balance in hand. The president is the Right Hon. Viscount Falmouth, and the honorary secretaries Mr. Henry Thomas and Mr. H. Bolitho.

A CORRESPONDENT, after hiving a swarm, noticed certain bees standing on the ledge before the entrance, rapidly moving their wings. It may be observed that when many

bees behave in this way they act as a lure to those outside the hive, and that each bee elevates the tip of her abdomen, and exposes a membrane there, situated between the fifth and the sixth dorsal segments. This membrane gives off a pungent scent, which the waving of the wings disseminates; no doubt the scent attracts bees that have lost their way to the entrance. A bee that has had a difficulty in finding the entrance, before she passes into the hive, stands for a short while on the alighting board to fan and expose her scent membrane. Thus, when many bees are uncertain about the position of the entrance, they are attracted there by the scent. A description of this scent-producing organ of the worker honey-bee, and the vibration of the wings to which our correspondent refers, will be found in Mr. F. W. L. Sladen's "Queen-Rearing in England," published at the office of the *British Bee Journal*, 23 Bedford Street, Strand, W.C.

A NATIONAL committee (of which the King, when Prince of Wales, acted as honorary chairman), representative of the colonies, of the Navy, of the shipping industry, and of the learned societies, has been formed under the auspices of the British Empire League to secure the erection in London of a memorial to Captain Cook. It is a reproach to the nation that no recognition should have been paid to the memory of a man whose intrepid explorations resulted in such notable additions to the British Dominions, and whose scientific work has been of the greatest value to mankind. For the purpose a fund of at least 3000*l.* will be needed, to which the committee now invites contributions. Nearly one-third of this amount has been subscribed by members of the committee. Cheques should be crossed Robarts, Lubbock and Co., and made payable to the treasurer, Lord Brassey, G.C.B., 24 Park Lane, London, W.

THE interesting speeches made on the occasion of the presentation of a marble bust of the late Dr. John Hopkinson, F.R.S., to the Institution of Electrical Engineers on November 11, 1909, are printed in the journal of the institution (vol. xlv.). In making the presentation on behalf of his mother, Prof. B. Hopkinson did not claim too much when he said that "so long as dynamos are made, so long will the designers of such machinery, and the inventors of new forms of it, have first to master and then to use the fundamental principles which my father laid down." Mr. W. M. Mordey, president of the institution, in expressing the thanks of the council and members to Mrs. Hopkinson for the gift, pointed out some of the landmarks laid down by Dr. Hopkinson in connection with the development of electrical engineering. Dr. Hopkinson not only raised the knowledge of the dynamo from chaos into engineering and scientific order, but also made valuable contributions to subjects of purely physical interest. He was distinguished as an investigator, inventor, and teacher, and the marble bust at the Institution of Electrical Engineers will remind all who see it of a life to be emulated as well as honoured.

THE third annual exhibition of the Society of Colour Photographers is now open at 24 Wellington Street, Strand, and will close on July 9. There is manifest a general levelling up in quality, and many, such as Mr. Hollyer's three-colour collotypes and Mr. Clifton's three-colour carbon prints, show what skilful manipulation can do with methods that allow much scope for error. Among the transparencies by the autochrome and similar processes are several examples on the new "Dufay" plates. The Thames Plate Company is bold enough to show four duplicates made from the same negative, and though any one alone might perhaps

be accepted as satisfactory, the slight differences between the colours in the four prints demonstrate in an interesting way the difficulty of making two colour photographs exactly alike. Messrs. Mees and Pledge show an interesting series of photomicrographs of eight different kinds of three-colour screens, with various spectra and resolving power tests of colour plates. Dr. Mees also shows one of Mr. Ives's new colorimeters. The exhibition presents in a small space an excellent summary of the present condition and possibilities of colour photography from a practical point of view, together with many analytical results of especial interest to the scientific student.

THE seventy-eighth annual meeting of the British Medical Association is to be held in London on July 22-29. The main business of the congress will be done in sections, which are, with their presidents, as follows:—anæsthetics, Dr. F. W. Hewitt, M.V.O.; anatomy, Prof. Arthur Keith; bacteriology, Dr. C. J. Martin, F.R.S.; dermatology, Dr. P. Abraham; diseases of children, Dr. A. E. Garrod; gynaecology and obstetrics, Dr. Mary Scharlieb; laryngology, Mr. H. Tilley; medical sociology, Dr. J. A. Macdonald; medicine, Dr. R. W. Philip; navy, army, and ambulance, Colonel A. Clark; odontology, Mr. J. H. Mummery; ophthalmology, Mr. C. Higgins; otology, Dr. E. Law; pathology, Mr. S. G. Shattock; pharmacology and therapeutics, Prof. A. R. Cushny, F.R.S.; physiology, Prof. W. H. Thompson; psychological medicine and neurology, Dr. T. B. Hyslop; radiology and medical electricity, Mr. J. M. Davidson; State medicine, Sir William Foster; surgery, Sir Victor Horsley, F.R.S.; and tropical medicine, Dr. F. M. Sandwith. The address in medicine will be delivered on July 27 by Dr. J. Mitchell Bruce, and the address in surgery on July 28 by Mr. H. G. Barling. The second annual meeting of the Medical Library Association, under the presidency of Prof. Osler, will be held on the mornings of July 27 and 28, at which papers will be read dealing with matters likely to be of practical interest and assistance to medical librarians, members of library committees, and readers. It is also intended to hold a bibliographical exhibition in connection with this meeting.

THE Horniman Museum at Forest Hill continues to advance in popularity and in the interest of its collections. In the ethnological department the most important accessions during the past year have been collections from the north-west of North America and the Eskimo region, and a series illustrating the structure of the anthropoid apes. Arrangements have also been made for a good series of illustrative lectures. In that of natural history some progress has been made in collecting a series describing the structural adaptations of animals to the chief modes of progression, and increased accommodation for vivaria and aquaria has been provided.

THE *National Geographic Magazine* for April, under the title of "The Spirit of the West," continues the graphic and well-illustrated series of articles by Mr. C. J. Blanchard, of the United States Reclamation Department, on the extensive works completed and in progress for extending irrigation in the Mississippi Valley. Thirteen million acres now produce harvests valued at 50,000,000*l.*, and support more than 300,000 families at present, with hopes of large increase in the immediate future. One of the most important of these works is the gigantic concrete dam, said to be the highest in the world, which bars the cañon of the Shoshone River collecting the drainage from the lofty mountains east of Yellowstone Park. This rises to a height of 328 feet, slightly higher than the summit of the dome of the Capitol at Washington.

In the second issue for the present year of the *Bulletins et Memoires* of the Société d'Anthropologie of Paris, Dr. A. F. Legendre publishes an elaborate anthropometrical study of that strange race, the Lolos of the Kien Tch'ang Valley, who have hitherto been a puzzle to ethnologists. In spite of the domination of the Chinese, who have taught them many vices, such as alcoholic drinking, they preserve some measure of independence, and in consequence of the ill-treatment to which they are accustomed they are so suspicious of strangers that there is much difficulty in investigating their ethnical characteristics. They seem to have decided affinity with the Tibetan stock, but they combine certain negroid characters with a curious fairness of skin. Dr. Legendre does not venture to give a decided opinion on their origin, but the elaborate measurements which he supplies will greatly assist in the solution of the problem.

In reference to the confirmation of the existence of pygmies in New Guinea, referred to in NATURE (p. 433), it should have been noted that Dr. A. B. Meyer in 1908 wrote ("Die Papuasprache in Niederländisch-Neuguinea," *Globus*, Bd. xciv., p. 192):—"The question whether the Papuans are a uniform race with a great breadth of variation or a mixed race was pronounced by me to be not yet ripe for decision ('Negritos,' 1893, 87, and 1899, 87). Now, however, after Ray's discovery of the Papuan linguistic family, I incline to the view that they are a mixed race of 'Negritos' and Malays (in the wider sense). I am eagerly looking forward to the exploration of the interior of the great island, when here too the Negrito element may perhaps be brought to light in its old and more constant form as still existing in the Philippines, Andamans and Malakka."

In the April number of *Biometrika* there is an article by Prof. Karl Pearson on "Darwinism, Biometry, and some Recent Biology." The article, which apparently is to be continued in the next issue, is a general criticism of recent biological work in which more or less inadequate statistical methods have been used, with unfortunate results, but the greater part is devoted to a useful discussion of some of the difficulties that arise if the theory of "pure lines" is accepted in its most stringent form—i.e. the hypothesis that there is absolutely no individual inheritance within the "pure line." As Prof. Pearson correctly points out, if this conception were true the correlation between offspring and parent, and that between offspring and grandparent, would be the same in any case in which the reproduction was mono-sexual. The work of Warren on *Daphnia* and on *Hyalopterus*, and that of Johannsen himself on *Phaseolus*, indicate that this is not the case, the grandparental coefficient being very distinctly smaller than the parental coefficient. The fact that Johannsen, Raymond Pearl, and Jennings have failed to find any sensible effect of selection within the pure line may probably be ascribed to the fact that they have all been working with characters for which the coefficient of inheritance is exceedingly low; to arrive at an appreciable result a character should be selected for which the inheritance is relatively high. In any case, of course, it remains true that for breeding purposes it will be much better to select by the method of pure lines than by selection of the characters of individuals, but the effect of selection of individuals from the mass of the population is of vital importance for the theory of evolution.

In the June number of the *Selborne Magazine* Mr. G. S. Boulger directs attention to the enormous crop of seeds borne by many elms in England in the spring of 1909, the

abundance of the crop being attributed to the fine autumn of 1908 and the sunny character of the following spring. The species which produced the seed is the smooth-leaved elm (*Ulmus glabra*), the common *U. surculosa* (or *campestris*) being infertile in this country. To the same issue Mr. J. Buckland contributes an article on the slaughter of egrets for the sake of their plumage.

MR. N. N. WORONICHIN contributes to the botanical section (parts iii. and iv., 1909) of the *Travaux de la Société des Naturalistes de St. Pétersbourg* a list, with descriptions, of Rhodophyceæ collected in the Black Sea. The number of species amounts to ninety-seven, of which Polysiphonia and Ceramium supply twelve and ten respectively; some new varieties are distinguished. Two species are cited as endemic, while a *Laurencia* and Ceramium are noted as being recorded from the Atlantic Ocean and North Sea, but not from the Mediterranean.

A REVISED catalogue of microscopes and accessories issued by Messrs. W. Watson and Sons, High Holborn, London, contains descriptions of the essential working parts and full particulars of their various instruments, ranging from the school pattern to the microscopist's van Heurck type; a new introduction is the inexpensive naturalist's microscope intended for general use. Great variety is offered in the shape of objectives and condensers; for low-power photomicrographic use a series of holostigmatic lenses have been designed, which are used without eye-pieces. Accessories of all kinds are listed for microscopists, bacteriologists, biologists, and for commercial purposes.

A DESCRIPTION of a singular purple-flowered *Cytisus* hybrid, for which an award of merit was given at the Temple Show, is communicated by Mr. R. A. Rolfe in the *Gardener's Chronicle* (June 18). The hybrid, *Cytisus × Dallimorei*, was raised in Kew Gardens by Mr. Dallimore from a crimson-winged variety of *Cytisus scoparius* crossed with pollen of the white broom, *Cytisus albus*. Of two seedlings obtained, only one produced purple flowers; the other bore flowers of a bright yellow. The purple colour of the seedling is traceable to the variety which is characterised by a deep crimson pigment in the wings and a slight tinge at the tip of the upper petal, the brown pigment, as the author suggests, being probably a suffusion of purple and yellow. Self-fertilised plants have been raised from both the yellow and purple hybrids, but, so far, the latter have not flowered.

THE steady progress that is being made in the application of science to agriculture in the West Indies is well shown by a comparison of the Bulletin of the Department of Agriculture, Trinidad, recently issued (No. 64, vol. ix.), with the corresponding number for last year (No. 63, 1909). The earlier issue was filled with short notes, many of which were extracted from other journals, and did not represent anything in the way of original observations; the notes might be helpful to the planters, but they were more of the nature of useful hints than of reasoned discussions of the planters' problems. The present issue is a distinct advance. It contains papers by the members of the staff on important problems connected with rubber, cacao, and cocoa-nut. Mr. Carruthers discusses the possibility of growing rubber successfully, and points out that, in spite of certain obvious similarities, there are certain fundamental differences in the conditions obtaining in Ceylon or Malaya and those in Trinidad. Chief among these is the supply of labour, which is only small in Trinidad; in consequence, the planters could not keep the plantations anything like so clean as is done in the East, nor could the tapping be done as frequently. It does not

appear, however, that the difficulties are insuperable. Mr. Farruthers also writes on the cacao canker, caused by a fungus, probably by *Spicaria colorans*, but possibly also by others; Mr. Rorer is working at the problem, and will, it is hoped, be able definitely to allocate the responsibility or the mischief. Mr. Rorer describes the witch-broom disease of cacao, Mr. Johnston writes on the cocoa-nut palm diseases, and Mr. Urich on "froghoppers" in the sugar-cane (*Tomaspis postica*, Walk.). Messrs. Carmody and Verteuil record certain analyses of local value.

IN a circular published by the U.S. Department of Agriculture (No. 118, Bureau of Entomology) Mr. F. M. Webster gives a description of a mite (*Pediculoides ventriosus*, Newport) occurring in grain which preys on the larvae of the grain moth, adults of the barley joint-worm, &c. It also attacks man, causing an itching skin eruption.

AN excellent little "Guide to the Preservation of Health in West Africa," by Dr. Strachan, C.M.G., principal medical officer of southern Nigeria, has been published by Messrs. Constable and Co., Ltd., price 6d. net. It deals in simple language with anti-malarial measures, the collection and storage of water, clothing, food, &c.

THE Bulletin of the Sleeping Sickness Bureau (vol. ii., No. 17, May) contains a very complete scheme of investigation on the bionomics of the tsetse-fly, *Glossina palpalis*, which conveys sleeping sickness, and should be in the hands of all who desire to do research in this subject. So much still remains to be done that probably everyone in the endemic areas might, with the aid of a scheme like this, add his mite to our sum of knowledge.

THE *Philippine Journal of Science* for December, 1909, contains several papers of considerable medical interest and importance. Messrs. A. F. Coca and P. K. Gilman record several cases of cancer treated with a "vaccine" prepared by grinding up a portion of the tumour removed by operation. The results seem promising. Dr. Clegg, by cultivating leprosy material on agar in symbiosis with amoebæ and cholera vibrios, claims to have grown an acid-fast bacillus which he believes to be the leprosy bacillus.

PROF. MINCHIN, in his presidential address to the Quekett Microscopical Club, discusses the phenomena of parasitism among protozoa. He concludes that "in the origin of species among parasites there are, as in other organisms, two steps: first, the appearance of variations, with the resultant disharmony seen in the lethal forms; secondly, by a gradual process of reciprocal adaptation between host and parasite, the establishment of more normal harmonic relations, associated with definite specific characteristics and reactions on the part of the parasite and the host" (*Journ. Quekett Microscop. Club*, April).

A RECENT publication from the Ottawa Government Printing Bureau contains a report by Mr. Einar Lindeman to the Canadian Department of Mines on the iron ore deposits of Vancouver and Texada Islands, British Columbia. Mr. Lindeman dwells on the importance of local magnetic surveys in the immediate vicinity of the outcrops of magnetite, which are a common feature in the district referred to, and gives two interesting charts based on such surveys. Unless an appreciable disturbing magnetic force exists for some distance all round an outcrop, Mr. Lindeman thinks it is pretty safe to conclude that the extent of the deposit is very limited.

IN the *Mémoires de l'Observatoire de L'Ébre*, No. 4, the Rev. J. García Mollá, S.J., describes the equipment of the electric section of the Observatory of the Ebro,

founded a few years ago. The work—a French translation from the Spanish—is handsomely illustrated, and extends to more than 120 quarto pages. It describes the apparatus, including a water-dropping electrograph, an Elster and Geitel dissipation apparatus, a Gerdien instrument for air conductivity measurements, a ceraunograph, or wireless installation for recording thunderstorms, and an earth-current apparatus. Father García Mollá also discusses in a practical way a number of the difficulties encountered in working the instruments, and goes in considerable detail into the theory of the observations and their reduction. The electrical section is but one of several, and, so far at least as equipment is concerned, the observatory promises to afford remarkable facilities for the study of geophysics.

IN a paper entitled "Storms and Storm-warnings on the German Coast in the Years 1896–1905," published in *Aus dem Archiv der Deutschen Seewarte* (vol. xxxii., part ii.), Dr. L. Grossmann discusses in great detail the storm frequency for various seasons and districts, and checks the accuracy of the signals hoisted by the Deutsche Seewarte in every imaginable way. An idea of the labour entailed in the investigation may be gathered from the fact that storm statistics have been tabulated from some 10,000 monthly registers supplied by the signal stations. The distribution of storms is divided into two principal types, those which spread in a W.-E. direction and those which take place in connection with depressions over north-east Europe and spread to the westward. About 70 per cent. of the storm phenomena over the North Sea reach the Prussian coast, while only some 47 per cent. of the storm phenomena on the latter coast also occur on the coast of the North Sea. The success obtained in warning of storms from easterly directions is not very satisfactory, especially in the summer months, but the success for those from westerly directions, especially in the winter season, is very considerable. These results agree in the main with those obtained in a similar inquiry for the preceding ten years (*Aus dem Archiv*, 1898).

PROF. CARL BARUS, in a report published by the Carnegie Institution of Washington (pp. vi+83), gives an account of further experiments on "Condensation of Vapour as induced by Nuclei and Ions." The report begins with a chapter on the nuclei left behind on the evaporation of the pure water drops which are produced in moist, dust-free air when a sufficient degree of supersaturation is brought about by sudden expansion. The colour phenomena associated with clouds formed by expansion—a subject to which Prof. Barus has devoted much attention in previous researches—are dealt with in a second chapter. The principal advance here has been in the use of an approximately monochromatic source of light—the mercury green light—in the study of coronas. The rest of the report deals with the application of the corona method of estimating the number of cloud particles to the study of the ions due to radium, and the determination of the ionic charge. On the assumption that only the negative ions are caught in his experiments, he obtains for the charge carried by the ion values agreeing fairly well with those which have been arrived at by other methods. The object of the author's investigation was primarily to test the accuracy of his optical method of determining the number of nuclei. An interesting feature of the experiments is the scale on which they were carried out. Other physicists who have used the condensation method of measuring the ionic charge have worked with expansion apparatus in which the cloud chamber contained only a few c.c. of air; Barus used a fog chamber containing many litres, the number of ions

per c.c. being also large, ranging up to a million or more. The electrical quantities to be measured were thus of considerable magnitude.

PART viii. of the *Verhandlungen der deutschen physikalischen Gesellschaft* contains a paper by Dr. H. G. Möller on the calculation of the Foucault currents in iron. He considers the case of a cylinder of iron surrounded by a coil through which an alternating current is sent, and calculates the magnetic induction at any instant, taking into account the induced currents produced in the iron itself. With 100 cycles per second the B-H curves for low values of the maximum impressed H are almost identical with the ordinary magnetisation curves, but as the value of H is increased the hysteresis loop contracts near the origin. This result is in exact accord with the experiments made last year by Dr. Hausrath, and justifies the conclusion that the magnetisation in iron responds instantaneously to changes in the resultant magnetising force.

WE have received from Prof. Merczyng, of St. Petersburg, a separate copy of his paper on the indices of refraction of liquids for electric waves of small wave-length, which appeared in the April Bulletin of the Academy of Science of Cracow. The electric waves were generated by a Righi oscillator, and were measured by means of the interference produced by reflection at two metal surfaces, one a little in front of the other. The measurement gave 4.5 cm. The indices of refraction of the liquids were calculated by Fresnel's formula from observations of the relative intensities of the incident beam and the beam reflected from the surface of the liquid. They lie, for the five liquids tested, between the indices found previously by the late Prof. Drude for waves of 75 cm. and the values for light waves.

A SERIES of measurements of the temperatures of the metallic filaments of incandescent electric lamps has recently been made by Dr. M. v. Pirani at the lamp works of Messrs. Siemens and Halske, and the results are given in part vii. of the *Verhandlungen der deutschen physikalischen Gesellschaft*. The filaments were of platinum, tantalum, and tungsten, and were, in general, stranded. They were heated in an inert gas or *in vacuo* either by an external heating coil or by the current traversing them, and the temperature was measured by a standardised thermo-element of fine wire introduced between the strands. Up to a temperature of 1600° C. it was found that temperature t and current i were connected by the relation $i = a + b.t^n$, where a and b are constants and n has a value between 1.5 and 2.5. This relation was used to determine the temperature above 1600° C. Observations were also made of the "black-body temperature" of the filaments by a standardised radiation thermometer of the Holborn-Kurlbaum type using red light. Tables are given of the resistances of the filaments up to temperatures just below the melting points, and it is shown that at these points the black-body temperatures are about 150° C. below the actual temperatures.

THE quality of surface waters in the United States, by Mr. R. B. Dole, is the subject of water-supply paper No. 236, issued by the United States Geological Survey. The numerous analyses are chiefly of local interest, but the account of the methods employed is worthy of note. The highest accuracy consistent with rapidity of analysis was aimed at, and an estimate is given of the limits of accuracy achieved for each constituent. The methods of presenting the results of water analyses are also discussed, the ionic form of statement being regarded as the best, as it gives a statement of facts and not of opinion.

THE Stumpf uni-directional flow steam engine forms the subject of an illustrated article by Prof. Stumpf, of the Charlottenburg Technical High School, in *Engineering* for June 10. In this engine the steam is carried through the engine in an unchanged direction. The live steam is admitted from below into the cover, which it serves to jacket, and enters the cylinder through the valve. At the completion of the working stroke it is exhausted through slots or ports which are provided in the middle of the cylinder, and are uncovered by the piston. This avoids the losses common to ordinary engines by the cooling of the live steam ports produced by the flow of wet exhaust steam through them, and the consequent condensation in the cylinder. Prof. Stumpf claims that the remarkable advantages offered by this type of exhaust, notably the great simplicity of construction, render the uni-directional flow principle particularly valuable for engines working with superheated steam. Stationary and portable Stumpf engines of a great variety have already been built on the Continent, and their manufacture has been taken up in this country.

COMMENTING on the salving of the French submersible boat *Pluviose*, *Engineering* for June 17 states that the practice in all British submarines is to have a diving dress for each member of the crew stowed away adjacent to the station which he occupies when the boat is submerged. There is a flexible lead from the usual air service, with a valve in close proximity to each dress. In the event of an accident the dress can be put on in half a minute and supplied with air by means of the flexible lead. A purifier is fitted to the dress, which ensures a supply of air sufficient to last the man for an hour and a half. Training of the members of the crew to effect exit in the British service, is conducted in a tank, the bottom of which is fitted up to resemble a submarine boat, and the test imposed upon the prospective members of a crew is to plunge to the bottom of the tank in an air lock, where he is required to put on the diving dress, proceed across the tank, ascend the counterfeit of a conning-tower in a submarine, and open the hatch, when he is enabled to rise to the surface. The period occupied for training the men in this important work has been found by experience to be not more than five days. Although the conditions are not quite those existing in a submarine after an accident, yet the method appears to offer the only likely solution of a very difficult problem; it is simple, and provides, at any rate, that each member of the crew will have a chance of saving his life.

WE have received from the Caxton Publishing Company Ltd., the first volume of "Nature-study on the Black board," by Mr. W. P. Pycraft and Miss J. H. Kelman, to be completed in three volumes at 7s. 6d. net each. We hope to review the work when the remaining volumes are available.

A SEVENTH edition of Mr. Charles Pendlebury's "Exercises and Examination Papers in Arithmetic, Logarithms, and Mensuration" has been published by Messrs. G. Bell and Sons, Ltd. About two-thirds of the contents of the present issue consist of new matter, and the portions of the older book which have been retained appear in a somewhat different order.

THE Selborne Society has issued the third of a series of leaflets on the Brent Valley Bird Sanctuary. This deal with curious nesting places, and, like those previously issued, is profusely illustrated, having been reprinted from *The Country Home*. Copies of the leaflet may be obtained

from Mr. Wilfred Mark Webb, honorary secretary of the Selborne Society, at 42 Bloomsbury Square, W.C., post free for three halfpenny stamps.

MESSRS. SWAN SONNENSCHN & CO. will publish at an early date an English translation of "Spiritism and Insanity," by Dr. Marcel Viollet. This book forms part of the Library of Experimental Psychology and Metapsychism published under the direction of Dr. Raymond Marcel, of Paris, and has been translated by Mr. Dudley Wright, editor of the *Annals of Psychical Science*.

THE report and transactions of the East Kent Scientific and Natural History Society for the year ending last September have reached us. The society is affiliated with the British Association and the South-eastern Union of Scientific Societies. The pamphlet, which has been edited by Mr. A. Lauder, the honorary secretary of the society, contains an account of the annual meeting in October, 1908, abstracts of the lectures delivered during the session, notes on the work done by the various sections of the society, and useful meteorological statistics for 1909.

MR. W. ENGELMANN, of Leipzig, has lately issued the third (enlarged) edition of Ostwald and Luther's well-known work, "Hand und Hilfsbuch zur Ausführung physiko-chemischer Messungen." The first edition was reviewed in NATURE of January 4, 1894 (vol. xlix., p. 219), and the second in the issue for December 4, 1902 (vol. lxxvii., p. 101). The volume provides teachers and students with details of apparatus and practical hints on manipulation not found in any ordinary text-book, and the new edition claims a place in every chemical and physical laboratory. A second edition of Prof. M. Verworn's lectures on the mechanism of psychical life ("Die Mechanik des Geisteslebens") has been published by Mr. F. G. Teubner, Leipzig. This little work appeared in 1907, and the original edition was reviewed in NATURE of April 16, 1908 (vol. lxxvii., p. 557).

Erratum.—In NATURE of June 9 (vol. lxxxiii., p. 445), column A, line 15 from bottom, for "Thaumatrocrinus" (a recent genus) read "Traumatocrinus" (a genus characteristic of Upper Trias).

OUR ASTRONOMICAL COLUMN.

JULY AND AUGUST METEORS.—With the advent of July every meteoric observer is induced to make preparation for the active campaign which the season offers. After the middle of July meteors usually become extremely abundant, and any patient watcher of the skies may record a plentiful harvest of meteor-tracks. In May and June there are comparatively few shooting stars, and perhaps the average hourly number is not more than four or six, but in the two succeeding months the rate of appearance often equals twenty or twenty-five per hour.

In July there is a very active display from Aquarius, which apparently reaches its maximum on July 27-31, though the meteors continue to fall from the same centre at about 339-11 during the first half of August—and in July there are many early Perseids displayed, though the latter are a different class of meteor to the Aquarids. Those which are directed from Perseus are of the swift, streaking order, while those from Aquarius are of the slow, trained variety, and they have long flights, the radiant being in low altitude.

This year both the Aquarids and Perseids may be observed to advantage, as the moon will offer little interference. On August 12, when we are led to expect the greatest abundance of meteors, our satellite will set at 10.9 p.m. and leave us with a dark sky, on which the meteors may be seen at their best; but, of course, in our English climate atmospheric conditions are always very doubtful. What we require is a series of beautifully transparent skies such as

we experienced during the first half of August, 1909. Observers should seize such opportunities as are available and determine the place of the radiant and hourly rate of meteoric apparitions on every clear night. The individual paths of those meteors equal to or brighter than first magnitude should be carefully recorded. The last few years have furnished average displays of Perseids; there is some reason to expect a richer shower this year.

THE LACINGS BETWEEN JUPITER'S BELTS.—Circular No. 124 from the Kiel Centralstelle contains a telegram from Prof. Lowell, dated June 14, announcing that the "criss-cross filaments interlace all Jupiter's belts." This refers to the lacings first observed between the equatorial belts by Mr. Scriven Bolton, and apparently means that similar lacings have been observed between all the belts.

OBSERVATIONS OF ORIONIDS IN 1909.—To No. 4418 of the *Astronomische Nachrichten* Prof. Dubiago communicates the results of the Orionid observations made at the Engelhardt and Kasan Observatories during October 17-20, inclusive, 1909. The times and apparent paths of ninety-six meteors were observed at the former station, and of forty-eight meteors at the latter. Eight meteors were observed at both stations, and for these real paths have been computed; the heights vary from 35 to 890 km. The following is the position of the radiant as determined from these observations: $\alpha = 88^\circ \pm 2.9^\circ$, $\delta = +21^\circ \pm 1.7^\circ$.

THE CAPE OBSERVATORY.—Mr. Hough's report of the work done at the Cape Observatory during 1909 contains several items of special interest. Among other things, we learn that Dr. Halm's new spectrometer, giving direct readings of wave-lengths, was extensively employed for the measurement of stellar spectra, and the results found not to be inferior in accuracy to those secured by the older methods. It is also of interest to learn that arrangements have been made to take daily photographs of the sun to supplement those taken at Greenwich and other observatories in the Empire. A large number of stellar spectra were secured and measured in the research on the solar parallax and for the examination of the systematic motions of stars in the line of sight. For Prof. Kapteyn's "Selected Areas" programme a number of proper-motion and parallax plates were secured; satisfactory progress in the *Carte du Ciel* programme is also reported.

THE TRANSIT AND TAIL OF HALLEY'S COMET.

THE question as to whether the earth passed through the tail of Halley's comet is discussed, from the point of view of the Helwan observations, by Mr. Knox Shaw in No. 4418 of the *Astronomische Nachrichten* (p. 31). On May 18, at 13h. G.M.T., the tail was seen to stretch as far as α Equuli, where it was 2° broad, although 8° broad where it involved γ Pegasi. At 13h. on May 19 there was no sign of the tail in the west, but it was traced to θ Aquilæ, where it merged with the Milky Way. The form was still tapering; and was 15° broad at α Pegasi. Similar observations followed on May 20, when still no tail was seen in the evening; but at 14h. it was traced to the Milky Way, and was about 10° broad in Pegasus. At 6h., G.M.T., on May 21 the tail was visible for a distance of 20° , but none could be seen at dawn. The narrowness of the tail (8°) on May 18 and the increased breadth next morning suggest that it was bent back in the orbit, and probably did not begin to sweep past the earth before 12h. on May 20. At this time the earth was some four million miles south of the comet's orbit plane, and consequently the tail probably passed well to the north of the earth, for the Helwan observations, during May, suggest that it was not nearly wide enough to envelop the earth at that distance. They also show that its length was well over twenty million miles, and would therefore have enveloped the earth had the planes coincided. No sign of the comet's transit of the sun's disc was observed, although observations were made with the 4-inch Cooke equatorial. Dr. Meyer mann also reports that, at Tsingtau, no trace of the comet was seen during the transit, nor were any extraordinary magnetic or meteorological effects recorded by the respective instruments.

Observations at the Stockholm Observatory were interfered with by heavy skies, but Dr. Bohlin reports that some photographs were obtained on orthochromatic plates used in conjunction with a yellow screen.

Further negative results, accruing from careful observations made on May 18 and the following days, are recorded by Father S. Chevalier in a special circular from the L^o-S^o Observatory. The sun was observed directly and by projection by several observers, but no trace of the comet was seen on the disc about the computed time of transit. Photographs were also obtained, and clearly showed dark pores of 2" diameter on the disc, but no trace of the comet. It therefore appears unlikely that any part of the comet having a diameter of 0.5", or, actually, 60 km., was dense enough to be registered on the plate. The magnetic curves, of which reproductions accompany the circular, obtained at the Lu-Kia-Pang Observatory on May 17, 18, and 19, show no perturbations which could with certainty be ascribed to cometary influence.

The *Comptes rendus* for June 13 (No. 24) contains several interesting notes concerning observations of the comet at various observatories.

M. Marchand reports that at the Pic-du-Midi station the solar halo seen from May 19 to 25 was still visible on May 31 and June 2 with the same diameter, 3° or 4°, but much paler, and a notable sunset effect was seen on May 31. Such an effect has not been recorded for several years, and is ascribed to the presence of very tenuous matter in the atmosphere at great altitudes.

MM. Cirera and Pericas describe the varying forms of the comet as observed at the Observatoire de l'Ebre (Spain) from May 1 to June 6. A table of the apparent and real lengths—the latter given in astronomical units—shows that up till May 12 the increase in the length of the tail was continuous, but a decrease was noted on May 26, followed by further progressive increase until June 2; observations on some of the intermediate dates were interfered with by clouds. It is suggested that the fluctuation was possibly produced by the earth capturing several million kilometres of the tail during the predicted passage on May 19. Photographs were secured on a number of dates during May and the first week in June, but bad weather prevented a continuous series from being obtained. The series shows, however, some striking changes in the form, extent, and brightness of the nucleus and head, especially about May 27; on May 30 the coma was much less bright and extensive.

M. Eginitis reports on the observations of the tail, made at the Athens Observatory on May 18, 19, and 20. On the Thursday morning, about an hour before the computed time of passage, the tail was seen to be nearly straight, but having a slight curvature, which may have been due to the proximity of the earth to the comet's orbit plane. At 3 o'clock on the Friday morning the tail was nearly 130° long, but no trace of it could be found on the Saturday morning. On the Friday evening, however, it was seen, like a crescent moon, and on Saturday evening was some 30° long. Observations of the sun's disc during the time of transit failed to reveal any sign of the comet.

MM. J. Baillaud and Boinot discuss, in detail, the transformations of the nucleus depicted on the photographs taken at the Paris Observatory on May 30 and 31 and June 2. A sudden transformation took place in the nucleus on May 31, the previously extensive elliptical form giving way to a circular condensation with bright extensions. Secondary condensations appeared, some of which were only temporary; but one of them persisted undiminished until June 2, and the authors liken the phenomenon to the doubling which occurred in the case of Biela's comet.

In No. 6, vol. lxx., of the *Monthly Notices (R.A.S.)* Dr. Rambaut publishes positions of the comet determined from photographs secured at the Radcliffe Observatory, with the 24-inch telescope, between November 7, 1909, and February 11. Such places depending upon stars generally taken from the *Astrographic Catalogue* will be invaluable in the subsequent discussions of the orbit; the comet was first picked up at the Radcliffe Observatory on November 5, 1909.

Mr. H. H. Gruning, of Ealing, sends us an interesting account of his observations of the comet. Between April 18 and June 18, using five-times field glasses (2-inch aperture), he saw the comet fourteen times, and on ten of these occasions it was visible to the naked eye. No tail was seen

except on May 31 and June 1, when, with the glasses, it was able to follow it to a distance of 1°. These carefully made observations well illustrate, when compared with the glowing reports from lower latitudes, the disadvantage under which we, in this country, have laboured during the present return of the famous comet.

Another correspondent sends us a cutting from the *Lancashire Daily Post* for June 1, in which Mr. L. Whitaker reports a remarkable phenomenon observed at Salterforth at about 3.30 a.m. on May 26. According to this report, a tail about 40° in length was seen rising from the eastern horizon. It would be of interest to have further records of this curious phenomenon.

THE ROYAL SOCIETY OF NEW SOUTH WALES.

THE Royal Society of New South Wales is the oldest scientific society in Australasia and in the southern hemisphere, unless there are older ones in South America or South Africa, and it will be able to celebrate its centenary in another eleven years.

It was started in 1821 in a similar way to the Royal Society of London, under the name of the Philosophical Society of Australasia, by a small band of friends, ten in number, under the presidency of the Governor, Sir Thomas Brisbane, K.C.B., F.R.S., who met at each other's houses where papers were read and discussed; there was a penalty of 10l. for any member failing to present a paper in his turn. They also lent each other books, as there was no public library in those days and hardly a bookseller in the whole of Australia.

The first members were Mr. Alexander Berry, whose brother, Mr. David Berry, died in 1889 at the age of ninety-seven, and left 100,000l. to his Alma Mater, St. Andrew's University, N.B., and the same amount to found a hospital in New South Wales—the writer of this, a member of the society, knew Mr. A. Berry, and thus the chain of membership has been kept up since 1821; Dr. Henry Grattan Douglas, who in after years was one of the prime movers in founding the first university of Australia, viz. the University of Sydney; Judge Barron Field, of the Supreme Court of Australia, author of a work upon Australia, published by John Murray in London in 1825; Major Goulburn, Colonial Secretary; Mr. Patrick Hill, Colonial Surgeon; Captain Philip Parker King, R.N., afterwards F.R.S. and Rear-Admiral, a son of Philip Gidley King, third Governor of New South Wales, who surveyed the north coast of Australia, and later on was engaged in the *Adventure* and *Beagle* surveying expedition along the coast of South America—it is interesting to note that the Hon. Philip Gidley King, M.L.C., a son of Admiral Philip Parker King, born in 1817, served as an officer on board the *Beagle* with Charles Darwin, and was a member of the society until four or five years ago; Lieut. John Oxley, R.N., Surveyor-General, who was one of the distinguished early explorers in Australia; Dr. Charles Staggard Rumker, astronomer, who started the first observatory in Australia; and Mr. Edward Wolstonecraft. As previously stated, the Governor, Sir Thomas Brisbane, F.R.S., was the president. For many years the Governor of Australia, and later of New South Wales up to 1871, was always the president, and some of the earlier ones, like Sir T. Brisbane and Sir W. Denison, F.R.S. (afterwards, for a short time, Governor-General of India), were men of scientific attainments who not only took a special interest in the society, but attended its meetings regularly and contributed several papers.

Some of the first papers read before the society were collected by His Honour Judge Barron Field, and published by John Murray in a book entitled "*Geographical Memoirs of New South Wales*," and it is interesting to note that the subjects which engaged the attention of the members in those early days are typical of the majority of the papers presented to the society ninety years later, e.g. the following were amongst those read in 1821:—(1) on the aborigines of New Holland and Van Diemen Land, by Barron Field; (2) on the geology of part of the coast of New South Wales, by Alexander Berry; (3) on the astronomy of the southern hemisphere, by D.

tumker; (4) on the maritime geography of Australia, by Captain Philip Parker King, R.N.

After a period of inactivity the society was resuscitated in 1850 under the title of the "Australian Philosophical Society," instead of Australasian, because, as the colony of Tasmania had been taken out of New South Wales in 1825, the term Australasian was no longer applicable. In 1850 the name was again altered, this time to that of "Philosophical Society of New South Wales, a further slice of New South Wales having been cut off to form the colony of Victoria. In 1866, by permission of H.M. Queen Victoria, it assumed its present title of "Royal Society of New South Wales," and in 1881 it was incorporated by an Act of the New South Wales Parliament.

The principal reason for discarding the term "Philosophical" was because the object and work of the society could not be considered as coming under the head of philosophy, and as the ground covered by the Royal Society of London was so well known, the then members decided to apply to the Crown for permission to use the more comprehensive title of "Royal"; this title had already been granted to the corresponding society in Tasmania. In later years the Philosophical Societies of Victoria, South Australia, and Queensland also changed their names in the same way.

The society was not in a position to publish until 1862; prior to that date some of its papers were printed in the daily newspapers, and others, up to 1859, appeared in the *Sydney Magazine of Science and Art*; several of these early papers are still of value, apart from the interest attached to the efforts of the authors to do what they could for the progress of science in a new country; and all honour is due to the early pioneers, for they worked under great difficulties, without the aid of libraries, collections, and modern instruments and appliances, and at a time when it took from six to nine months to get a reply from home, and their work should not be forgotten.

So early as 1851 the society endeavoured to encourage the development of the natural resources of the colony by offering gold medals for the growth and production of madder, cotton, and sugar, and for the extraction of metals from colonial ores.

Later on, to stimulate and encourage scientific research, the society for some years, viz. from 1882 to 1896, offered a medal (and a grant of 25*l.* to help defray the expenses of the investigations) for original researches and observations upon certain specified subjects, of which notice was given three years in advance, but after fourteen years' experience it was decided to discontinue these competitions. The following list gives an idea of the range of the subjects:—the chemistry of the Australian gums and resins; the tin deposits of New South Wales; the iron ore deposits of New South Wales; the marine fauna of Port Jackson; the silver ore deposits of New South Wales; on the origin and mode of occurrence of gold-bearing veins and of the associated minerals; influence of the Australian climate in producing modifications of diseases; on the Infusoria peculiar to Australia; anatomy and life-history of the Platypus and Echidna; anatomy and life-history of Mollusca peculiar to Australia; the chemical composition of the products from the so-called kerosene shale of New South Wales.

The society now awards one medal only, viz. the medal which was established, together with a lectureship, in memory of the late Rev. W. B. Clarke, F.R.S.; amongst the non-resident recipients of this medal have been:—Sir Richard Owen, F.R.S., 1878; Prof. George Bentham, F.R.S., 1879; Prof. Huxley, F.R.S., 1880; Prof. James Dwight Dana, 1882; Baron von Mueller, 1883; Alfred R. Selwyn, F.R.S., 1884; Sir Joseph Dalton Hooker, 1885.

From 1866 to 1875 the papers read before it were published under the title of "Transactions," but this was considered rather pretentious, and in 1876 they were brought out as the "Journal and Proceedings" as an annual volume; later they were issued for a few years in parts, and this method has been revived.

The volumes, of which forty-three have been issued, vary in size, but those for the last thirty years run from 300 to more than 600 pages. They are well printed in good type on good paper, and well illustrated.

The papers naturally are, for the most part, devoted to

Australasian subjects; those upon astronomy, meteorology, geology, mineralogy, botany, ethnology, water supply and irrigation, and similar matters bulk most largely; some of the papers are, and will remain, of permanent interest. The first eleven volumes are out of print and are difficult to obtain, but, fortunately, the volumes have been widely distributed to public institutions and societies in all parts of the world, so that anyone really interested can generally manage to refer to them.

It is not proposed to give any specific account or review of the recently published volumes, inasmuch as abstracts of all the principal papers read have appeared in the columns of *NATURE* month by month during recent years under the head of "Societies and Academies." The volume for 1909 has been issued in four parts instead of the single annual volume, in the hope that its usefulness may be increased, and the society is to be congratulated upon having done so.

In 1875 a series of sections was inaugurated in order that the members might be able to meet together for the discussion of matters of scientific interest with less formality than at the ordinary meetings of the society; some of these were very successful, and they helped to make the society more popular, and the number of members rapidly increased to 494, the largest during its history; but of late years interest in the sections has decreased. The medical section was a very active one for several years, and did useful work until it was superseded by the formation of an outside independent professional society.

The engineering section is at the present the only active one, and it is doing extremely good work, as shown by the papers and proceedings appearing in the society's volumes; it practically supplies all the advantages afforded by an independent society, and, further, has the use of the Royal Society's library, meeting rooms, printer, office staff, &c., without any extra subscription.

Most of the other sections will probably re-awaken to their former activity in due course. The sections are:—A, mathematics, physics, astronomy, meteorology, &c.; B, chemistry and mineralogy, and their application to the arts and agriculture; C, geology and palæontology; D, botany and zoology; E, microscopical science; F, geography and ethnology; G, literature and the fine arts, including architecture; H, medical science; I, sanitary and social science and statistics; J, engineering science; K, economical science.

The society distributes its publications to about 400 similar societies, institutions, and public libraries, not only to all parts of the British Empire, Europe, and America, but to China, Japan, Mexico, the Philippines, Straits Settlements, Chili, Peru, Mauritius, Brazil, &c., and in almost all cases receives publications from these places in exchange. At one time the society undertook the collection and delivery of scientific publications for other institutions in New South Wales, but this is now done by the Government Bureau for Scientific Exchanges. In addition to the exchange of publications, the society endeavours to maintain touch with scientific workers in other parts of the world by appointing a limited number of non-resident men of science as honorary members; the society has had special pleasure in the acceptance of its honorary membership by such men as Darwin, Hooker, Wallace and others, who have done scientific work in Australasia and Oceania.

In addition to its ordinary meetings, the society arranges for series of popular lectures, to which friends of the members are freely invited, and short courses of lectures are also given upon the geology of Australasia, known as the Clarke lectures, founded in memory of the Rev. W. B. Clarke, F.R.S., a former president of the society, who gave a large part of a long life to geological research in Australia.

It also gives an annual conversazione, which is held at the University, on account of the extensive and suitable accommodation afforded by it, as the conversazione is very popular and largely attended; all the scientific departments, laboratories, the libraries, and lecture rooms are thrown open for the occasion, and suitable exhibits of new apparatus and specimens are shown in them, as well as experiments and practical illustrations where possible. Lectures are given upon recent discoveries or matters of interest.

Usually some of the visitors attending the lectures and conversazione become sufficiently interested to join the society and become useful members; the University also profits in turn, as the conversazione enables many persons to see it and learn what it is doing who otherwise would not have an opportunity.

The society does not restrict itself to work which is done by its own members, but, where possible, it is always willing to assist others; e.g. it greatly assisted in the formation of the Australasian Association for the Advancement of Science; it also took an active part in the foundation of a marine biological laboratory near the entrance to Sydney Harbour, which, unfortunately, was required a few years afterwards by the Government for defence purposes, and it is to be hoped that the trustees, who received compensation from the Government, will see their way before long to start a new marine station and laboratory; it has on several occasions brought matters of importance under the notice of the Government where legislation has been necessary for the good of the public health, the preservation of the native flora and fauna, also for the assistance of scientific exploring expeditions in the Antarctic and elsewhere and in other similar matters, and it has helped in the extension of the British Science Guild in Australia.

For many years it has been one of the main objects of the society to get together a good library of the principal British, American, French, German, and other scientific journals, and it now has complete series of many of these, some by purchase, others by gift and in exchange for its own publications, so that, taking the limited resources of the society into account, quite a creditable and useful library has been gradually built up. Without such books of reference the research student is at a great disadvantage, and the society regards the formation of such a reference library as of equal importance to the publication of papers read before it.

In 1878 the society obtained possession of its present freehold premises in Elizabeth Street, Sydney. Since then it has twice added to them, in 1896 and again in 1905; the last time it was to increase the accommodation required for the growing library, and also to provide accommodation for kindred societies by sub-letting some of the rooms, not immediately required, to them at low rentals; in this way it affords (as was stated in an article on the Australasian Association for the Advancement of Science, *NATURE*, December 30, 1909) some of the advantages enjoyed by the English societies in Burlington House.

The Parliament of New South Wales has generously helped the society for some years; for several years the Government printed the society's annual volume of papers and proceedings; of late years, in place of printing the volume, it has contributed 10s. per annum for each 20s. of the members' subscriptions; but, in spite of this, the society's income is insufficient to enable it to undertake many things it would like to do for the advancement of science, and it finds difficulty in carrying on its present efforts.

A. LIVERSIDGE.

THE AMERICAN PHILOSOPHICAL SOCIETY.

THE general meeting of the American Philosophical Society was held at Philadelphia on April 21-23, and we have been favoured by the secretaries with a report of the proceedings. The afternoon of April 23 was devoted to a symposium on experimental evolution, the principal papers being given by Prof. H. S. Jennings, on inheritance in non-sexual and self-fertilised organisms; Mr. G. H. Shull, on germinal analysis through hybridisation; and Dr. C. B. Davenport, on new views about reversion.

At the session on April 22 the following were elected to membership:—*Residents of the United States*: Dr. S. E. Baldwin, Dr. F. G. Benedict, Dr. C. F. Brush; Dr. D. H. Campbell, Dr. W. E. Castle, Dr. G. B. Gordon, Dr. D. J. Hill, Dr. H. C. Jones, Dr. L. Loeb, Mr. J. McCrea, Dr. R. C. Maclaurin, F.R.S., Dr. B. O. Pierce, Dr. H. F. Reid, Dr. J. F. Rhodes, and Dr. O. W. Richardson. *Foreign residents*: Dr. A. von Baeyer, Madame S. Curie, Sir David Gill, K.C.B., F.R.S., Dr. E. Meyer, and M. C. E. Picard.

NO. 2121, VOL. 23]

In addition to the symposium on evolution, fifty-one papers were presented. Brief summaries of the contents of a few of these papers are subjoined.

Physical notes on Meteor Crater, Arizona, Prof. W. F. Magie. Meteor Crater is a vast crater situated in Coconino County, Arizona, formed by the impact of an iron meteorite or group of meteorites. Scattered specimens of these meteorites (the Canyon Diablo siderites and the "shale ball" siderites) are found around the crater, but the main mass has not yet been found. It probably is buried 1000 feet below the surface. (1) The Canyon Diablo iron shows a magnetic permeability not very different from that of cast iron. The shale ball iron seems to be generally similar to it in its magnetic properties. Several observations indicate an intrinsic magnetisation, peculiarly arranged, in the shale ball iron. The magnetic field of the crater shows no local peculiarities such as would be expected from the presence of a large continuous mass of iron. The inference is that the mass is fragmentary, perhaps intrinsically magnetised, and also, perhaps, largely oxidised. (2) The distribution of the ejected material and the inclinations of the exposed strata around the crater wall show a remarkable symmetry with respect to a nearly north and south axis. This symmetry, even in details, appears in holes made by bullets in a suitable mass of compacted powder. The inference is that the crater was formed by a projectile. (3) The mass ejected is estimated at 330 million tons. The energy used to lift it out of the hole is a negligible fraction of the energy expended. Most of the energy expended was used in crushing the rock. An estimate based on the assumption that the powdered sandstone was heated to 2500° C. would indicate an expenditure of 92.5×10^{12} ft. tons of energy. Taking everything into account, it seems reasonable to estimate in all an expenditure of 60×10^{12} ft. tons of energy. Taking this for the energy expended, and estimating the probable velocity of the meteor as lying between three and forty-eight miles a second, the mass of the meteoric group would lie between fifteen million and sixty thousand tons. The size and shape of the crater lead one to estimate a mass larger than this lowest limit, and the final estimate is that the mass is 400 thousand tons, and that its velocity was from eighteen to twenty miles a second.

The conversion of the energy of carbon into electrical energy by solution in iron, Prof. Paul R. Heyl. It is found that carbon dissolves in molten iron with a liberation of energy, which, by providing a suitable negative element, may be obtained as an electric current. The electromotive force thus developed has not yet been definitely determined, but is probably not more than one or two-hundredths of a volt. There is no possibility of compounding this electromotive force with the accompanying thermal effect, as the two are opposite in direction.

The one-fluid theory of electricity, Prof. F. E. Nipher. The author has shown in a former paper that what have been taken for discharges from the positive terminal of an electrical machine are really optical illusions. The positive discharge is really an inflow of the electrical discharge which flows outward from the negative terminal. This is in harmony with the one-fluid theory of Franklin. With this paper he presents photographic plates showing the discharge from its first stages until the disruptive spark appears. These plates fully confirm the former conclusion that there is no positive electrical discharge. The discharge comes from the negative terminal and goes to the positive. The illusion which has led to the idea of a positive discharge is compared to one which might prevail if Niagara Falls should suddenly recede from Lake Ontario to Lake Erie. It might deceive us into the idea that there had been a positive discharge into Lake Erie.

The past and present status of the æther, Prof. A. G. Webster. The history of the conception of the luminiferous æther was covered from the time of Newton and Huygens to the present. For the last hundred years the belief in the æther as necessary to transmit light has been universal. Lord Kelvin devoted most of his life to establishing its properties. The various mechanical theories were succeeded by Maxwell's successful electromagnetic theory, confirmed twenty years later by the electric wave experiments of Hertz. To explain astronomical aberration and the phenomena due to the earth's motion, Maxwell's theory was severely strained, and was perfected by Lorentz. The

classic experiment of Michelson on the apparent fixity of the æther of the earth in its motion was explained by Lorentz, though by the violent assumption that motion changes the dimensions of bodies, and that the local time of a moving observer is different from that of an observer at rest. From this comes Einstein's principle of relativity, which profoundly modifies our ideas of space and time, and leads many radicals to abandon the æther.

The æther drift, Prof. Augustus Trowbridge. Prof. Trowbridge spoke very briefly upon the general question of relative motion of matter and the æther—nest to point out that, in spite of the experimental work of various investigators, we are still in doubt as to whether the earth in its motion through æther-filled space entrains the æther in its motion or not. Next, he explained in what respect the experimental method adopted by Prof. Mendenhall and himself differed from that of former investigators so as to be free from the objections which have rendered the previous work inconclusive.

The effects of temperature on fluorescence and phosphorescence, Prof. E. L. Nichols. A summary of observations on the fluorescence and phosphorescence from temperature of liquid air to ordinary temperatures, showing that the theory of Lenard is inadequate to correlate all the facts.

Infra-red and ultra-violet landscapes, Prof. R. W. Wood. Photographs taken with infra-red and ultra-violet, using appropriate absorption screens, show greatly altered contrasts. Thus some substances which are white when viewed by ordinary light appear black when photographed with ultra-violet light. By such photographs it may be possible to obtain additional details concerning the surface markings of the moon and planets.

The cause of epidemic infantile paralysis, Dr. S. Flexner. A report on the experimental study of poliomyelitis in monkeys, which has yielded a large number of important facts relating to the spontaneous disease in man. The nature of the virus has been discovered, many of its properties have been ascertained, some of its immunity effects have been established, the clinical and pathological peculiarities of the disease have been elucidated, and a basis has been secured on which to develop measures of prevention.

Dermal bones of *Paramylodon* from the asphaltum deposits of Rancho La Brea, near Los Angeles, California, W. J. Sinclair. This paper describes the mode of occurrence, shape, and microscopic structure of the skin bones of an edentate animal from the Los Angeles asphaltum beds. These bones, which are small, pebble-like elements in the skin, resemble closely similar bones occurring in a piece of skin found in a cave at Last Hope Inlet, Patagonia. They are also known to occur in *Myloodon*, a genus of ground sloths formerly living in North and South America. As the structure of the skin bones in *Myloodon* is quite different from what it is in *Grypotherium*, the form from the Last Hope Inlet locality, it was a matter of interest to find out to which of these genera the specimens from the asphaltum showed the closer resemblance. Thin sections of the bones were cut, and these prove that *Paramylodon* from the asphaltum beds is almost identical, in the structure of the skin bones, with *Grypotherium*, a contemporary of early man in Patagonia.

A note on Antarctic geology, Prof. W. M. Davis. It is well known that fossil plants have been found in various formations in the Arctic and Antarctic regions, indicating the former prevalence there of a much milder climate than that of to-day. Our prepossession naturally favours the present polar climate as having been the ordinary or normal polar climate of all geological time; but inasmuch as milder climates have sometimes occurred, it is eminently possible that they, and not the present rigorous climate, may have been the usual polar climate through the geological ages. Hence a peculiar interest attaches to studies of the minute structures of stratified formations, particularly of such as are of continental origin, for from such studies it may well be possible to determine climatic conditions even in the absence of fossils.

Some recent results in connection with the absorption spectra of solutions, Prof. H. C. Jones. The absorption spectra of dissolved substances are not simply a function of the nature of the substances, but also of the nature of the solvents. When a salt like uranyl chloride is dissolved in water we have one spectrum in water. Another in

alcohol, still another in acetone, and a spectrum in glycerol which is very different from any of the above. The only way in which we can account for these results is in terms of the solvate theory. The different solvents combine with the dissolved substance and form solvates having very different compositions. These affect the resonance of the vibrators that are the cause of light absorption differently, and, consequently, the absorption in the different solvents is different. The second point upon which stress is laid has to do with the action of one acid on the salt of another acid. In terms of prevailing chemical theories, when a salt of one acid is treated with a small amount of another acid, a part of the salt is transformed into the salt of the second acid. With the addition of more and more of the free acid, more and more of the initial salt would pass over into the salt of the second acid. In such solutions we should expect to have the bands of both salts occurring simultaneously, with varying intensity, depending upon the amounts of the two salts present. The fact is that when a salt is treated with a free acid we have neither the bands corresponding to the initial nor the final salt present, but bands occupying positions intermediate between those of the two salts, and these bands can be made to occupy any intermediate position by suitably varying the amount of the free acid relative to the salt. This shows that between the initial salt and the one finally formed there is a series of intermediate compounds or systems corresponding to the various positions of the bands. The number of reactions showing the above relations is not small, and this raises the question whether chemical reactions in general are not much more complex than is usually represented by our chemical equations, which deal only with the initial and final stages.

Suppression and extension of spore-formation in *Piper betel*, Prof. D. S. Johnson. The interesting feature of the structure of the flower in this plant is the presence of male flowers, female flowers, and flowers bearing the organs of both sexes, on three separate kinds of spikes; but flowers of each sex often bear some rudiments of organs of the other sex. This shows that while some flowers are apparently of one sex only, they really possess, in some degree, the power to develop the organs of the opposite sex. In other words, the cells from which the flowers arise are capable of forming the organs of both sexes, and the fact that one sex only is formed is probably due to some influence, internal or external, affecting the cells at the time that the flowers are being initiated. Experimental work on certain plants has shown that a change in the light or soil supplied to apparently unisexual individuals may cause the organs of the other sex also to appear. This seems clear evidence that both sexes may really be present in all apparently unisexual plants, but that sometimes one, sometimes the other, of these is suppressed or fails to become evident. The only plants of which this seemingly cannot be true are those well-known unisexual plants like the sago palm, cottonwoods and willows, in which each individual bears only male flowers or only female flowers year after year throughout the life of the plant. Another case is that of one of the mosses, in which it has been shown by Noll that the sex remains constant for thirty generations when male or female plants are propagated by budding.

Solar activity and terrestrial magnetic disturbances, Dr. L. A. Bauer. A recent examination of the times of beginning of magnetic disturbances, as recorded at observatories over the entire globe, showed that, without doubt, magnetic storms do not begin at absolutely the same instant of time, as heretofore believed. Instead, they progress around the earth, the times generally increasing as we go around the earth eastwardly; for the quick and abrupt disturbances, which are usually comparatively minute in their effect on the compass needle, the complete passage around the earth required from three to four minutes. For the bigger effects, or for the greater magnetic storms, the rate of progression is slower, so that it would take them half an hour or more to get around the earth completely. There is thus introduced a new point of view in the investigation of the origin of magnetic storms. In addition to negatively charged electrified particles coming from the sun, to which recent theories sought to attribute our magnetic storms, but which the author found would produce effects not in harmony with

those actually observed, we also receive radiations, such as the Röntgen rays, for example, which are not deflected by the earth's magnetic field, as they do not carry electric charges. Their chief effect will be to ionise the gases of which the atmosphere is composed, i.e. make the air a better conductor of electricity. Ultra-violet light has the same effect. It is known that a small part of the magnetic forces acting on a compass needle is due, not to the magnetism or electric currents below the earth's surface, but to electric currents already existing in the atmosphere, and which the speaker showed were brought about by the atmosphere cutting across the earth's lines of magnetic force in its general circulation around the globe. If the regions of these upper electric currents are at any time made by some cause more conducting, electricity will be immediately set in motion, which in turn affects our compass needles. This new theory, called "the ionic theory of magnetic disturbances," satisfactorily explains the principal features of magnetic storms. As the currents get lower down in the atmosphere their velocity is checked, so that, instead of taking but three to four minutes to circulate around the earth, as do the higher currents, it may take them half an hour and more; however, their actual effect on the magnetic needle would be greater, because of their coming nearer to the earth. The theory also opens up the possibility of accounting for some of the other changes and variations experienced by the earth's magnetism, and likewise has a bearing on the peculiar formation of the magnetic fields in sun-spots discovered by Prof. Hale.

Magnetic results of the first cruise of the *Carnegie*, Dr. L. A. Bauer. The non-magnetic vessel *Carnegie* completed on February 17 the first cruise, covering in all, since September 1, 1909, 8000 miles. Special tests made at Gardiner's Bay, Long Island, and at Falmouth, England, proved conclusively that there are no corrections to the magnetic instruments of the kind encountered on vessels in which more or less iron occurs in the construction. Thus in a single voyage errors could be disclosed in the compass charts used by mariners on their Transatlantic voyages between New York and England of importance, not alone from a purely scientific standpoint, but from that of practical and safe navigation as well. The errors found by the *Carnegie* in the declination at various points along the track followed by the vessel amounted, on the average, to about 1 degree—an error which persisted in the same direction for long distances. After leaving Falmouth the *Carnegie* headed for Funchal, Madeira. From thence she sailed to Bermuda, and finally arrived at Brooklyn on February 17. In spite of the unusually adverse conditions frequently met with during this first cruise, more or less extensive magnetic observations were secured almost daily. The errors of the compass charts were found, in general, even more pronounced for the southerly half of the cruise, viz. Madeira to Bermuda, than for the northerly half, and were again shown to be systematic in their nature. Some of the charts were in error 2 to 3 degrees. For the entire cruise important corrections were also disclosed for the magnetic charts which give the lines of equal magnetic dip and of equal magnetic force. The *Carnegie* is now being fitted out for a circumnavigation cruise of about three years. In the meantime, the magnetic surveys of unexplored countries are pushed on, so that it is confidently expected that by the year 1915 the general magnetic survey of the greater part of the globe will have been completed in sufficient detail to permit the construction and issuing of a new set of magnetic charts.

On the distances of red stars, Prof. H. N. Russell. Comparison of the parallaxes of stars, derived by the author from photographs taken at the Cambridge Observatory (England) by Mr. A. R. Hinks and himself, and their spectra, determined at Harvard under the direction of Prof. Pickering, shows a marked correlation between spectral type and parallax. The proportion of orange and red stars (types K and M) among those of large proper motion, and especially among those shown by direct measurement to be our near neighbours, is very much greater than among the general run of stars of the same apparent brightness. Conversely, stars of the same apparent brightness and proper motion are, on the average, nearer to us the redder they are. It follows that these stars

are intrinsically fainter the redder they are, the reddest ones being, on the average, only one-fiftieth as bright as the sun. On the other hand, many bright red stars (such as Arcturus) are at great distances, and are actually at least 100 times as bright as the sun. All this can be explained on the hypothesis (now well established on other grounds) that the reddest stars are the lowest in temperature. With the latest determinations of temperature and surface brightness, it appears that the fainter red stars are somewhat smaller, and presumably denser, than the sun, while the brighter ones are very much larger than the sun, and presumably of very small density. The latter class probably represent an early stage of evolution, and the former the latest stage that can be observed.

A standard system of photographic stellar magnitudes. Prof. E. C. Pickering. Since 1879 about two million photometric observations of one hundred thousand stars have been made at the Harvard College Observatory. The results, published in vols. I., liv., and lxx. of the "Harvard Annals," furnish a standard scale for determining the brightness of the stars in all parts of the sky, according to a uniform system. The general introduction of photography in nearly all departments of astronomy has created an urgent need for a similar scale to give the photographic magnitudes of the stars. The two scales will differ, since red or yellow stars will always give fainter images. The scale proposed will be the same for white stars as the visual scale. Three methods are adopted in this work for determining the photographic brightness—first, correcting the visual magnitude by the class of spectrum; secondly, by measuring with great care the photographic brightness of a sequence of stars near the North Pole, and superposing this photographically on the stars to be measured; thirdly, by attaching to the object-glass of the telescope a small prism, a second image of each star, five magnitudes fainter than the principal image, is formed. All three of these methods are in use on a large scale at the Harvard Observatory, and it is hoped that, as the result of many thousand measures, a satisfactory solution of the problem will be found.

Some interesting double stars, Prof. Eric Doolittle. The many thousand double stars in the sky may be divided into two classes. There are some in which the two stars are not really near each other, but merely happen to lie in the same direction as viewed from the earth, and there are others which form true systems composed of two suns revolving about their common centre of gravity. In the latter case, measures show that one sun revolves about the other in an elliptic orbit. It often happens that a very few measures of such a system secured at certain critical times throw unusual light on the nature of the motion and the size of the orbit. This is especially the case when the companion star apparently ceases its motion in one direction and begins to move backward, and also when the companion is passing nearest the principal star. Several diagrams were shown describing measures of this kind which had recently been secured. An account was also given of the discovery of a very close double star during its occultation by the moon.

THE ROYAL OBSERVATORY, GREENWICH.

READ at the annual visitation of the Board of Visitors on Saturday last, the Astronomer Royal's report of the work done at the Greenwich Observatory during the year ended May 10 contains many items of general interest.

On the transit circle the new central illumination was further compared with the annular illumination of the field, and it was found that, with the latter, transits were observed 0.24s. earlier than they are with the new form. Six stars from Newcomb's Fundamental Catalogue are observed each night in order to connect the observations of the reference stars for the Oxford Astrographic Zones with any system that may ultimately be adopted by the Permanent International Committee.

Observations of the diurnal changes of level and nadir during 1909 showed that changes of level were less, and of nadir slightly greater, than the means for 1897-1905. The lunar observations with transit circle and altazimuth are in good agreement, and, for 1908, show the mean error of the tabular place to be -0.395s. in R.A. and

0.00" in N.P.D. The moon was observed on 146 days during the year, and observations of Mars and of Halley's comet, in and out of the meridian, were also secured.

Double stars and planetary diameters were measured with the 28-inch refractor, 150 of the pairs having separations less than 0.5" and 296 pairs less than 1.0".

With the 26-inch refractor 146 planetary photographs were secured, including sixty-two of Mars, taken between July 23, 1909, and May 14, for an investigation of its orbit.

Planets, satellites, and comets 1909a, b, c (Halley's), and c were also photographed with the 30-inch reflector; among these were twelve photographs of Saturn and Phœbe, thirteen of Jupiter and J. viii., and forty-four of Halley's comet. The first photograph of J. viii. during this opposition was secured on January 19, and the observed correction to the position given by the Cowell-Crommelin-Davidson orbit was only 7"; this satellite has now performed one complete revolution since its discovery. A slight elongation of the images taken with the 30-inch reflector was attributed to a small shift of the mirror cell, and has been completely eliminated by rounding the ends of the supporting screws and making hollows to receive them in the bed on which the cell rests. A 6-inch lens, kindly lent by Mr. Franklin Adams for photographing the extensions of the tail of Halley's comet, and a prismatic camera for photographing the spectrum, were attached to the 30-inch reflector, but the bright twilight and low altitude of the comet prevented the latter observations.

The work on the Greenwich astrographic zones being complete, the 13-inch astrographic refractor was employed until April for cometary and various other photographic observations. Since then it has been used for photographing the astrographic zones +25° to +31°, originally allotted to the Oxford University Observatory. The stars on these chart plates are also to be counted at Greenwich, as are also those on the catalogue plates, which are being re-taken for the purpose. For photographing Halley's comet a new Ross lens of 4 inches aperture and 16 inches focal length has been attached to the 10-inch finder of the astrographic instrument.

Of the 3.07 days' difference between the perihelion passage of Halley's comet and the date predicted by Drs. Cowell and Crommelin, one day has been accounted for in a re-discussion of the perturbations during 1828-42, but the further discordance of two days is as yet unaccounted for by any attraction of known matter in the solar system. The observations show that none of the other elements was so much as 1' in error.

During the period dealt with by the report the sun was photographed at Greenwich on 194 days, and the Royal Observatory contributed 171 days towards the record for 1909, which is now complete, with the assistance of the Dehra Dûn and Kodaikanal Observatories, except for two days. In this work the Cape Observatory now replaces the Royal Alfred Observatory, Mauritius, and the hope is expressed that the yearly record may be made up almost entirely from the plates taken at the two Royal Observatories, Greenwich and the Cape; during March their record was complete except for one day.

The magnetic observations were carried on as usual, but the registration of earth currents was discontinued at the end of 1909 because new wiring was found to be necessary, and was considered unjustified owing to the disturbances produced by the electric trams, &c.

For 1909 the principal magnetic results were:—

Mean declination	15° 47' 6" W.
„ horizontal force	{ 4.0179 in British units
„ dip (3-inch needles)	{ 1 8526 „ metric „
	66° 53' 57"

Two days of "greater" and six days of "lesser" disturbance were registered by the magnets.

The reductions of the meteorological observations are complete to date, and show that the mean temperature of 1909 was 48.6°, 1° below the 65-year average 1841-1905. The rainfall for the year ended April 30 was 27.72 inches, 3.6 above the average, and the number of "rainy days" was 192, the highest for many years.

The performance of the chronometers tested was satisfactory, and in future non-magnetic watches are to be received and submitted to the same tests as the chrono-

meter watches. A new trial of box chronometers commenced on June 18, and the next trial of pocket chronometers and chronometer watches will commence on July 30. The time-signal service was also satisfactory, and the performance of the Westminster clock ("Big Ben") left little to be desired. On 41 per cent. of the days its error was less than 0.5s., on 77 per cent. less than 1.0s., and on 98 per cent. less than 2.0s.; it never exceeded three seconds.

The vacancy on the *personnel* caused by the resignation of Dr. Cowell has not yet been filled, and, in closing the report, Sir William Christie tenders his hearty thanks to the staff for their loyal cooperation in the prosecution and extension of the observatory's work during his tenure of the office of Astronomer Royal. Although the work has been enormously extended during the past thirty years, the financial provision for it has been increased by only 2200l. per annum.

AGRICULTURAL RESEARCH.

THE need for widely extended facilities for agricultural research is being more and more recognised both by men of science and by our administrative authorities. At the last meeting of the executive committee of the British Science Guild a memorial to the Prime Minister on the subject of research in agriculture was approved. The President of the Board of Agriculture and Fisheries has now appointed a committee to advise the Board as to how agricultural research may be best encouraged and improved. Lastly, a society has been incorporated to secure the development and extension of the investigations inaugurated and endowed by the late Sir John Lawes. These are all excellent indications that a determined and united effort is to be made to place agricultural practice upon a scientific basis, and to secure for the British farmer all the help science is able to provide.

The committee appointed by Earl Carrington to advise the Board of Agriculture on all scientific questions bearing directly on the improvement of agriculture will deal especially with the methods to be adopted (a) for promoting agricultural research in universities and other scientific schools; (b) for aiding scientific workers engaged in the study of agricultural problems; and (c) for ensuring that new scientific discoveries are utilised for the benefit of agriculturists.

The committee will consist of the Duke of Devonshire, Lord Reay, Sir Edward Thorpe, C.B., F.R.S., Mr. David Davies, M.P., Dr. J. J. Dobbie, F.R.S. (principal of the Government Laboratories), Prof. J. B. Farmer, F.R.S., Dr. S. F. Harmer, F.R.S. (keeper of zoology at the Natural History Museum), Dr. R. Stewart MacDougall (technical adviser in zoology to the Board of Agriculture and Fisheries), Mr. T. H. Middleton (one of the assistant-secretaries to the Board of Agriculture and Fisheries), Mr. Spencer P. Pickering, F.R.S., Lieut.-Colonel David Prain, C.I.E., F.R.S. (director of the Royal Botanic Gardens, Kew), Mr. H. S. Staveley-Hill, M.P., Mr. Stewart Stockman (chief veterinary officer of the Board of Agriculture and Fisheries), Dr. J. J. H. Teall, F.R.S. (director of the Geological Survey and Museum), and Dr. David Wilson. Mr. Middleton will act as chairman of the committee, and one of the officers of the Intelligence Division of the Board will act as secretary.

A meeting of the Society for Extending the Rothamsted Experiments was held at Rothamsted on June 16 under the presidency of the Duke of Devonshire. The society has been incorporated with the object of obtaining additional funds for the development of the agricultural investigations which have been carried on so long under the late Sir John Lawes and the Lawes Agricultural Trust which he afterwards founded. The immediate object of the society is to obtain a sum of 5000l. in order to secure about 200 acres of land adjoining the present experimental fields, and erect thereon the buildings required for feeding experiments with the crops under investigation.

An appeal for subscriptions towards thus securing a small self-contained farm for the Rothamsted Experimental Station is now being circulated, and at this meeting of the society a first list of donations was reported from the Duke of Devonshire, Lord Iveagh, Sir J. T. Brunner, Colonel E. H. Carlisle, M.P., Mr. J. F. Mason, M.P., and Mr. J. Martin White, amounting to 1450l.

CHEMISTRY AND PHARMACO-THERAPEUTICS.

THE Hurter memorial lecture was delivered recently before the Liverpool Section of the Society of Chemical Industry, by Dr. C. A. Keane, on modern iatrochemistry (Journal of the Society of Chemical Industry, Liverpool Section, April 15). Dr. Keane traced the development of various synthetic products used in pharmacy, and discussed the relations of physiological properties to structure so far as they may be said to be known. He illustrated his discourse by three typical groups of compounds—the antipyretics derived from *p*-aminophenol, the hypnotics derived from malonyl urea, and the local anæsthetics related to cocaine. Referring to the first group, he showed that the toxic properties of aminophenol may be reduced and its antipyretic action increased by introducing radicals into the hydroxyl and amino groups. He pointed out the importance of a sufficiently stable combination to resist decomposition by the acid of the gastric juice, as otherwise the radical is split off in the stomach with the production of the parent substance. The practical outcome of these investigations has led to the recognition of phenacetin as the most suitable for medicinal use.

Among the substitutes for salicylic acid as an anti-rheumatic he mentioned salol (phenyl ester), aspirin (acetyl salicylic acid), and salophen (salicyl acetaminophenol), substances which, being stable towards acid, pass through the stomach unchanged, but are subsequently hydrolysed by the alkaline pancreatic juice, when the constituents begin to exert their specific effect. Passing on to the hypnotics, veronal and sulphonal and their analogues, it was observed that each contains a hypnotic group in which alkyl radicals (R, one of which must be ethyl) are necessary to produce hypnotic action.

Dr. Keane then gave an account of cocaine, the nature of the groups which are responsible for local anæsthesia, and the successful application of this knowledge to the production of new drugs, such as α and β eucaine, orthoform, stovaine, novocaine, holocaine, &c.

The address concluded with a table of statistics giving the quantity of synthetic drugs imported from Germany (the seat of the industry) to this country, which on six drugs alone amounts to about 20 tons, of the value of 16,000l. annually.

THE BEGINNINGS OF HUMAN SPEECH.

AN interesting attempt by Dr. C. Täuber to trace human speech back to its first beginnings appears in *Globus* for May 12 (Bd. xcvi.). For this purpose the writer classifies the simplest conceptions and the sounds representing them into six divisions, as follows:—(i.) *m*+vowel, meaning liquid food (e.g. milk, melt, Germ. Ge-müse, &c.); (ii.) *p* (*b* or *v*)+vowel, solid food (e.g. bread, Germ. Futter, Lat. panis, &c.); (iii.) *n*+vowel, sometimes *sn*, fluidity (e.g. Lat. navis, Germ. nass, snow, &c.); (iv.) dental+vowel, sometimes *st*, wood or forest (e.g. timber, Germ. Stuhl, throne, Germ. Tanne, &c.); (v.) liquid+vowel, feeding or drinking place (e.g. Gk. libadion, lake, Germ. Loch, &c.); (vi.) guttural+vowel, animal world (cow, Lat. caper, Germ. Hund, &c.).

For each division Dr. Täuber draws up a table of derived ideas represented by the same root-syllable in various Indo-Germanic languages, e.g. under (i.) we find Mama, Germ. Mutter on one side and Germ. Meer, Lat. mare, &c., on the other. From mater, mother, is derived the idea of to feed, and from that, again, the conception well-fed, large. It must be confessed that considerable ingenuity is required to trace the connection in some instances, but the author freely owns to setting forth speculative results.

NO. 2121, VOL. 83]

It is extremely interesting to note that these six sound-groups appear with the same force in many non-Indo-Germanic languages; for instance, (i.) *m*+vowel in Hebrew manna (food), maim (water), mâtâr (rain), málal (wine mixed with water); in Bantu languages *ma*=water occurs very frequently in compound words; also in Chinese (in Siamese *n-am*); in the form *mu* in the Ural-Altaic languages (Tungus and Manchurian *mu-ke*=water, Japanese *u-mi*=sea, *a-me*=rain); *ma*, meaning water, rain, or drink, is widespread in the Australian, Polynesian, and Malay languages; the Eskimo have the word muk for water. The derived conception *mag*=large occurs in Caucasian, Ural-Altaic, and Dravidian languages. Instances from Semitic, Caucasian, and other languages are also given for the other five sound-categories. Dr. Täuber would like to see his scheme worked out and amplified and the *Ursprache* established beyond question, after which it might be possible to ascertain the points at which the great linguistic branches differentiated.

ASSOCIATION OF TEACHERS IN TECHNICAL INSTITUTIONS.

THE annual conference of the Association of Teachers in Technical Institutions was held at Birmingham in the Birmingham Municipal Technical School on Friday and Saturday, June 17 and 18. In his address, the president of the association, Mr. J. Wilson, Battersea Polytechnic, emphasised the importance of scientific and technical education to industrial progress. As an example of this, it was pointed out that, owing largely to the limited appreciation of technical education by the English manufacturing world as a whole, nearly all the chief industrial developments of the last twenty years are either of German, French, or American origin or commercial development. The present national and municipal expenditure on technical education in Great Britain is approximately one and a half millions sterling per annum. This is very small when compared with the "gross" annual output of the engineering and chemical industries alone, amounting to about 258 millions per annum. Mr. Wilson discussed the position of the London polytechnics with reference to the London University. He considered that any diminution in the effective facilities now offered by the polytechnics to the working and lower middle classes to participate, not only in advanced technical education, but in higher and university education, would be a grave retrograde step.

In a paper read at the afternoon session by Dr. Price, of the Birmingham Technical School, on "The relation between the technical school and the university," it was pointed out that, generally speaking, the average technical student, however highly qualified he may be by previous study and experience, cannot possibly attend the university, owing to the high fees and cost of maintenance. In reply to certain criticisms by Prof. Meldola and Sir William Ramsay on the value of evening instruction, it was stated that at the present time many evening students in technical institutions are taking courses in the highest branches of technical knowledge, with advantage to themselves and to the industry with which they are connected. In Birmingham, for instance, there are men holding responsible positions who have received all their scientific training in the evening classes at the technical school. Many drawbacks in the highly valuable system of external examinations of the London University could be obviated if a satisfactory system could be devised by means of which technical institutions of sufficient standing could be affiliated to the local universities. Many of the larger technical schools are well equipped and have a highly trained staff which is able to, and does, carry out research.

A number of general resolutions on technical education were passed dealing with subjects such as:—(a) the co-ordination of education in the primary, secondary, and continuation schools with technical school work; (b) the necessity for the provision of technical education of a more advanced and more highly specialised character than exists at present; (c) technical schools to be allowed to develop their work as highly as local requirements demand; (d) urging upon the Government the desirability of appointing a Royal Commission to inquire into the need for the organisation of technical education throughout the country.

KEW AND ESKDALE MUIR OBSERVATORIES AND THE METEOROLOGICAL OFFICE.

BY arrangements recently concluded between the Lords Commissioners of H.M. Treasury, the Royal Society, the National Physical Laboratory, and the Meteorological Office, the administration of the work of the Kew Observatory, in so far as it is concerned with observational and experimental work in meteorology and geophysics, will be transferred to the Meteorological Office as from July 1. The Kew Observatory will be the central observatory for the office. All communications respecting that side of the work of the observatory should thenceforth be addressed to the director of the Meteorological Office, Kew Observatory, Richmond, Surrey.

By another provision of the arrangement the administration of the observatory at Eskdale Muir will be associated by the Royal Society with the Meteorological Office instead of, as heretofore, with the National Physical Laboratory.

In the conduct of the administration of the observatories the director of the Meteorological Office will have the assistance of an advisory committee—the Gassiot Committee, appointed by the Royal Society to administer the funds of the Gassiot Trust, representing an endowment of 10,000*l.* vested in the Royal Society in 1871 by Mr. J. P. Gassiot.

One of the provisions of the new scheme is that the superintendents of the three observatories—Kew, Eskdale Muir, and Valencia—under the direction of the Meteorological Office shall be appointed by the Meteorological Committee upon the nomination of the Gassiot Committee. On this nomination the appointments of Dr. C. Chree, F.R.S., as superintendent of the Central Observatory, and of Mr. G. W. Walker, of Eskdale Muir Observatory, have been continued by the Meteorological Committee. Dr. Chree has further been appointed assistant-director of observatories for the Meteorological Office. Mr. J. E. Cullum remains superintendent of Valencia Observatory.

The work of testing instruments now carried on at Kew Observatory by the National Physical Laboratory will be removed to Teddington as soon as the necessary provision for its transference can be made. The laboratory will retain the well-known K.O. mark for use with those classes of instruments which have hitherto been tested at the observatory. For the time being the work will be carried on at the observatory as a department separate from the observational work, but under the superintendence of Dr. Chree. Communications respecting this side of the work should be addressed to the director of the National Physical Laboratory, Observatory Department, Richmond, Surrey.

INDUSTRIAL WORK AND EDUCATIONAL DEVELOPMENT.¹

LOCAL authorities have tried in various ways to secure in their work for further education the cooperation of employers of labour in their areas. Under present industrial and educational conditions, great importance attaches to any action taken by employers either in increasing their employees' opportunities for attending technical classes or in urging, and granting practical recognition to, the gain which systematic study in such classes brings to workmen who attend them. In 1905 the Board prepared a circular describing some of the more fruitful efforts which had been made in securing the co-operation of employers in these and similar ways, and the issue of this circular stimulated further efforts of the kind in various parts of the country. It is now generally recognised that one of the duties of managers of technical schools is to establish and maintain the closest possible relations with those under whom their students are employed.

The development and strengthening of the relation which the work of the teaching institution bears to the practice and to the commercial aspects of industries may do much to promote industrial progress, and it is not unreasonable to expect that in making their arrangements with their younger workpeople employers should give some consideration to the conditions necessary for the

work of the school. Individual employers and groups of employers have in practice found it compatible with economy of production in trade workshops to allow some reduction in the ordinary working time to those of their employees who attend approved courses of instruction in technical schools. The usual combination of workshop and school in the preparation for industrial work assigns the evening only to school, and requires the young worker during the day to give full-time attendance in the workshop. It is true that even in these conditions large numbers of students have made great progress in their technical education. For students of energy, strength, and ability evening classes have afforded, and still afford, opportunities of advancement in knowledge which, when coupled with the experience of practical work, of men, and of commercial conditions which they acquire in their daily occupations, enables them to qualify for positions of responsibility in the industries. Evening classes have indeed provided an open avenue for talent—an avenue by which not a few have advanced to positions in which they have done marked service for the industrial welfare of the country. Where, however, studies have to be carried on in evening classes alone, they are subject to difficulties which in all cases retard the student, and in many cases dishearten him before he has obtained even such knowledge of principles as he requires if he is to be an intelligent hand-worker. The movement towards an extension of the opportunities for part-time study during the day is therefore one which may have far-reaching results.

The forms in which additional facilities for school work are afforded differ considerably; the main cause of this variety of form is that the conditions of different trades vary considerably both as to the nature of the part taken in the work by young workmen and as to the continuity of the demand for work throughout the year.

There are now, however, in successful operation courses of part-time study under arrangements involving time off from the works for such periods as one or two afternoons a week, one day a week, three days a week, or, it may be, daily during two months of a slack period of the year. In all cases of this kind the authorities of the local technical school arrange courses of instruction for the hours available, and that instruction is definitely related to the requirements of the groups of students in attendance. Under these conditions the students have the advantages of class instruction in the daytime, and they can without strain supplement this by home-work in the evenings, and yet have time throughout the year for other interests. Part-time study in the day in this way has been proved possible and of much advantage in connection with engineering and building trades, with painters' work, with plumbers' work, and other trades.

Coupled with schemes of this kind, as well as in connection with the ordinary evening-school system, there have been established in many places scholarships or other facilities by which promising students may devote longer periods entirely to study—periods in some cases six months, in others one, two, or even three years.

There can be no doubt that the increase of day classes for part-time students will do much to advance technical education. Such an increase would not be costly, for in most towns there have now been provided technical schools on a scale commensurate with the demand for specialised technical instruction in the evening, and during the day these schools are generally but little utilised. The extension of such day work gives occasion for a better division of the time of technical teachers, and thus makes it possible for school authorities to obtain greater value for their expenditure in retaining the services of well-qualified teachers.

The possibilities involved in even a slight re-distribution of the hours young people devote to work and to instruction, respectively, are so important that it is of special value to have good tests of what can be attained in this way in actual practice without disturbance of economic conditions. The arrangements made in connection with day classes recognised under the Board's regulations afford numerous examples of methods by which employers of labour and local education authorities have been able to work together in providing special classes adapted to a particular trade or industry and to local conditions of

¹ From the Report of the Board of Education for the Year 1908-9. [Cd. 5130.] Price 9*d.*

employment, and details of some such instances of part-time day work may be indicated here.

In a town in the north of England a number of apprentices are set free from their employment at certain times so that they may attend classes which have been specially arranged for them in the local technical school in engineering and allied trades; the courses extend over two sessions of eight months each; students in their first year attend for one morning and one afternoon a week, and those in their second year for two afternoons a week, or four hours in all. The fees are paid by the employers; the apprentices pay for books and materials, but receive their wages for the periods of absence from work granted to enable them to attend the classes. The time spent by apprentices in attendance at the day classes is counted in their term of apprenticeship, and preference is given by the employers in filling vacancies in their works to those who attend the classes. The employers are represented on the governing body of the technical school.

The local education authority at a railway centre in the south of England has provided in the technical institute classes for engineering apprentices in the employment of the railway company. The apprentices are allowed to attend a four years' course, arranged in the case of the first year of instruction for 2½ hours for one morning a week, and in the case of the second and third and fourth years for 3½ hours a week, spread over two mornings. Again, at a railway centre in the north of England, the technical school carries on a course on the construction and management of the locomotive to meet the requirements of engine drivers, firemen, and engine cleaners; the instruction here is for two hours on one morning a week, and is given by teachers who are district locomotive foremen.

In a centre of chemical manufacture we find special arrangements for the instruction of trade apprentices of large engineering and chemical works. In the case of one firm the employers require that their employees shall attend an evening school until they are nineteen years of age, but some of the apprentices of this and of another firm are allowed to attend for instruction for four hours on two afternoons a week for forty weeks in the year during the last two years of their apprenticeship, without loss of wages during their absence from the works at the classes; the employers pay the fees, and attendance at these classes is regarded by them as a very important part of the apprenticeship.

In a large industrial centre the local education authority has provided apprentice day courses for engineering, plumbers' work, and painters' and decorators' work; the various courses range over two or more years, and meet for one whole day a week throughout the year. Seasonal periods of less pressure or slackness of work are peculiarly liable to occur in summer in some departments of the building trade, such as painting and plumbing, and accordingly the same authority has succeeded in establishing a suitable special summer course for plumbers who can utilise the opportunity in order to improve their knowledge and efficiency by attending on four full days and two half days weekly throughout a complete month for instruction in subjects cognate to plumbing.

Again, in the case of a closely related trade (gas-fitting), where, however, the conditions of work are somewhat different, another local authority has arranged that boys who are under training to become gas-fitters may have the advantage of concurrent technical education in the daytime. The boys attend at the local technical institute for three hours on each of three afternoons a week. The instruction they receive is in continuation and development of their previous work at the public elementary school, and includes English, workshop arithmetic, and mechanical drawing.

Among the advantages of close relations between school authorities and the employers of the students who attend the schools, not the least is the increased confidence with which school authorities can advise their pupils—especially young pupils—as to the studies they ought to take up. In the arrangements made for giving such advice there is room for great improvement; at present it is not possible to say more than that this is an essential feature in all schemes of evening-school work that succeed in securing large and continued attendance of pupils.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following are the speeches delivered by the Public Orator, Dr. Sandys, on Tuesday, June 14, in presenting Sir Oliver Lodge, principal of the University of Birmingham, and Prof. William Henry Perkin, professor of organic chemistry in the Victoria University of Manchester, for the degree of Doctor in Science *honoris causa*:—

Adest vir scientiarum physicarum in regione quadam caelesti investiganda iam per annos triginta praeclarè meritis, qui praesertim aethera illum exploravit, per quem solis stellarumque lux et calor "immemorable per spatium" confestim, sine ullo phaenomenorum terrestrium impedimento, in orbem terrarum nostrum transmittuntur. Idem diligenter inquisivit, fulgurum vis electrica quomodo fila tectorum securitati inservientia percurrat, quamobrem subito deserat. Inde progressus, etiam vim electricam, non aliter quam lucem, undarum more moveri eo ipso tempore argumentis idoneis ostendebat, quo vir quidam insignis, Henricus Hertzius, illud ipsum experimentis comprobavit et Maxwellii nostri vaticinationes veras esse demonstravit. Iure igitur optimo Regia Scientiarum Societas numisma lucis et calor's legibus investigandis propositum huic potissimum viro donavit; iure optimo nos quoque, et haec et alia eius merita plurima admirati, eundem inter scientiarum doctores nostros honoris causa collocamus. Eum certe, qui Anglia in media, ipsius Volcani in domo dilecta Sapientiae sedem serenam nascentem fovit, crescentem adjuvit, etiam nostra Mater Alma voltu benigno respicit.

Praesentatur vobis Universitatis illius novae praeses dignissimus, rerum naturae explorator felix, eques insignis, Oliver Lodge.

Abhinc annos quattuor et quinquaginta unus e nostratibus (juvat gloriari) primus omnium indicavit etiam e liquore piceo, qui carbonis fossilis e bitumine exsudat, colores quosdam roseos posse exoriri. Utinam etiam inventi tam pulchri repertorem illustrem purpura nostra decorare nobis contigisset! Laetamur tamen patris tam illustris in filio insigni eandem laboris patientiam, eundem scientiae eundem veritatis amorem simplicem sincerumque agnoscere. Vir in experimentis elaborandis solertissimus, in experimentorum interpretatione perspicacissimus, (ne plura commemorem) non modo "narcotinam" illam, quae papaveris in succo est, sed etiam rerum naturae odores quosdam suavissimos artificio suo aemulatus est. Viro tali ideoque praesertim gratulamur quod ei, propter labores eius assiduos, primum a Societate Regia Londinensi numisma aureum donatum est; deinde Victoriana in Universitate Mancunien'si, viri huius e studiis novam gloriam adeptae, cathedra nova constituta. Laetamur denique tot colorum inventor's filium, in eadem scientiarum provincia exploratorem felicem, honoris causa purpura nostra vestitum videre.

Duco ad vos scientiae chemicae professorem Mancuniensem, nominis magni heredem magnum, Willelmum Henricum Perkin.

LEEDS.—At a meeting of the council of the University held on June 15, the following resolution was passed:—"The council record their deep sense of the honour done to the University by the offer of a fund raised as a memorial to the late Sir George Livesey for the endowment of a professorship of applied chemistry relating to the coal-gas and fuel industries. The council gratefully accept the offer, and hereby establish a Livesey professorship of coal-gas and fuel industries, subject to the conditions prescribed in the deed of gift submitted on behalf of the donors or the Livesey Memorial Fund." The fund referred to amounts to about 11,000*l.*, and has been collected from corporations, companies, and private donors associated with the industries with which Sir George Livesey was so honourably connected.

LONDON.—At a meeting held on June 15 the Senate elected Dr. M. J. M. Hill, F.R.S., Astor professor of mathematics, to be Vice-Chancellor of the University for a second term of office, viz. until June, 1911.

OXFORD.—The electrical laboratory presented to the University by the Drapers' Company, and erected on the north side of the University Museum at a cost of 23,000*l.*,

was opened in the presence of a large company on June 21. The Master of the Drapers' Company, Mr. K. R. Fletcher (upon whom the degree of Doctor of Civil Law *honoris causa* was conferred), made the presentation of the laboratory, and the Chancellor (Lord Curzon) acknowledged the gift in a speech, in the course of which he said that eight years ago, when a statement was drawn up of the needs of the University, a very prominent place was given in it to the need for a laboratory for the Wykeham professor of physics, and only three years ago, when the Vice-Chancellor and he wrote their first letter to the Press on behalf of the appeal for the re-endowment of the University, they summed up the requirements of the University in this respect in the laconic phrase, 'We need an electrical laboratory.' Oxford needed it, not merely to enable the professor to give the best teaching to candidates for honour degrees, but also to enable him to keep in touch with the most modern scientific discovery by the pursuit of independent research with the aid of the most recent appliances, and also, of course, to provide opportunities for similar investigations to outside people. He would not, however, have anyone to go away with the idea that, even after this splendid gift, the scientific requirements of the University were exhausted. The department of chemistry, both in respect of teachers and of laboratories, was quite unfit for the great institution to which it belonged. He was sure, also, that in the department of engineering science a laboratory was badly wanted.

COLUMBIA UNIVERSITY has conferred its doctorate of science on Sir William White, K.C.B., F.R.S.

It is announced in *Science* that Bryn Mawr College has obtained money sufficient to pay its debts, and in addition 50,000*l.*, which entitles it to the appropriation of 50,000*l.* of the General Education Board. The sum raised by the Alumnae Association was 60,800*l.*, which is to be used for the endowment of chairs in mathematics, English, and economics.

THE Imperial University Congress, which will be held in London in 1912, is likely to be one of great importance and of far-reaching influence. All the universities of the Empire are to be invited to send representatives to the congress, and the invitations are being issued in the names of the Universities of London, Oxford, and Cambridge, while the University of London will have the duty of organising the congress. It has been suggested that a preliminary meeting of representatives of British universities might be held next year with the view of preparing materials for the congress. Dr. R. D. Roberts, formerly Fellow of Clare College, Cambridge, and one of the registrars of the University of London, will act as secretary of the congress.

As announced already, the third International Congress on School Hygiene is to be held in Paris on August 2-7 next. The organising committee of Great Britain and Ireland, of which Sir Lauder Brunton, Bart., F.R.S., is president, is appealing specially to all who were associated with the London congress in 1907 to attend the Paris meeting. Travelling and hotel accommodation are being arranged by the committee at moderate charges, and full particulars concerning them can be obtained from Mr. Durrie Mulford, assistant secretary, 90 Buckingham Palace Road, S.W. The general meetings of the congress will deal with uniformity of method for physical examinations in schools, sexual education, and the training and appointment of the school doctor. The other business of the congress will be done in eleven sections, dealing with every aspect of the question of securing the health of the teachers and pupils in schools.

THE Johns Hopkins University Register, 1909-10, which has reached us from Baltimore, contains an interesting historical statement. From this we find that the original endowment of the University amounted to a little more than 600,000*l.* This sum has been supplemented by several gifts, including the endowment fund of 1902, amounting to 200,000*l.*, and the John W. McCoy fund of 100,000*l.* The income-bearing funds have a "book value" of 916,000*l.* The real estate and buildings, books, scientific apparatus, and general equipment are valued at 380,000*l.* The total value of the assets of the University is thus about

1,300,000*l.* In June, 1909, the General Education Board offered to contribute 50,000*l.* towards the endowment of the University provided the institution is able to secure 150,000*l.* on or before December 31 next. It is expected that the conditions of the gift will be met by the date specified. The Legislature of Maryland recently made an appropriation of 5000*l.* a year for 1911 and 1912.

We have received a copy of a syllabus for the "teaching of science of home affairs," drawn up by a committee of the Association of Teachers of Domestic Science, in conjunction with certain teachers of chemistry and hygiene. The object of the syllabus is to indicate a course of instruction up to a "matriculation" or "school-leaving" standard suitable for girls in a secondary school. The course is designed to include those portions of elementary physics, chemistry, hygiene, and physiology necessary for the proper understanding of the scientific principles underlying home management. It is hoped that courses, somewhat on the lines of those suggested in the syllabus, will in the future be generally adopted in girls' secondary schools, thereby bringing about a much needed correlation of the science teaching with the instruction in cookery work, laundry work, &c. The committee suggests the desirability of the inclusion of this modified science course as one of the optional subjects for girls in the scheme of examinations held by the authorities now conducting public examinations of a "matriculation" or "school-leaving" standard.

THE Royal Commission on University Education in London has issued its first report, which consists of the minutes of evidence taken up to April, 1910. It will be remembered that the commissioners were appointed to inquire into the working of the present organisation of the University of London, and into other facilities for advanced education (general, professional, and technical) existing in London for persons of either sex above secondary-school age; to consider what provision should exist in the metropolis for university teaching and research; to make recommendations as to the relations which should in consequence subsist between the University of London, the incorporated colleges, the Imperial College of Science and Technology, the other schools of the University, and the various public institutions and bodies concerned; and, further, to recommend as to any changes of constitution and organisation which appear desirable, regard being had to the facilities for education and research which the metropolis should afford for specialists and advanced students in connection with the provision existing in other parts of the United Kingdom and of our dominions beyond the seas. In a letter to the *Times* of June 17, Prof. M. J. M. Hill, Vice-Chancellor of the University of London, points out that, in addition to the evidence already published, further evidence from persons representing other views held in the University will be submitted to the Royal Commission, and suggests that it would be well to suspend judgment and to abstain from drawing conclusions from the evidence now available until the whole inquiry has been completed and the commission has issued its final report.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 16.—Sir Archibald Geikie, K.C.B., president, in the chair.—D. Thoday: Experimental researches on vegetable assimilation and respiration. VI.—Some experiments on assimilation in the open air. In these experiments Sachs's half-leaf dry-weight method has been employed, with modifications suggested in a previous paper for avoiding errors due to shrinkage of the isolated half-leaves. Turgid leaves of *Helianthus annuus* were found in bright sunlight to increase in dry weight 17 mg. per hour per sq. decim.; thus Sachs's high value is confirmed. Even a slight loss of turgor, however, was accompanied by a diminution in the rate of increase. For this high rate of assimilation a leaf-temperature of 23° C. to 24° C. is probably required. It is suggested that Brown and Escombe's low results in bright diffuse light indicate that the stomata of *Helianthus* leaves open to their full extent only in light which is similar in quality to sunlight and approaches it in intensity. Detached leaves of

Catalpa bignonioides when fully turgid increased 5-6 mg. per hour per sq. decim. in bright sunlight; in this plant stomata occur only on the underside of the leaf. The effect of detachment from the plant upon the rate of assimilation is considered, and evidence is adduced in support of Sachs's assumption, in the case of *H. annuus*, that, concurrently with assimilation, part of the products of photosynthesis are translocated from leaves still attached to the plant.—Prof. Ronald Ross and D. Thomson: A case of sleeping sickness studied by precise enumerative methods; regular periodical increase of the parasites disclosed. The enumerative methods referred to consist of modes of detecting blood parasites when very scanty, and of counting them accurately. The methods have been applied to a case of sleeping sickness in the clinic of Prof. Ross in Liverpool for seventy-three days continuously, and have shown that the numbers of *T. gambiense* in this patient's blood undergo remarkable periodical variations about every seven to eight days. The authors state that, so far as they can ascertain, though the numbers of trypanosomes had been known previously to vary from time to time, the regular periodicity revealed in their case appears to have been overlooked, possibly owing to insufficient methods of counting. The authors report that numerous parallel researches are being conducted, and give a chart.—Dr. C. Todd and R. G. White: The recognition of the individual by hæmolytic methods (preliminary communication). (1) The immunisation of the ox with the red blood corpuscles of other oxen gives rise to the formation of a hæmolytic amboceptor in the blood of the immunised animals. (2) The amboceptor so formed is an *isolsyn*, but not on *autolysin*. (3) The race of the animal appears to have very little influence on the resulting hæmolysins. (4) The serum of an animal so treated acts very differently on the red blood corpuscles of different individual oxen. (5) The sera of different individuals similarly immunised differ from one another in their action on the corpuscles of different individuals. (6) If the serum of a single immunised animal be "exhausted" with excess of the corpuscles of one other individual, the serum loses its power of hæmolyzing the corpuscles of this individual, while retaining the power of hæmolyzing the corpuscles of many, but not all, other individuals. (7) If, however, a polyvalent serum be made by mixing the sera of a large number of immunised animals, and this serum is exhausted with the corpuscles of any one individual, the serum entirely loses its power of hæmolyzing the corpuscles of this individual, but remains strongly hæmolytic for all other individuals not closely related to the individual the corpuscles of which were employed for the exhaustion of the serum. (N.B.—It is possible that exceptions may be found, but these have not yet been met with, except in the case of close blood-relations.) (8) The red blood corpuscles of any individual are thus characterised by a definite individuality of their own, and can be distinguished from those of any other individual of the same species.—F. M. Tozer and Prof. C. S. Sherrington: Receptors and afferents of the third, fourth, and sixth cranial nerves. Examination of the several extrinsic muscles of the eyeball in the monkey, cat, and rabbit, shows that these muscles contain, besides nerve-endings of the motor kind, large numbers of receptive (sensorial) nerve-endings, both in the fleshy part of the muscles and in the tendons. Investigation of these by experimental methods shows that all the receptive end-organs, as well as the motor endings, derive their nerve-fibres from the third, fourth, and sixth nerve-pairs respectively. These cranial nerves are therefore not purely motor, as generally supposed, but are sensory as well as motor. The number of afferent nerve-fibres they contain is very considerable. In addition to their sensory and motor supply from third, fourth, and sixth nerves, these muscles and their tendons receive a small supply of nerve-fibres from the ciliary ganglion. This ciliary-ganglion supply is largely, if not wholly, vasomotor in function, and no evidence was found that it is in any way sensorial. Nor does the fifth cranial nerve supply any sensory nerve-fibres to these extrinsic eye muscles. The afferent divisions of the third, fourth, and sixth cranial nerves are entirely proprioceptive in function; the receptive organs they subserve are entirely proprioceptive.—Sir David Bruce, Captains A. E. Hamerton and H. R. Bateman, and Captain F. P.

Mackie (Sleeping Sickness Commission of the Royal Society, 1908-9): (i.) Trypanosome diseases of domestic animals in Uganda, I. (ii.) Experiments to ascertain if cattle may act as a reservoir of the virus of sleeping sickness (*Trypanosoma gambiense*). (i.) The commonest trypanosome disease among cattle in Uganda is caused by a trypanosome of the *dimorphon* type, which is probably similar to that sent from the west coast by Dutton and Todd under the name of *T. dimorphon*, and described by Laveran and Mesnil, and Thomas and Breinl. It seems now that probably Dutton and Todd's *T. dimorphon* is quite different from that which they sent to Liverpool under that name. The original strain of *T. dimorphon* described by them had well-marked dimorphic characters, whereas the trypanosome sent to Liverpool was monomorphic. There is some evidence forthcoming that the *T. dimorphon*, as described by Dutton and Todd, really exists, and has been described as occurring in north-west Rhodesia by Montgomery and Kinghorn, and also on the west coast. In these circumstances it seems better to give the monomorphic form, which has up to the present been known by the name of *T. dimorphon*, a new name. It is a small trypanosome, short and stout in form averaging 13.2 microns in length, with a maximum of 16.0 and a minimum of 10.6. It has no free flagellum, and is restricted in its movements. The conclusions are that:—(1) there is an important trypanosome disease of domestic animals in Uganda; (2) the trypanosome is similar in morphology, action on animals, and cultural characters, to *T. dimorphon*, as described by Laveran and Mesnil and to Dr. Edington's trypanosome from Zanzibar, except that this trypanosome is not pathogenic to guinea-pigs; (3) the carrier is unknown, but is probably a *Tabanus*, possibly a *Glossina*, and improbably a *Stomoxys*.—Clement Reid and E. M. Reid: The lignite of Bovey Tracey. In 1863 Heer and Pengelly published in the Philosophical Transactions an account of these lignite beds and their flora. Heer classed the lignite as Lower Miocene, considering it equivalent to the Aquitanian of France and to the Hampstead beds of the Isle of Wight. These latter are now referred to the Middle Oligocene. A statement by Starkie Gardner, that Heer's Bovey plants are the same as those found in the Bournemouth beds (Middle Eocene), has caused the Bovey beds to be classed as Eocene in recent text-books and on recent maps of the Geological Survey, leaving a great gap in the geological record in Britain. The authors' researches have not supported this view, but tend to show that Heer was right, the Bovey lignite being highest Oligocene, or perhaps lowest Miocene. The authors made a collection in the Bovey deposits, so far as the state of the lignite pit would allow, in order to settle, if possible, the true age. The results were unexpected, for, by using new methods, they obtained a considerable number of species, mainly identical with well-known plants of the lignite of the Wetterau, which is generally classed as Upper Oligocene. In certain cases better specimens showed also that Heer's supposed peculiar species of Bovey belong to well-known forms of the Rhine lignite, his *Vitis britannica*, for instance, being only a crushed seed of *Vitis tautonica*. Several curious new species were discovered, including the earliest known *Rubus*, a peculiar *Potamogeton*, and a new genus of *Boraginæ*. A study of the cone and leaf of *Sequoia coultsiae* proves that it is a true *Sequoia*, and not a species of *Athrotaxis*.

Mineralogical Society, June 7.—Prof. W. I. Lewis, F.R.S., president, in the chair.—A. Russell: The occurrence of phenakite in Cornwall. Phenakite was unknown in the British Isles until the discovery by the author in 1905 of a single specimen at the Cheesewring Quarry, Linkinhorne, Cornwall. In 1906 he collected further specimens showing numerous small, but well-formed, crystals from a tin lode at South Phoenix Mine, Linkinhorne. In an old Cornish collection acquired by him in 1909 he found a specimen with as many as forty fine crystals; it was labelled "Topaz on Quartz from St. Agnes." Phenakite was also recognised on a specimen found about the year 1870 by Mr. J. H. Collins at South Crofty Mine, Illogan, Cornwall. Search at the Natural History Museum and the Museum of Practical Geology brought to light other specimens of phenakite placed under apatite.—Dr. G. F. H.

nith: (1) Phacolite from near Belfast. Two types were described. In the first the crystals were large (about 14 mm. across) and much striated, and in the second they were small (about 1-2 mm. across), but with plane faces; in both instances the crystals were twinned about a trigonal axis, the individuals interpenetrating one another, and the forms present were $r(1011)$, $t(3142)$, $o(12)$, $s(0221)$. The measurements accord closely with the data given for chabazite. (2) The crystalline form of trogen sulphide. Crystals of this rare substance have recently been prepared by Mr. F. P. Burt, University College, London, by sublimation. The constants obtained were $a:b:c=0.8879:10.8480:\beta=90^\circ 23'$, and the observed d values were (100), (010), (001), (110), (101), (011), (101), (101), (111), (121), the last four being new. The crystals are invariably characterised by polysynthetic twinning about (101). A biaxial interference figure with strong positive double refraction was visible through (101).—Dr. G. T. Prior and Dr. G. F. H. Smith: A new arsenate and phosphate of lime and strontia from the Indian manganese deposits. Chemical analysis showed that the mineral approximates to the arsenic analogue of apatite. The crystals were not well formed, but the physical characters, so far as they could be determined, accord with those of apatite. The name fermorite, after Dr. L. L. Fermor, of the Geological Survey of India, who has made an exhaustive study of the manganese deposits, is proposed for this analogue. The presence of strontium, which has not yet been detected in apatite, is of interest.—L. J. Spencer: (fifth) list of new mineral names.

Royal Meteorological Society, June 15.—Mr. H. Jellish, president, in the chair.—J. I. Craig: England, Abyssinia, the South Atlantic; a meteorological triangle. The idea that there may be an organic connection between the annual or seasonal total of rainfall in western Europe and the amount of the Nile flood is no new one, for in 1882 Prof. Balfour Stewart gave reasons for claiming such a connection between the flood of the Nile and the flow in the Thames. More recently Colonel H. E. Rawson has indicated a connection between the weather in South Africa and that in Africa north of the equator, and in particular the Nile flood. Dr. G. T. Walker has found a connection between the monsoon rainfall in India and pressure six months previously in Argentina, and Sir Norman and Dr. W. J. S. Lockyer have proved the existence of an inverse barometric relationship between India and Argentina. Dr. W. N. Shaw has also directed attention to certain correspondences between the velocity of the wind at St. Helena and the intensity of rainfall in the south of England, and pointed out that in the steady current of the south-east trade wind we may expect to find evidence of the throbbing of the aerial pulse consequent on the greater or smaller supply of solar radiation that reaches the earth and is transformed into kinetic energy. Within the last few years an organised meteorological service has been started in Egypt, and the results obtained therefrom have enabled Mr. Craig to carry out this investigation more closely. He finds that there is a distinct tendency for the south-east trade wind of the South Atlantic to divide into two branches, the first continuing the general northward movement, and the second turning to the right and moving across into the interior of Africa. He concludes that the moisture for the Nile flood comes from the South Atlantic, and that an increase in the velocity of the current will show itself in a proportional increase of the flood. There are too many gaps in the velocity records for the summer months to allow of a statistical test being applied, but it is not improbable that an intensification of the Transafrican current is connected with a similar intensification of the south-east trade wind of the Atlantic, which, as Dr. Shaw has shown, is not improbably connected with an increase of rainfall in the south of England.

DUBLIN.

Royal Irish Academy, June 13.—Dr. F. A. Tarleton, president, in the chair.—Miss M. C. Knowles and R. A. Phillips: *Leucojum aestivum*, the summer snow-flake. This well-known garden plant is a native of Asia Minor and Europe. In these countries it grows in swamps and wet, marshy meadows along river banks and on the shores of large lakes. In England the plant has a wide range on

the southern rivers under exactly similar conditions. The snow-flake has recently been found in Ireland, growing spontaneously and abundantly with exclusively native vegetation, along the banks of the Shannon, the Slaney, the Nore, and the Suir, and with surroundings and associates in no way differing from those prevailing on the Continent, where the plant has always been considered native.

PARIS.

Academy of Sciences, June 13.—M. Émile Licard in the chair.—G. Lippmann: A brake for the balance in the form of a plumb-line. A silk fibre, stretched by a small weight, is arranged so that it can be brought lightly in contact with the beam of the balance. The oscillations are thus rapidly reduced, and the weighings rendered more rapid.—Armand Gautier: The action of hydrogen upon carbon monoxide; the formation of water and methane. The action of water at a red heat on the same oxide. Applications to volcanic phenomena. Hydrogen and carbon monoxide commence to react at 400°C ., water and carbon dioxide being formed. The production of water passes through a maximum at about 1200°C . At higher temperatures some methane is also produced. Carbon monoxide and water at temperatures between 500°C . and 900°C . give minute traces of formaldehyde.—Paul Sabatier and A. Mailhe: The formation of the thiols and their decomposition: synthesis of the neutral alcoholic sulphides. Starting with isoamyl alcohol, the yield of sulphide in the presence of seven catalytic substances has been studied, the best result (70 per cent.) being obtained with thoria. With phenol, thoria again proved the best catalytic agent, although the yield even with this reagent was poor. For the catalytic decomposition of the thiols cadmium sulphide was used at temperatures between 300°C . and 380°C . The principal reaction was the formation of the alkyl sulphide and hydrogen sulphide, but some hydrocarbon, C_4H_{10} , was formed by a secondary reaction.—Émile Marchand: New observations concerning the effects of the passage of the earth through the tail of Halley's comet. A correction in the date mentioned in an earlier communication (May 30), together with some remarks on the appearance of the solar corona.—MM. Cirera and Pericas: A résumé of the observations on Halley's comet made at the Observatory of Ebra, Spain. Observations of the length of the tail showed a distinct diminution after the passage of May 19. A series of photographs taken on thirteen days between May 5 and June 6 brought out the changes in aspect and dimensions of the comet.—D. Eginitis: Observations of Halley's comet.—J. Baillaud and A. Boinot: Changes in the nucleus of Halley's comet. A detailed account of the change of the nucleus from elliptical to circular form, and the appearance of a secondary nucleus.—Léon Autonne: The commutative groups of hypercomplex quantities.—A. Buhl: The transformation of asymptotic series into series of convergent Taylorian polynomials.—N. Saitykow: The applications of the theorem of S. Lie generalised.—René de Saussure: Opposed solid bodies.—J. Le Roux: Bending.—J. Arnould: The movement of a wire in space.—Rodolphe Soreau: The thrust on the bearing surface of aeroplanes.—Paul Mercanton: The stability of magnetisation of lake pottery. The method of G. Folgheraiter for determining the sense and magnitude of the magnetic inclination by means of natural and artificial baked earths depends essentially on the hypothesis that the magnetisation taken by the clay in the course of its baking has not sensibly varied in the course of ages. By means of a study of the magnetic properties of the pieces from a single pot (Neuchâtel) the author comes to the conclusion that the method of Folgheraiter is justified.—M. Barre: Some double sulphates of thorium.—P. Roger-Jourdain: The oxidation of aluminium amalgam. From a study of the gases evolved from the product of the oxidation of aluminium amalgam, it is shown that there is present a mixture of aluminium carbonate and peroxide.—P. Mahler and E. Charon: The examination of the liquids produced by the action of air on coal at temperatures between 125°C . and 200°C . The liquid obtained by passing air over heated coal and cooling the issuing gas contained considerable quantities of acetic acid, together with traces of formic acid, acetone, and methyl alcohol.—P. J. Tarbouriech:

1-Methyl-2-ethanoyl-cyclohexane.—Marcel **Delépine**: Some new cases of spontaneous oxidation with phosphorescence. The compounds $\text{CH}_3\cdot\text{O}\cdot\text{CS}\cdot\text{Cl}$, $\text{C}_2\text{H}_5\cdot\text{O}\cdot\text{CSCl}$,

all show this phenomenon.—H. **Gault**: Remark on the acidity of the derivatives of oxalacetic acid. These acids can be titrated with phenolphthalein as indicator either in alcohol or acetone solution.—MM. **Brocq-Rousseau** and Edmond **Gain**: The excretions of roots.—Jean **Daniel**: The structure of the short old branches of some trees.—E. **Voisenot**: The formation of acrolein in the disease causing bitterness in wines. The presence of this aldehyde in bitter wines was conclusively proved.—C. **Gessard**: The fibrin ferment.—Mieczyslaw **Oxner**: Biological analysis of the phenomenon of generation in *Lineus ruber* and *Lineus lacteus*.—Lucien **Mayet** and Laurent **Maurette**: The discovery of a burial cave, probably Neolithic, at Montoulis (Hérault). Fourteen human skulls and other bones were found, probably of Neolithic age.—H. **Guilleminot**: Exposure in medical radiography, with or without a reinforcing screen.—Armand **Dehorne**: The mechanism of reduction in *Sabellaria spinulosa*.—Jules **Welach**: The peat deposits on the coast of the west of France.—Carl **Störmer**: Photographs of the aurora borealis and a new method of measuring their altitude. More than 400 successful photographs have been taken of the aurora, and by means of simultaneous photographs at two stations 4.3 kilometres apart the height has been determined. The altitudes found were between 50 and 190 kilometres.

FORTHCOMING CONGRESSES.

JULY 10-25.—International American Scientific Congress. Buenos Aires. Address for inquiries: President of the Executive Committee, c/o Argentine Scientific Society, 269 Calle Cevallos, Buenos Aires.

JULY 27-31.—International Congress on the Administrative Sciences. Brussels. Secretary of British Committee: Mr. G. Montague Harris, Caxton House, Westminster.

AUGUST 1-6.—International Congress of Entomology. Brussels. Chairman of Local Committee for Great Britain: Dr. G. B. Longstaff, Highlands, Putney Heath, S.W.

AUGUST 1-7.—French Association for the Advancement of Science. Toulouse. President: Prof. Gariel. Address of Secretary: 28 rue Serpente, Paris.

AUGUST.—International Congress of Photography. Brussels. Correspondent for United Kingdom: Mr. Chapman Jones, 11 Eaton Rise, Ealing, W.

AUGUST 2-7.—International Congress on School Hygiene. Paris. General Secretary: Dr. Dufestel, 10 Boulevard Magenta, Paris. Hon. Secretaries for Great Britain: Royal Sanitary Institute, 90 Buckingham Palace Road, S.W.

AUGUST 15-20.—International Zoological Congress. Graz (Austria). President: Prof. Ludwig von Graff. Address for inquiries: Präsidium des VIII. Internationalen Zoologen-Kongresses, Universitätsplatz 2, Graz (Österreich).

AUGUST 18-26.—International Geological Congress. Stockholm. General Secretary: Prof. J. G. Andersson, Stockholm 3.

AUGUST 29 TO SEPTEMBER 6.—International Union for Cooperation in Solar Research. Mount Wilson Solar Observatory. British Member of Executive Committee to whom inquiries should be addressed: Prof. A. Schuster, F.R.S., Victoria Park, Manchester.

AUGUST 31 TO SEPTEMBER 7.—British Association. Sheffield. President: Prof. T. G. Bonney, F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

SEPTEMBER 8-14.—International Congress of Americanists. Mexico City. General Secretary: Sr. Lic. D. Genaro Garcia, Museo Nacional, Mexico, D.F.

SEPTEMBER 13-15.—International Congress of Radiology and Electricity. Brussels. General Secretary: Dr. J. Daniel, 1 rue de la Prévôté, Brussels. Correspondents for United Kingdom: Prof. Rutherford and Dr. W. Makower, University of Manchester, and Dr. W. Deane Butcher, Holyrood, Ealing, W.

SEPTEMBER 18-24.—German Association of Naturalists and Physicians. Königsberg. Secretaries: Prof. Lichtheim and Prof. F. Meyer, Drummstr. 25-29, Königsberg.

SEPTEMBER 27-30.—International Physiological Congress. Vienna. President: Prof. S. Exner. General Secretary for United Kingdom: Prof. E. B. Starling, University College, London, W.C.

OCTOBER 6-12.—Congrès International du Froid. Vienna. Correspondent for United Kingdom: Mr. R. M. Leonard, 3 Oxford Court, Cannon Street, E.C.

DIARY OF SOCIETIES.

THURSDAY, JUNE 23.

ROYAL SOCIETY, at 4.30.—The Damping of Sound by Frothy Liquids: A. Mallock, F.R.S.—Dispersion of Light by Potassium Vapour: Prof. P. V. Bevan.—Additional Refractive Indices of Quartz, Vitreous Silica, Calcite and Fluorite: J. W. Gifford.—The Absorption Spectra of Sulphur Vapour at Different Temperatures and Pressures, and their Relation to the Molecular Complexity of this Element: J. I. Graham.—The Wave-making Resistance of Ships: A Study of certain Series of Model Experiments: Dr. T. H. Havelock.—The Blood Volume of

Mammals as Determined by Experiments on Rabbits, Guinea-pigs and Mice: and its Relationship to the Body Weight and to the Surface Area. Expressed in a Formula: Dr. Georges Dreyer and William Ray.—Autotoxæmia and Infection: E. C. Hort.

FRIDAY, JUNE 24.

PHYSICAL SOCIETY, afternoon.—Visit to National Physical Laboratory.

TUESDAY, JUNE 28.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—The Classification of the British Stone Age and some New and little-known Horizons and Cultures: W. J. Lewis Abbott.

WEDNESDAY, JUNE 29.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.

THURSDAY, JUNE 30.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: A New Method for the Quantitative Estimation of Hydrocyanic Acid in Vegetable and Animal Tissues: Dr. A. D. Waller, F.R.S.—On the Comparative Toxicity of Theobromine and Caffeine as measured by their Direct Effect upon the Contractility of Isolated Muscle: Dr. V. H. Veley, F.R.S., and Dr. A. D. Waller, F.R.S.—(a) "Muhinyo," a Disease of Natives in Uganda; (b) The Natural Food of *Glossina palpalis*: Sir David Bruce, F.R.S., and others.—The Relation of Light Perception to Colour Perception: Dr. F. W. Edridge-Green.—The Anatomy and Morphology of the Leaves and Inflorescences of *Heliotropium mirabilis*: Miss M. G. Sykes.—The Relative Atomic Weights of Nitrogen and Sulphur: F. P. Burt and F. L. Usher.—And other papers.

A TREATISE ON ANTS.

Ants: their Structure, Development, and Behaviour.

By Prof. W. M. Wheeler. Pp. xxv+663. (New York: Columbia University Press; London: Macmillan and Co., Ltd., 1910.) Price 21s. net.

FROM the classic work of Huber to that of Forel our knowledge of ant life made comparatively little progress. Forel's remarkable researches, however, gave it a great impetus, and since then the students of this most fascinating department of natural history have been numerous and their discoveries most interesting.

Prof. Wheeler, who shows a most generous desire to do justice to other observers, and has himself contributed much to our knowledge, gives a bibliography which occupies no fewer than seventy pages of his work.

The most comprehensive contributions, he says, "have been made by Forel and Emery, but important work has been done by Adlerz, Ernest André, Bates, Belt, Bethé, Brauns, von Buttel-Reepen, Ebrard, Escherich, Goeldi, Heer, J. Huber, von Ihering, Janet, Karawaiew, Lameere, Lespès, Lubbock, Mayr, Moggridge, Reichenbach, Reuter, Rothney, Santschi, and Sykes."

Yet for many years there has been no comprehensive treatise on the subject. Prof. Wheeler, who promises us also a systematic monograph which will no doubt be most useful, has endeavoured, as he tells us,

"to appeal to several classes of readers—to the general reader, who is always more or less interested in ants; to the zoologist, who cannot afford to ignore their polymorphism or their symbiotic and parasitic relationships; to the entomologist, who should study the ants if only for the purpose of modifying his views on the limits of genera and species; and to the comparative psychologist, who is sure to find in them the most intricate instincts and the closest approach to intelligence among invertebrate animals."

Chapter i. the author devotes to "Ants as Dominant Insects," discussing their interest for man, the probable causes of their dominance, the comparison of human and ant societies, the analogy between the ant colony and the cellular organism, the economic importance of ants, and their great interest as objects of biological study.

He then proceeds to their external structure—the segmentation of the body; the integument; the head, thorax, and abdomen. In the third chapter he deals with their internal structure—the alimentary tract; the glandular system; the reproductive organs and poison apparatus; the circulatory system and fat body; the respiratory, and, lastly, the muscular, system.

The fourth chapter is also devoted to the internal structure, and especially that of the nervous system and sense organs. In chapter v. he takes up their development—the care of the young; the egg, larva, pupa, and perfect insect; their length of life, and resistance to noxious influences. Chapter vi. deals with polymorphism, its extent and character; the

phylogenetic origin and development; Weissmann's, Spencer's, and Emery's theories; the three aspects of the problem—physiological, ethological, and psychological; and the explanation of the development of the worker.

The same subject is continued in chapter vi., and especially the origin of the worker; the relation of instinct to polymorphism; the differentiation in function as the precursor of differentiation in structure.

Chapter viii. deals with the history of myrmecology and the classification of ants; ix. with their distribution; x. with fossil ants; xi. with habits; xii. and xiii. describe the various forms and structure of nests, their characteristics, the method of construction, &c.; xiv. deals with the Ponerine ants, which the author regards as unmistakably primitive, and the ancestors of the higher and more developed groups; xv. is devoted to the driver and legionary ants; xvi. to the harvesting ants; xvii. to the relations between ants and vascular plants; xviii. to the fungus-growing ants; xix. to the relations of ants to aphides, scale insects, tree hoppers, and caterpillars; xx. to honey ants; xxi. and xxii. to ant guests and parasites, especially beetles, flies, hymenoptera, diptera, mites, and nematodes.

Interesting as these chapters are, the next are even more so. They deal with the extraordinary relations existing between ants of different species; compound nests and mixed colonies; ant parasites; slave-making ants; degeneration as the result of dependence on others—a lesson, as he justly points out, to our statesmen and electors.

In chapter xxviii. the author comes to the sensations of ants, different types of behaviour, the senses as a basis for study, touch, smell and taste, hearing and vision.

The ocelli, which occur in the earliest known fossil insects, are supposed to give an indistinct visual image of very near objects, but, as he says, this view is not yet clearly established.

In chapters xxix. and xxx., Prof. Wheeler discusses the question of instinct, and concludes with five appendices, on (a) methods of collecting, mounting, and studying ants; (b) key to the subfamilies, genera, and subgenera of the North American Formicidæ, for the identification of the workers; (c) a list of described North American ants; (d) methods of exterminating noxious ants; (e) literature.

Any one of these chapters would afford ample materials for review, but this would involve too great a claim on the space at my disposal.

I will only say a few words on the concluding chapters, in which Prof. Wheeler deals with the instincts of ants (chapter xxix.) and their plastic behaviour (chapter xxx.).

He accepts the old scholastic distinction between "memory" and "recollection," one being used

"in the sense of having ideas of absent objects, rather than in the sense of behaving differently to present objects because of past experience with them. The dog shows clearly that he remembers his master in the latter sense by displaying joy at the sight of him. Can we be sure that he has remembered him in the

former sense during his absence; that is, that he has had a memory image of him?"

For my part, I cannot doubt this.

Prof. Wheeler attempts to explain away the evidence on which good naturalists—Leuckart, Romanes, and others—have relied, and in several cases it seems to me that he does so satisfactorily. I do not myself regard the supposed case of ants dropping intentionally from ceilings on to food as definitely proved, but when Prof. Wheeler explains, or attempts to explain, it away by suggesting that "it may be a much more frequent method among ants of clearing vertical distances than has been supposed," one cannot but ask how it originated, and how it became so frequent.

The evidence, indeed, is contradictory, and difficult to reconcile. This applies not merely to the facts recorded by different observers. I have myself met with cases apparently showing intelligence, and others which seemed to imply the very reverse. Might not, however, the same be said in the case of man himself?

In conclusion, I may say that the illustrations are numerous—nearly 300—well chosen, and most of them good. Prof. Wheeler is much to be congratulated on having produced an excellent work, for which naturalists will, I am sure, be grateful.

AVEBURY.

PRACTICAL METHODS FOR THE BIO-CHEMICAL LABORATORY.

Handbuch der biochemischen Arbeitsmethoden. By Prof. Emil Abderhalden. I., Erster Band, allgemeiner Teil, erste Hälfte. Pp. iv+512. Price 18 marks. II., Zweiter Band, spezieller Teil, erste Hälfte. Pp. iv+496. Price 18 marks. (Berlin and Vienna: Urban und Schwarzenburg, 1909.)

THESE two volumes form the first consignment of a comprehensive handbook of practical methods for the biochemical laboratory, which is being written by no fewer than sixty-four contributors under the guidance of Prof. Emil Abderhalden.

The second halves of each of the present volumes are promised shortly, and the third volume within the year. When it is remembered that the editor is also engaged upon research work in the laboratory, as well as his many contributors, and is, moreover, editing an equally colossal work now appearing, one can but wonder at the rapidity of German cooking of literature of this sort.

It is a pity that the articles are not published separately, as monographs for those specially interested in the individual subjects, for this would save purchasers buying a great deal of matter which they, in most cases, do not want in order to possess a much smaller part of value to them.

As it stands the work has no general interest, and while it may be serviceable in parts as a reference laboratory book, it will scarcely prove attractive or profitable for the private purchaser.

One wonders, in looking over the table of contents of the present and contemplated volumes, why the pretence is made that it is issued in three volumes, since

by the simple device of making two halves of each of these divisions it comes to be in six volumes. It might equally well have been issued in one volume of six parts, each part forming a good sized volume; or in two volumes each of three parts; or in six volumes each of one part; or there might have been another and even better alternative.

The work can only be intended for the assistance of the research worker in a biochemical laboratory, and, looking at the matter from his point of view, it is surprising that the editor has allowed the first of the present volumes to appear in his work. All that is novel or interesting to the researcher in biochemistry of the five hundred pages it contains might readily, and with great gain in interest and utility, be compressed into fifty pages. As it stands it looks like nothing more than a glorified collection of catalogues of dealers in laboratory supplies; with the names of the dealers and prices of the commodities left out, much to its disadvantage. Scores of pages are sacrificed to drawings, photographs, and descriptions of apparatus with which we all have been familiar from our youth onwards in our everyday laboratory work. The first article in the volume dealing with this kind of thing occupies 282 pages; the new matter in it could easily be put into thirty pages. If the prices and makers' names were given, it might be of some service in the laboratory; as it is, to order any of the newer apparatus which suited any particular purpose, one would have to refer from the present work to the original paper by the inventor of the apparatus where possibly the information might be obtained.

In striking contrast with this article of 282 pages is the one succeeding it, of less than seven pages, on the ultra-microscope, written by Fr. N. Schulz, of Jena. Knowing the valuable work of this author in the particular field in question, one expected something good here; but there is nothing new. It might almost be a reprint, as are the illustrations in it, of one of the advertisements of Carl Zeiss advertising the instruments.

There follow on this all too short article a number of lengthy ones on ultimate organic analysis, ash determinations, &c. Nearly all this matter has been written many times before, is contained in all practical works on organic chemistry, and is familiar to any but the merest tyro in biochemical work. For example, illustrations with descriptions of the combustion furnace and the combustion tube and its filling are given; eighteen pages are used up in descriptions of the Kjeldahl method for determining nitrogen, and illustrations are given of most of the modifications which perverted human ingenuity and waste of genius have given rise to for carrying out that somewhat simple method of analysis. Fourteen pages in a special article go to a description of specific-gravity methods—why not instead refer the reader to an elementary work on physics?

The second of the two volumes before us will be of more service to the biological chemist whose path is touched by the articles contained therein; these articles deal with the preparation, separation, and qualitative and quantitative estimation of the important lower and

higher alcohols, the carbohydrates, the fats and waxes, the phosphatides, the vegetable proteins, and the animal proteins. The volume concludes in the middle of an article by the editor on the disintegration products of the proteins, characterised by much work of a patient and laborious type. The reader is deserted in the middle of a sentence, with "möglichst" for his last word, but it may be confessed that one can wait for the next issue of the fascinating narrative with more patience than one was able to command in earlier days of reading serial literature.

The articles in this part are of unequal value and exhaustiveness; that on the phosphatides is much too short; very valuable are the three articles, on sugars by B. Tollens, that on glycogen by K. Grube, and especially that on the proteins of the vegetable world by T. B. Osborne, which is a model of what an article on practical methods for the laboratory ought to be.

Such articles as these make the work essential in a biochemical laboratory, but it is a pity that they cannot be purchased as monographs in the particular subjects.

BENJAMIN MOORE.

THE LIGHT FROM THE SKY.

Meteorologische Optik. By Prof. J. M. Pernter. Section IV. Pp. i-xvii, 559-799. By Felix M. Exner. (Vienna and Leipzig: W. Braumüller, 1910.)

THIS volume is the fourth part of the late Prof. Pernter's work on meteorological optics, a notice of the earlier parts of which appeared in *NATURE* on April 18, 1907. It was undertaken in March, 1908, by Dr. Exner at Pernter's request, at a time when the latter's condition of health not only made it impossible that he should complete the work himself, but prevented him from giving any material assistance or advice in its preparation. The scope of the section was clearly indicated in the original plan of the work, and as regards the method of presentation Exner has successfully followed that of the preceding sections; but he had no notes to assist him, and the volume must therefore be regarded as Exner's work, except in so far as he has utilised, in some portions, Pernter's previously published papers.

In pursuance of the general scheme outlined in the previous notice above referred to, this fourth section is devoted to the discussion of those phenomena which are due to the action of the minute particles of all kinds which are always present in the atmosphere, among which must be included the gaseous molecules themselves. Thus the first two chapters deal with the colour and polarisation of sky-light, the third treats of the loss of light in passing through the atmosphere and the general brightness of day-light, while in the fourth chapter is given a brief account of what are called the phenomena of twilight, the optical effects associated with sunrise and sunset.

Of all the many interesting problems the discussion of which falls under the head of meteorological optics, that of the colour of the sky, with the associated questions as to the polarisation of sky-light, its intensity and composition, and the effects of atmospheric absorption, is perhaps the most fascinating. Less

striking only because not exceptional, in the sense in which this adjective applies to the appearances dealt with in the earlier sections, even for the unscientific observer the everyday recurrence of the phenomena fails to diminish their appeal to his artistic sense and imagination. For the physicist, the satisfactory explanation of all the main features, apart from the quantitative uncertainty in the details which is an almost inevitable consequence of the complexity of the conditions, must be ranked among the triumphs of science, and constitutes one of the most beautiful applications of the wave theory of light.

The view has long correctly been held that the colour of the sky is due to the presence in the atmosphere of suspended particles, and the explanation was rendered more certain by the experiments of Brücke in 1853 and of Tyndall in 1868 on the colour and polarisation of the diffused light from artificially "clouded" media. The first exact account as to the manner in which the particles produced the effects observed was, however, given by Lord Rayleigh in 1871, in his paper on the light from the sky, its polarisation and colour. It was there shown that the presence in the atmosphere of particles of dimensions small compared with the wave-length of light would give rise to secondary radiations of intensity inversely proportional to the fourth power of the wave-length, and completely polarised in the plane at right angles to the direction of the primary radiation from the sun. In this secondary, diffused radiation, the short waves would therefore greatly preponderate, and the colour seen would be blue or violet, while the long waves would be the more readily transmitted, and the primary radiation seen through such an atmosphere would tend to be orange or red. At the same time, Rayleigh disposed of Clausius's theory that the phenomena were due to the presence in the atmosphere of small—but not small relatively to the wave-length—hollow spherical vesicles reflecting and refracting according to the ordinary laws for extended media. In a much later paper Rayleigh has given good reason for inferring that at least one-third of the scattered light is diffracted from the molecules of the air themselves (see also *NATURE*, March 10, 1910, p. 49).

One of the merits of Exner's discussion of the subject is the care with which he has followed out the application of Rayleigh's theory in the light of the best recorded observations. These relate to colour, polarisation, extinction coefficients, the general brightness and the distribution of brightness of the sky, &c.; indeed, the whole volume may almost be regarded as an excursus on the Rayleigh theory. In dealing with the more detailed phenomena of Arago's "positive" and "negative" polarisation, and the neutral points of Arago, Babinet, and Brewster, the author follows Soret in attempting a general explanation in which account is taken of the further action of other particles on the light already once diffracted, and of the form of the limited portion of the atmosphere from which the light reaching any individual eye can be received; but the conditions are too complicated to admit of quantitative treatment for exact comparison with observation.

The optical appearances connected with sunrise and sunset are somewhat briefly treated, reference being especially made to Kiessling's monograph "*Untersuchungen über Dämmerungserscheinungen*" for a more complete description of the phenomena. Some account of the observed effects due to the Krakatoa eruption and other similar disturbances is included.

Dr. Exner has followed Prof. Pernter in the careful reproduction of the best recorded and historically interesting observations of the phenomena. He has himself emphasised the impossibility of reproducing the charm of Pernter's work, dependent as it was on the latter's extensive knowledge of the literature of the subject as well as on his critical judgment. This volume will, however, be welcomed both as a fitting completion of the task undertaken by Prof. Pernter and as a valuable survey of the progress which has been made in the interpretation of the phenomena with which it deals.

THE PHILOSOPHY OF MATHEMATICS.

Methodologisches und Philosophisches zur Elementar-Mathematik. By Dr. G. Mannoury. Pp. viii + 279. (Haarlem: P. Visser Azn., 1909.) Price 8s. 10d.

THIS work is the outcome of lectures delivered by the author at the University of Amsterdam, and retains in different ways the marks of its origin. Its frequent digressions, its general discursiveness, and its rather sketchy character make it difficult to describe; and many of the topics are so controversial that where one reader will agree with the author, another, equally competent, will entirely dissent. Still, it is an honest and interesting attempt to deal, from the philosophical side, with the fundamental difficulties of mathematics, and as such deserves attention.

The first part contains five chapters dealing respectively with unity and plurality, finite and infinite numbers, the elementary laws of arithmetic applied to whole numbers, the extension of the idea of number, and, finally, the definition of irrationals. The second part is devoted to geometry, and its four chapters discuss respectively mathematical logic; elementary constructions, postulates, and theory of measurement; non-Euclidean geometries; and the notion of space from the standpoint of physiology and psychology.

A few examples must suffice to illustrate the merits and the defects of the author's procedure. Take the question of defining a unit. After pointing out, rightly enough, that there is no such thing as an objective unit directly perceived, he gives as a formal definition (p. 31):—"Units are sensation-complexes (*Empfindungs-Komplexe*), and a plurality (*Vielheit*) consists of mutually related units." Now, if there is one thing that recent mathematics has done, it is surely to clarify and make precise the notion of a unit apart from all elements of sensation. Verbal definition of a unit is a small matter, of course; the thing to be desired is the complete notion. As a matter of fact, everybody does acquire the notion more or less exactly, long before thinking about defining it; and as to the definition, a kindergarten teacher will suc-

ceed where a philosopher will fail. "These are toys; each toy is a unit among the toys"; "You are my class; each of you is a unit of the class"; such examples will convey the meaning of the term "unit" better than any formal definition. At the same time, if we must have a metaphysical example of a unit, the ego seems to be the best, for it cannot be denied, or affirmed to be a plurality, without an intrinsic contradiction in terms. If Jones makes a statement or forms an opinion, however erroneous, it is *his*, and this "he" is an irreducible entity which has a preeminent claim to be called a unit. It may be remarked that Dr. Mannoury expressly objects to this line of argument, apparently on the ground that the idea of the ego is a derivative one; this may be admitted in a sense, as a fact in the development of an individual consciousness, but it does not make the ego derivative, any more than the deciphering of hieroglyphics in recent times affects the date at which they were carved. Is not this one of those cases where psychology is appealed to where it is really irrelevant, the question being one concerning metaphysical data? We must have something *a priori* and undefined in any science; the question is, how few and how fundamental (or elementary) may we assume these data to be?

A more striking example of the same sort of thing is to be found on p. 263, where the author speaks of "the four-dimensional space-time-notion which is to be regarded as an image of the whole group of sensations." It is almost impossible to give any sense to this phraseology, consistent with either popular or mathematical usage. If it merely means that in abstract kinematics in three-dimensional space there are four independent variables (x, y, z, t), it is a very unsatisfactory way of stating a simple fact; and it is very doubtful whether kinematics is, properly, an image of sensations, any more than our sensation of the colour of homogeneous light is imaged by its wave-length.

In treating of the elementary laws of arithmetic, the author, in the text, mainly follows those who appeal to the principle of analogy or "permanence"; he does not give a detailed discussion of the elementary operations. The definition of irrationals is Dedekind's, which is wrongly attributed to Dirichlet; there is a brief account of Peano's system of shorthand, and a section on mathematical induction, with quotations from Poincaré, Couturat, and others. Dr. Mannoury is evidently dissatisfied with Poincaré's arguments, but here, as in other cases, he does not bring forward any very definite statements of his own.

In the geometrical section there are several features of interest, and this is the most readable part of the book. A fair account is given of the different types of three-dimensional geometry, of Hilbert's non-Desarguanian system, and of metrical geometry based on a movable standard assumed to be rigid. But there is no discussion of a system of definitions, and the only element treated in any detail is the straight line. With regard to the different types of geometry, the author adopts the sensible attitude that it is now, and always will be, impossible to fix on one as the

"actual" geometry of space, and he would probably assent to Poincaré's dictum that the science of mathematics is neither true nor false.

There is one remarkable statement made which deserves mention. Dr. Mannoury says that in December, 1818, F. K. Schweikart sent to Gauss a note asserting the existence of a geometry in which the sum of the angles of a triangle is less than two right angles, and in which the altitude of an isosceles triangle with a finite base has a finite upper limit. This goes far to demolish the claim made for Gauss that he was the first to assert the possibility of a consistent system of geometry distinct from that of Euclid.

G. B. M.

THE PROTOZOA: AN IMPRESSIONIST SKETCH.

Protozoölogy. By Prof. Gary N. Galkins. Pp. 349. (New York and Philadelphia: Lea and Febiger; (London: Baillière, Tindall and Cox, 1909.) Price 15s. net.

TO attempt to condense our present knowledge of the Protozoa into some three hundred pages is—to anyone acquainted with the subject—to attempt the impossible. This book, however,

"does not aim at being an exhaustive treatise on the Protozoa; it aims, rather, to give an introduction to the study of modern protozoology as seen from the author's point of view."

It would therefore be unfair to draw comparisons with Doflein's recent masterpiece on the subject which appeared almost simultaneously.

As we differ fundamentally from the author in many matters of interpretation—both as regards general principles and detailed facts—we can here consider only a few points which a perusal of the work has suggested.

With regard to the tentative classification of the Protozoa which is adopted, we can only say that it is, perhaps, as good as any which has so far been advocated. With our present knowledge, it is not possible, we believe, to arrive at a satisfactory classification of the whole group. At present there must be many tadpoles among our fish. It may be noted, however, that the author does not accept Hartmann's group "Binucleata"—for trypanosomes and their allies and *Hæmosporidia*—and in this we heartily agree with him. It may be noted, further, that the *Spirochætes* are classified (with some reservation) among the *Mastigophora*; the *Mycetozoa* are ranked under the *Rhizopoda*; the *Opalinidæ* are placed among the *holotrichous Ciliata*; and the *Mastigamœbæ* are placed, in the order *Monadida*, with the *Mastigophora*. Though these groupings are usual, they are none the less, we believe, unjustifiable in the light of recent work.

In dealing with the trypanosomes, the author adheres to Schaudinn's much-debated work, because he finds

"the schematic figures and categorical descriptions of Schaudinn's original contribution are still the most convincing of all such attempts to describe the nuclear changes."

The life-cycle of *Paramecium* is described as a "typical" one. With this we cannot agree, because we consider the *Ciliophora* to be very different from all other organisms. Moreover, we regret to find no allusion to the recent important work of Enriques and others in this connection.

A remarkable account of autogamy in *Amoeba limax* is given, apparently from the author's own (unpublished?) observations, though no indication of this is given. Autogamy is again alleged to take place in *Amoeba proteus*, though this has not been by any means proved. It is disappointing to find no reference, in this connection, to Prandl's important work on *Cryptodiffugia* ("Allogromia").

It seems to us that undue prominence has been given to many very questionable organisms, such as "*Cytorrhcytes variolae*," the "Negri bodies," &c. (described, by the way, under "*Parasitic Rhizopoda*"), whilst many important life-histories, e.g. *Opalina*, *Mastigella*, *Trichosphaerium*, *Stylorhynchus*, &c., receive little more than passing mention.

The remarkable form *Aggregata* is mentioned only in the classification, where it is placed among the cephaline gregarines! One can only suppose that this is an oversight; and we regret to see that the very doubtful work of Dallinger and Drysdale has found its way into yet another text-book.

Throughout the book, generic names are often written in ordinary type, without a capital letter, although in many cases the customary convention is adopted—frequently in the same paragraph. We think this is to be deplored, more especially so because medical men—to whom, on account of the large amount of space devoted to parasitic forms, the book will specially appeal—are at present particularly prone to write zoological names incorrectly. In addition, the author's apparent dislike of diphthongs causes him to adopt the spellings not only *Paramecium* (correctly), but also *Ameba*, *Actinosphaerium*, *Spirocheta*, &c., and even *Jenia* (for *Joenia*).

These criticisms are, however, of minor points. The chief value of the book lies in the fact that it gives us a unified picture of the many problems of protozoology as they present themselves to a worker who has devoted many years of original research to his subject. Without doubt, the book will be welcomed by many, because there exists no other modern work in English which attempts to deal with the present state of protozoology within the compass of a single volume.

C. CLIFFORD DOBELL.

BEE-KEEPING IN AMERICA.

How to Keep Bees for Profit. By Dr. D. E. Lyon. Pp. xii+329. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1910.) Price 6s. 6d. net.

THIS is a book on bee-keeping in the United States. The author is a well-known bee-keeper, and an entertaining writer; he has a happy way of briefly explaining the chief operations of the apiary in a personal style that does not weary the reader. Dr. Lyon tells us that many years ago he acquired the "bee fever," "from which he has never recovered,

and never expects to recover." The chief symptoms of this affection, enthusiasm and optimism, pervade his book, but he is careful not to exaggerate the profits of bee-keeping; the methods and appliances he describes are all well known and well tried, though some of them are unsuited to bee-keeping in England.

The clipping of queens' wings to prevent swarms absconding is recommended, but this practice is seldom employed in England, chiefly because the queen is likely to perish in the grass unless the bee-keeper happens to be present at the moment of swarming; to find her and put her back into the hive.

The author, in saying (p. 52) that "it has not been definitely determined whether in laying an infertile egg from which springs the drone, the queen lays it through choice, or is compelled to owing to the increased size of the drone cell," seems to be unacquainted with the fact that a queen will sometimes lay large numbers of fertile eggs in drone cells.

Among the enemies of the honey-bee that the American apiarist has to contend with are skunks, "who seem to have a fondness for bees, and the little rascals will, in the shadow of night, scratch on the alighting board of a hive to lure the sentinels out for investigation, only to be gobbled up by their odoriferous enemies." "In warm climates the dragon-flies kill a large number of virgin queens when in flight, and in certain sections they are so numerous that commercial queen-rearing is well-nigh an impossibility."

Dr. Lyon finds he is less liable to be stung in a white cotton suit than when he wears dark woollen clothes, and wonders whether it is because the bees detect the animal scent in the woollen goods or have a natural aversion to black.

On pp. 12 and 13 we are unfortunately informed that the eggs of workers, drones, and queens hatch respectively in twenty-one, twenty-four, and sixteen days, instead of that these are the periods taken by these bees to develop from the time the egg is laid; but this will no doubt be put right in a second edition, which is likely to be wanted before long by the great nation across the ocean, in whose favoured country the bee-keeping industry has grown to great importance.

Very attractive features of the book are its handy size, clear, large type, and beautiful photographs. Bee-keepers, both prospective and actual, will appreciate this evident effort of printers and publishers to give them their best.

F. W. L. SLADEN.

OUR BOOK SHELF.

Ektropismus oder die physikalische Theorie des Lebens. By Felix Auerbach. Pp. v+99. (Leipzig: W. Engelmann, 1910.) Price 2.60 marks.

EACH fresh theory of life which is put forward by thinkers will doubtless find a certain number of adherents, even if, as in the present instance, it is unsupported by anything in the nature of experimental evidence. This sort of evidence is just the kind which it is so difficult to obtain, and new theories lead one but very little nearer to the solution of the great problem. Auerbach's brochure contains nothing really

new, and he clothes his ideas in a considerable amount of verbiage. No one can doubt that life with its characters of growth and development is a form of energy, but the psychical aspects of life have always been a stumbling-block in the full acceptance of a purely physical theory. Ectropism, the term selected by the author, is not entirely a physical theory; he tells us that ectropism is neither materialism nor idealism, neither formalism nor phenomenalism; it is certainly not monism, but, in a certain sense, it is dualistic. From this one learns what ectropism is not, and one could wish that the rest of the book, which tells us what it is, was equally explicit. We must, however, leave those of our readers who are interested in speculations of this nature to unravel it for themselves.

A Text-book of Physical Chemistry, Theory and Practice. By Dr. Arthur W. Ewell. Pp. ix+370. (Philadelphia: P. Blakiston, Son and Co., 1909.) Price 2.25 dollars net.

TEXT-BOOKS of physical chemistry are generally written by chemists, which is natural enough, since the subject is much more widely studied by chemists than by physicists. It is therefore a pleasant change to come across a text-book of physical chemistry written by a physicist. As one might expect, the treatment is less descriptive and more mathematical, with greater precision in the definition of physical magnitudes and greater strictness in the deductions. The work under review is an excellent example of this type, being brief, pointed, and consistent. It is not exactly a book which the young chemist without previous knowledge of the subject would be likely to read with profit, but it can be warmly recommended to those who, either by hearing a course of lectures, or by the perusal of one of the more chemical text-books, have attained some acquaintance with the subject-matter and desire to systematise their knowledge.

The value of the book is greatly enhanced by the inclusion of questions and mathematical exercises on the subjects discussed. The directions for practical work err occasionally on the side of conciseness, but should in any case prove useful to the student who cannot always have a demonstrator by his side.

Vorträge und Aufsätze über Entwicklungsmechanik der Organismen. Edited by Prof. W. Roux. Heft x., Über die gestaltliche Anpassung der Blutgefäße. By Prof. Dr. Albert Oppel. Pp. ix+182. (Leipzig: W. Engelmann, 1910.) Price 4.40 marks.

THIS is a useful and interesting contribution to the study of development, dealing, as its name indicates, with the blood-vessels, and the way in which they are adapted to the needs of the organs or tissues they supply and to the changes which these undergo. This adaptation is divided into three periods, the first during which inherited characters determine the course of development; the third is the period of full functional life during which the changes are the result of functional stimuli; the second or intervening period is that in which both factors come into play. The changes dealt with in detail are not merely those dependent on quantity of the blood supply; but the various coats of the blood-vessels, especially the muscular coat, with its nerves, undergo alterations in consonance with the needs of the tissues. An important section deals with the collateral circulation, and another, by no means the least interesting, with the recent remarkable results which have attended attempts to transplant organs from one animal to another. The value of the book is increased by a copious bibliography.

LETTERS TO THE EDITOR.

The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

The Descent of a Sphere in a Viscous Liquid.

STOKES's formula for the terminal velocity of a sphere descending in a viscous liquid under the action of gravity has been recently tested by Prof. John Zeleny and Mr. A. Keehan ("British Association Report," 1909, p. 107), and they found that the values of the velocity furnished by it were considerably larger than those which they obtained from their experiments. Since Stokes's formula is obtained on the hypothesis of no slipping, it furnishes an inferior limit to the velocity, and consequently be discrepancy between theory and observation cannot be explained on any hypothesis that slipping takes place.

I think that a possible explanation is the following. The equation determining the current function contains the term $d\psi/dt$, the origin being some fixed point in the line of motion of the sphere; and if the motion be referred to the centre of the sphere as a moving origin, $d\psi/dt$ must not be put equal to zero when the motion is steady, but must be replaced by $Vd\psi/dx$, where V is the constant velocity of the sphere. The retention of this term creates so difficulty so far as the integration of the differential equation for ψ is concerned, but the solution is quite different from that given by Stokes.

A. B. BASSET.

Fledborough Hall, Holport, Berks, June 20.

Popular Biological Misconceptions.

THE object of science is to increase the knowledge of mankind in general, and not merely that of the workers in a science. The methods of science may be only understood by the workers in each particular branch, but the conclusions are for all, and should be made accessible to all. The methods by which Newton established the law of gravitation can only be understood by good mathematicians, but the results can be put into words that can be understood by any educated man. I think most will agree that students of science should, so far as possible, make known their discoveries in such a way as to be understood by the layman.

In making these remarks I have biology in mind. Nothing is known of biology outside the ranks of biologists. Even Darwin's theory of evolution is most imperfectly understood by the ordinarily educated man. Probably working biologists have no idea how much it is misunderstood. When the late Lord Salisbury at Oxford said that there was nothing except pure chance to ensure the transmission of an advantageous variation, he left out of consideration the survival of the fittest, an integral part of the theory. Sir Oliver Lodge, in "Man and the Universe" (p. 38), speaking of the persistence of favourable variations, says, "given their appearance, their development by struggle, inheritance, and survival can be explained; but that they arose spontaneously, by random change, without a purpose, is an assertion that cannot be justified." This passage shows that the writer has not fully grasped the elements of the theory; the changes take place in every direction, but all variations except those in a favourable directions are wiped out in the struggle for existence; such, at any rate, is the theory. When we consider that Darwin's theories are not fully grasped by scholars, it is hardly to be wondered at that the ordinarily educated man has but the vaguest ideas of biology, ideas made still more vague by the ordinarily educated writers in the daily, weekly, and monthly Press. To the ordinary man the word Darwinism means the theory that his ancestors were monkeys; he will have heard the words "survival of the fittest" used as a catch phrase, but he will have no idea of their meaning; "struggle for existence" will have no biological sense for him; "selection" he will think has something to do with sex. Biologists may say either that I am exaggerating or that the educated men of my acquaintance must be singularly few; but I can assure them that such misconceptions are shared

by very many men who have been educated at our public schools and universities, which is generally (though perhaps erroneously) considered the criterion of a good education. It is quite common to come across persons who say that Darwinism is discredited by new discoveries, especially by Mendelism; they have no other idea of the meaning of Mendelism, and, seeing that their notion of Darwinism is no more than I have stated above, they arrive at conclusions that would rather astonish the average biologist.

I think it is the duty of biologists to educate the uneducated in biological matters, to tell them how matters really stand, and to tell them how far old theories are, or are not, modified by new views; but we should be educated by first-class masters, and not by second-hand popular writers. This has been done for a long time for astronomy, and, to a certain extent, for physics; it is very desirable that it should be done also for biology.

C. C.

Anomalous Reading of Hygrometer.

ON June 11 I observed a case of the wet-bulb thermometer reading higher than the dry bulb, which cannot be attributed to a falling temperature, as this anomalous condition continued for more than two hours, during the greater part of which the temperature was slowly rising. A gradually dispersing fog prevailed at the time, and the dry bulb was at first covered with precipitated moisture, but after being wiped dry it continued to read lower than the wet bulb, without any further visible deposition of moisture. This, however, may only imply that evaporation was proceeding too rapidly to allow of the fog particles aggregating into visible drops. This evaporation might account for the temperature of the dry bulb being as low as that of the wet bulb, but not lower. As thermal equilibrium will be attained by each thermometer when its rate of heat-loss is equal to its rate of heat-gain, and as the only loss of heat is by evaporation, which at most can only lower the dry-bulb reading to that of the wet, it is necessary to suppose that the wet bulb absorbs heat more rapidly than the dry. This may be accounted for by the greater thermal diffusivity of the wet bulb with its saturated muslin covering.

Experiments made by Prof. A. W. Porter at University College, London, show clearly that, in the case of steam pipes of small diameter, the effect of a lagging of badly conducting material is to promote the transference of heat from the interior to the exterior, and it is evident that if the external temperature be higher than the internal, the effect will be reversed, and, further, that it will be increased if the covering is not a bad conductor. We have such a covering on the wet-bulb thermometer, and as owing to evaporation the temperature of the thermometers will be lower than that of their surroundings, the direction of heat transfer will be inwards, and its rate more rapid in the "lagged" wet bulb than in the bare dry bulb. We should accordingly expect the former to come to a state of thermal equilibrium at a higher temperature than the latter.

J. ROWLAND.

St. Beuno's College, St. Asaph, June 20.

Pwdr Ser.

DOUBTLESS many of your readers will suggest that Pwdr Ser may, in some cases at least, be the jelly-like plasmodium of *Spumaria alba*, D.C., a common British myxomycete. The size, colour, time, and places where found agree well with Prof. McKenny Hughes's description, but how it should be connected with meteors this identification, if correct, would in no way explain.

AGNES FRY.

Failand House, Failand, near Bristol.

THE article on "Pwdr Ser" in your issue of June 23 has brought to my remembrance a tale of a shooting star which fell upon a connection of mine many years ago. The man was working in the field, when a mass of jelly fell upon him. I discredited the story at the time; but this article seems to lend weight to the story. I believe the man was unhurt. The occurrence happened in Wales.

ROWLAND A. EARP.

Preston Brook, near Warrington, June 27.

THE FRESH-WATER LOCHS OF SCOTLAND.¹

A PATHETIC interest is associated with this great work. A bathymetrical survey of the Scotch fresh-water lochs, which had been already attempted in a few instances, was in vain pressed upon the Government in 1883 by the Royal Societies of London and Edinburgh, and was undertaken in 1897 by Sir J. Murray and Mr. F. P. Pullar, a young Scotchman who added to a deep interest in meteorological and hydrographical problems much practical skill as an engineer. Considerable progress had been made when, on February 15, 1901, Mr. Pullar was drowned in Airthing Loch, near his own home. The ice had broken, immersing a number of people; he rescued three, and perished in an heroic, though vain, attempt to save a fourth. As a memorial, the bereaved father, Mr. L. Pullar, devoted a sum of 10,000*l.* to the completion of the task, so that the book will be an enduring memorial to one who died to save others.

A staff was organised, and the work resumed in the spring of 1902. By the end of 1906 all the Scottish lochs of any importance, 562 in number, had been surveyed, and altogether more than 60,000 sound-

floods may be among the causes. Mr. E. M. Wedderburn writes on temperatures. In that respect the bottom water of a deep loch such as Loch Ness varies little throughout the year, and is sometimes hardly less than 2° F. below the mean temperature of the year, but conduction produces considerable intermixture in the upper layers of water. This indirectly affects the distribution of plant and animal life, and presents some interesting problems, which must be left without further notice. Mr. G. West gives the results of studies of the phanerogams and higher cryptogams in seven Scotch lake areas. This flora like that of the mountains, has been much affected directly or indirectly, by the Glacial epoch, but the vertical range of the plants, strictly aquatic in habit depends on a number of factors—such as the amount of humic or other acids in the waters, the surrounding rocks, and the altitude. A full discussion of these and summaries of the results form a contribution which will be of permanent value to the botanist. Dr. Caspar gives a useful summary of information about the chemical composition of lake waters, and has also examined about seven hundred samples of bottom deposits from these lochs, of which, however, the mineralogical aspect is fairly uniform, as might be expected from the generally similar geological conditions. Mr. John Hewitt writes on the distinctive characters of the fresh-water plankton, Dr. W. A. Cunnington on the nature and origin of fresh-water organisms, Dr. C. Wesenberg-Lund on various limnological problems, and Mr. James Murray on the biology of the Scottish lochs. According to the last-named, the following peculiarities are noteworthy:—a richness in species of Desmids (only approached by the lakes of Ireland), a conspicuous Arctic element in the Crustacea, the local distribution of many of the one and some of the other, and, lastly, the absence or rarity of certain species common to the general European plankton.

As a prelude to the second volume, which is occupied by a detailed description of the several lake basins, grouped according to the drainage, Drs. B. N. Peach and

FIG. 1.—Loch Maree, the Islands in the Middle Distance. From "Bathymetrical Survey of the Scottish Fresh-water Lochs."

ings had been taken. Biological and physical work was continued during the next three years; but from time to time the maps, with some of the results, enriched the pages of the *Geographical Journal*, and these, together with much new material, are now collected into the present work. The first two volumes contain the text, with various illustrations, from which we are able to reproduce two of the smaller size; the remaining four volumes the tinted maps, which—though it adds considerably to bulk and cost—are wisely mounted on linen.

The first volume deals with general scientific questions. Prof. Chrystal discusses seiches; for these abnormal oscillations in the water-level—first noted in the Lake of Geneva, and first seriously studied there by Prof. Forel—can be observed on the Scottish lochs, though on a much smaller scale. They are mainly due, as Prof. Chrystal shows, to variations in barometric pressure, though winds or heavy local rains or

J. Horne contribute to the first one an article on the relation of the lochs to the general geology of Scotland, ending with a sketch of the mountain regions and valley systems, and of its history during the Glacial epoch. In their opinion, the ice attained its maximum during the earlier part of this, when it buried the whole region in a vast sheet which, as they tell us, was met on the bed of the North Sea by another one from Scandinavia, and thus diverted northwards and southwards. In the latter part of this epoch, probably after a warmer interlude, valley glaciers, which occasionally became confluent, radiated from the several mountain groups, and to their action, according to the authors, the lake basins are mainly to be attributed. In regard to the subject, though it may be thought presumptuous, I venture to remark that both the map illustrating the maximum extent of the ice and some statements about the erosive action of the latter involve difficulties which it would have been better to warn the ordinary reader.

The maps and sections, which occupy the remaining four volumes of the work, will, however, sup-

¹ Bathymetrical Survey of the Scottish Fresh-water Lochs, conducted under the Direction of Sir John Murray, K.C.B., F.R.S., and Laurence Pullar, during the Years 1897 to 1908. Report on the Scientific Results. 2 vols. of text with illustrations, and 4 mainly of maps. (Edinburgh: Challenger Office, 1910.) Price 5*l.* 5*s.* the set.

fin with materials from which he may form his own conclusions. In two of the four, the intervals between the contour lines are differently tinted, both above and below water; in the other two, this is done only or the latter. Sections show the relation of depth to length, not only on an exaggerated scale, but also which is of great value) on a true one. Most of the Scotch lakes occupy actual rock basins, but this fact of itself is not conclusive evidence of their origin. Many tarns in mountain districts are probably due to the erosive action of ice, but no one would attribute the Dead Sea to the "rooting" of a Lebanon glacier, or the Central African lakes to ice-sheets from the mountains of the Moon. Earth movements are among the possible causes of rock basins, and to which agency should the Scotch lochs be attributed? Increased erosion, due either to a confluence of glaciers or to a sudden diminution of slope in the valley floor, may account for the smaller, but difficulties present themselves in applying this explanation to some of the larger. For instance, we should expect that if the basin of Loch Maree had been excavated by ice, it should be a fairly uniform trough, descending from

Far from the least valuable part of the text is Sir John Murray's chief contribution—a clear and concise account of the various lakes known to exist on the surface of the globe. No abstract could do justice to this, so replete is it with interesting facts, the collection of which must have entailed great labour, for, as the bibliography shows us, they are dispersed among numerous publications. For many years to come this section will be invaluable to all students of limnology, in the widest sense of the term.

But we must conclude our notice of this encyclopædic work. We have to thank Sir John Murray, Mr. L. Pullar, and their able coadjutors for an admirable and sumptuous monograph, which, owing to the complete organisation, tells us more of the lochs of Scotland than Dr. H. R. Mill could ascertain about our English lakeland or Dr. T. J. Jehu about the llynys of Wales. We now know at least as much about them, and in some cases more, as Delebecque has been able to ascertain about the lakes of France, Forel and his coadjutors about those of Switzerland, the investigators of other European nations about the lakes of their own countries, or has yet been accomplished by energetic American surveyors on their own continent. We heartily congratulate Sir J. Murray and Mr. L. Pullar on this splendid and successful result of their labours. T. G. BONNEY.

THE WHITE MAN'S RULE.¹

TO the great majority of people in this country the name Sierra Leone is nothing more than the vague geographical expression of a colony situated somewhere in Tropical Africa, once more familiarly known as the "white man's grave," and long regarded as the last resort of the hopelessly incompetent or the incurably vicious. That such a term of reproach is no longer applicable is shown in "A Transformed Colony," by Mr. Alldridge, whose personal knowledge dates so far back as 1871.

In a clear and attractive manner the author gives a description of the marvellous changes which have taken place as a result of the white man's rule. Situated amidst beautiful scenery, some little distance up the Rokell river, Freetown, the first settlement, now the capital and port of the colony, was originally the dumping ground for the liberated slaves drawn from all parts of West Africa; and from this collection of motley races has grown up a curious mongrel population, bound by no family or tribal ties, speaking no language of its own, and connected only by the common bond of a quaint English patois, and a paternal system of English government. To this has of recent years been added the Hinterland, peopled by numerous aboriginal tribes, each speaking its own language, preserving its own customs, and living under a more or less well-defined feudal system. As a result of the former conditions the Freetown creole has developed, a semi-civilised being with a superficial veneer of civilisation, an overwhelming mass of self-conceit, and a ludicrous capacity for imitating the less desirable qualities of the European. Never is he more happy

other end towards the middle, perhaps deepening and broadening a little near the mouth of any important affluent. Instead of this, it is nearly blocked in that part (where it is more than double its general breadth) by low islands (Fig. 1), rising from a submerged plateau, and besides this, the greatest depths, about 300 feet on the western and 350 feet on the eastern side, do not correspond with any marked topographical features. The fact also that south of the islands is a narrow water-basin, irregular in outline, and reaching a maximum depth of 230 feet, is difficult to explain on any hypothesis. Loch Ness, which is almost the longest of the Scotch lakes (for, with Loch Dochfour, it exceeds twenty-four miles), might seem, because of its depth—the maximum being 754 feet, fully 700 feet below sea-level—and of its uniform slopes, to support the hypothesis of ice-erosion; but some evidence might have been given that its division into two basins was due only to the deposits of the Foyers river, for the delta of the Moriston river on the northern side is more suggestive of a submerged valley.

than when, clothed in silk hat and frock coat, he struts proudly to church, the observed of all observers.

On the other hand, we find the aborigine, still the

given. The results so far are encouraging, and such a scheme appears to offer the best prospects for the evolution of the negro on rational lines.

During the last few years the material development of the colony has been most striking. Railways and roads are spreading fan-like from the Port of Freetown through the "bush," carrying up the products of the Manchester looms and other luxuries of civilisation into villages where, a few years ago, the face of the white man had never been seen, and bringing back in return a rich harvest of palm oil, palm kernels, and rubber, from the hitherto untapped regions of the interior. The extent of this may be realised from the fact that the exports have increased threefold in ten years, from 290,991*l.* in 1898 to 831,259*l.* in 1907, and the revenue from 117,681*l.* to 359,104*l.* during the same period.

There is much else of interest to which only a brief allusion can be made. Mr. Alldridge draws a striking picture of the condition of the Protectorate twenty years ago—perpetual inter-tribal warfare, constant slave raiding, deserted villages with their fringe of skeletons whitening in the sun, and depopulated districts; contrasting vividly with the peaceful prosperity and

commercial progress which are now to be found on all sides. But the book is full of such contrasts; on the one hand, the civilising in-

untutored savage, clothed in his loin cloth and little else, carrying out his ancestral pursuits of agriculture and war, but withal more likeable and trustworthy.

The author skirts very delicately the negro problem in West Africa (and we should have welcomed a bolder presentation of this question from one of his experience), but he does not fail to point out the evils of the purely clerical system of education which has been largely adopted in Freetown, with the result that a race of middlemen traders and clerks has arisen for whom it is becoming increasingly difficult to find employment. An interesting educational experiment is, however, being carried out in the Government school at Bo, in the Protectorate, which is of a different character, and will be followed with much interest by those who have the welfare of the negro at heart. It is intended only for the sons of chiefs, or the nominees of the townspeople, the object being to train the children to become good rulers when they grow up. There is no attempt at Europeanising them; on the contrary, it is strictly forbidden; native clothing is worn, native food eaten, native customs and institutions, so far as they are good, are encouraged, tribal patriotism is strengthened, and there is no interference with the religious beliefs of the pupils. Education proceeds on simple lines, and practical instruction in farming, carpentry, road-making, &c., is

fluences of the bank, the ice factory, the railway, and the telegraph; on the other, the primitive barbarism of the bush, rudimentary arts, primeval marriage

customs, the law of the Porro, the savage ritual of the Bundu, and, dominating all, the ineradicable thralldom of the fetish. It is an interesting story of the making of empire among the savage races of West Africa which will well repay perusal, and the value of the work is much enhanced by the numerous capital photographs of scenery and native customs with which it is illustrated.

W. T. P.

GEOLOGICAL NATURE-STUDY.¹

THE sixth volume of "The Book of Nature Study" is devoted to what is styled "the Physical Environment." This, again, is subdivided into "Meteorology, &c.," written by Dr. Marion I. Newbigin, and "Geology, &c.," by Prof. W. W. Watts. The titles of these subdivisions have been omitted, curiously enough, from the headings on pp. i and 92. Both authors, in pursuance of the plan of the work, guide the reader towards personal observation; and Dr. Newbigin especially addresses herself to the teacher, and considers throughout how certain facts are to be brought home simply to a class. Prof. Watts's pages are therefore more closely written and more enjoyable as literature, while those of his colleague are intentionally more didactic.

Throughout Dr. Newbigin's work there is a consistent attempt to impart just enough information to excite interest, and no more. The apostles of the centimetre scale will be shocked at the willingness of the author to accept "slovenly" results. The teacher is invited to direct attention later to the difficulties that arise from careless measurement. In the case selected, however, that of the rain-gauge (p. 25), the errors would cause no difficulty at all; the results would simply be wrong at the end of a given time, and there would be no means of finding out the truth. This is just the sort of easy-going procedure that would suit the average child; but does it conduce to education? Is it not wiser to explain and illustrate methods of observation, but to refrain from records that cannot be accurate within reasonable limits? All

explanations of natural phenomena have a partial character; we are always making suppositions in regard to an unknown. Dr. Newbigin, however, shows a real preference for the partial explanation, and we fear that the teacher would often have to go much further than is here indicated, when confronted with the child's persistent "Why?"

The passages on "floods," "drought and deserts," or "rainfall and vegetation," show how well the author writes and teaches, within the limits expressly imposed upon herself. Astronomical considerations, sunrise and sunset, time, summer and winter, involve more difficulty, and we cannot see our own way, in such instruction, to dispense with the good old-fashioned terrestrial globe—one, of course, without an elaborate setting, and preferably turning on a wire axis supported at one end only. Dr. Newbigin (p. 53) leaves this to a later stage and to the teacher of geography. Meanwhile, the child is instructed in

Spring issuing from Limestone. From "The Book of Nature Study."

nature-study geocentrically, and will surely soon find something to unlearn.

One point insisted on by the author, in common with many other writers, is that the atmosphere carries a "load of moisture." This phrase is, of course, singularly misleading when applied to invisible vapour, especially when the air is said to "throw down its burden" on cooling (p. 21, for instance, where this is stated in three different ways). How is the child to realise that the air, when it has done this, becomes heavier than it was before? The matter was so well treated long ago in Sir A. Geikie's "Physical Geography" that it is wonderful how it is slurred over in ordinary teaching. Surely, again, the cold surface of a hill (pp. 20 and 22) has very little to do with the formation of cloud around it. "Vapour" is used in two senses on pp. 19 and 21, where invisible vapour is postulated, and yet a cloud is said to consist of vapour. Are we not, in

our desire to be untechnical, building in these matters without foundations, and was not Huxley's original scheme of "Physiography" a really sound guide to nature-study, even if it made its appeal to children somewhat older than those contemplated in the work under review?

Prof. Watts, at any rate, agrees with Huxley, and presupposes, in his geological section, a knowledge of the fundamental constituents of the earth. He refers freely to "silica," "carbonic acid," "minerals," "mica," and even "hydrated silicate of alumina." After all, is there more in this than is expected of the child when he is told to take one quart of milk to James Stewart of Auchencairn and one pint and a half to Mistress Campbell of Drumochter? The milk, the persons, and the farms are realities to him, and are therefore easy of comprehension. Is there any objection to making him equally well acquainted with the fundamental materials of the land? Prof. Watts gives the teacher the essential conceptions of geology, and leaves him to select what is suited to the comprehension of his class. His style is terse and vivid, and the illustrations selected by him, often from the photographs of Mr. Godfrey Bingley, are in every way worthy of the text. Since the principles of geology are so greatly concerned with the form of the earth's surface, the making of maps and models is included in the course, and the use of the plane-table, so attractive to beginners in geography, is explained and illustrated. Several of the technical terms in the chapter on the geological record, "brachiopoda," for instance, are not included in the index to the six volumes of the work; but the author moves on without hesitation—the teacher who undertakes the geological branch of nature-study must be ready to explain such technicalities to his class. Altogether, we cannot conceive a more effective introduction to geology than is here put forward.

To make two small criticisms, in the diagram on p. 210 the relations of the upper series of beds seem unnecessarily complicated by a surface-creep towards the valley on one side; and the chapter headed "Igneous Rocks" is mainly concerned with clastic rocks and earth movement. Since the conclusions stated are drawn from observation in our own islands, glaciers and volcanoes are more lightly treated than in many popular works. Prof. Watts has not gone out of his way to be popular, and has succeeded in being so in the highest of all senses.

Prof. Walther, in his "Vorschule der Geologie," has set much the same goal before himself. In five years his simple little book has run into four editions, and still forms a treatise that can be easily slipped into the pocket. The author is one of a band of German leaders in education who wish to see geology taught in all secondary (*höhere*) schools. He here leads on his reader to observe nature out of doors, and in a number of practical exercises shows the varied activities and changes on the surface of the earth. His diagrams are equally simple and convincing, whether of a tree forced to modify the form of its stem through the down-creep of a talus (p. 11), or of the formation of a granite tor (p. 29) by successive stages of decay. Even Dr. Newbigin would shake her head over Prof. Walther's rain-gauge (p. 42); but his charming directness of style gives one great confidence in his experiments. He permits us chemical formulæ, and even crystallographic systems; yet his work is quite unlike the text-books familiar in German schools. His little local sketches, such as the section of a swampy area in Fig. 30, are real lessons in geography; indeed, we have shown these pictures to a class in the field in explanation of the broad features of a landscape. We may differ

with him on small points, such as his treatment of trough-faulting, which surely arises most frequently through the faulting of a fault by one of opposite hade; but he guides us onward from our first observations on a hillside until we can grasp the complexities of a geological map. He expects us to purchase one and use it, and supplies index maps for all the German surveys, with considerable lists of literature to assist our summer holidays. This confidence in the attractiveness of his subject is one of the charms of Prof. Walther's treatise; but we must remember that he appeals to pupils trained by longer working hours than our own, and to the sons and daughters of a people that regards education with respect.

Dr. Haas, in "Die vulkanischen Gewalten," adds one more to Herre's series of popular scientific monographs. The black-letter type, and occasional sentences in the long black-letter style, show that it is intended for general readers beyond the colleges. It is not concerned with personal observation, but contains, logically stated, the results of a wide range of research. The description of a volcano in time introduces us to earthquake problems and the constitution of the earth's interior. Though the writers referred to are naturally for the most part German, the author has read widely, and even quotes (p. 97) Albert Bruns' view that the volcanic cloud consists of salts of ammonia. This leads on to an interesting discussion of how volcanoes might be produced without the presence of water in the original igneous mass, and of Stübel's theory of the formation of calderas by magmatic expansion and subsequent sinking of the central areas. There is much in this "popular" work that will be useful to the teacher of geology and the illustrations of dust-clouds and lava-flows are refreshingly recent, after the oft-repeated woodcuts which we have become inured.

GRENVILLE A. J. COLE.

THE MEDIUM OF CELESTIAL SPACE.

THE physicist knows well that the problems with which he has to deal are insignificant, or at best subsidiary, when compared with the great questions so intimately connected, What is matter? and What is æther? The astronomer, though he observes the operations of nature on a vaster scale, deals with problems of a less ultimate character. Thus, when he seeks to investigate the properties of that medium in which the solar system and the stars alike are moving, he is far removed from any metaphysical abstraction, and only seeks the answer to perfectly definite, concrete questions concerning the transparency and dispersive qualities of the medium. But if the questions are concrete, they are by no means simple, and though the last two years have seen a simultaneous attack on the problem on several converging lines, the main result has been to make us realise the immense difficulties which lie in the way of a definite conclusion.

Whether there is a general absorption of light space, from whatever cause arising, is a point which suggests itself most obviously. Without attributing any absorptive power to the æther itself, it is easy to see reason for inferring that a loss of light does take place. The streams of meteors which enter our atmosphere have not always been within the sphere of influence of the solar system, but have probably come in incalculable numbers from outer space. There is a continual drain on the atmospheres of the sun and planets owing to the loss of the fastest-moving molecules. The empty spaces which have been found to exist in the midst of the densest star clouds, and the curious rifts which interrupt the continuity of certain

bright nebulae, suggest the presence of obstructing nebulous masses such as that which was only revealed by the outburst of Nova Persei. It is thus reasonable to suppose that a sensible amount of absorbing matter exists in space. But to form a quantitative estimate of its effect is a task of which our increased knowledge makes us only the more appreciate the difficulty.

The problem would be simpler if we could accept the conditions supposed by the earlier astronomers. For them the extent of the universe was indefinitely large, and the distribution of the stars roughly uniform. Moreover, they imagined that the intrinsic brightness of all stars was nearly constant, and that the observed differences of magnitude were almost entirely attributable to the effect of varying distance. But for an effective general absorption we ought, in these circumstances, to expect the whole sky to shine with the average brilliance of a stellar surface, and Halley, in supposing otherwise, was guilty of a simple error. The truth of this was perceived by Cheseaux (1744), and later by Olbers (1823), and both astronomers inferred an extinction of light in space without estimating its amount, or even supporting it by direct evidence, rather than admit that the universe was finite. The first estimate based on these premises was given by W. Struve in his "*Études d'Astronomie Stellaire*" (1847), a work of great historical interest. Using the data provided by Herschel's gauges, and the counts of Bessel and Argelander, Struve concluded that light coming from the mean distance of sixth-magnitude stars suffered a loss of 8 per cent. of its intensity. But we have ceased to regard as valid the premises on which this conclusion was based. We know now that the variability of the intrinsic light of the stars is so great that distance can no longer be considered as the chief factor in determining their apparent magnitudes. There are also grave difficulties in the way of assuming that the universe extends with finite density to an infinite distance. Seeliger has pointed out that unless the Newtonian law of gravitation be modified, an infinite strain will exist at every point; and even if the smallness of the total light of the sky be accounted for by some kind of absorption, a thermal difficulty remains; for any part of an infinite and eternal universe will be, as it were, within an isothermal enclosure, and the temperature at every point will be at least 6000° C. Such considerations, and the facts of observation, have led us to abandon the idea of an infinite universe, and Newcomb asserted, not only that the system of the stars was finite, but that there was no evidence that any extinction of light in space occurred. That will not hinder us from seeking for evidence. If we possessed a knowledge of the spatial relations and the luminosities of the stars, if, in a word, we held the key to the sidereal problem, we should be in a position to assess the absorption of light in space. But without assessing the loss of light according to distance, the sidereal problem cannot be solved. In fact, the two problems are interdependent, and it may be long before a satisfactory solution is reached.

There is, however, a subsidiary line of attack possible. The absorption may be selective in its character, or, in other words, its amount may be a function of the wave-length. This will be the case if it is due to scattering by particles the dimensions of which are of the order of a wave-length of light. It is not absolutely clear that a similar effect may not be produced by the æther itself. In either case a corresponding dispersion is to be expected, and the rate of propagation will depend on the colour of the light. If any celestial phenomenon be carefully observed which is strictly localised in space and in time, the relative rate of transmission for different parts of the spectrum can

be detected. Newton approached the subject from this point of view, and suggested the eclipses of Jupiter's satellites as suitable phenomena for investigation. It is well understood now that the conditions of a gradual eclipse are quite unfavourable for the detection of subtle colour changes, and the distance in this case is altogether too small. The circumstances of stellar aberration have also been invoked to set a limit to the possible dispersion. But the sensitiveness of this test is also too small, for a difference of as much as one-half per cent. in the rate of transmission would at best produce a spectrum 0.1" in length (and this is about the estimated width of the fine micrometer wire of the largest refractors). As nothing of this order is to be looked for, a finer test must be sought. Arago conceived the possibility of detecting a change of colour in variable stars according to the light phase. Contenting himself with the simple inspection of certain variables, he concluded that there was no such effect. As a matter of fact, more careful observers have noticed a change of tint accompanying the change of brightness; but even so the natural explanation is to be found in the physical character of the stars. This illustrates the need for a cautious interpretation of results, as well as for the most careful and refined methods of observation.

A great advance in practical methods has been made recently by M. Nordmann, of Paris. His plan has been to study the light curves of certain variable stars, using the light from different regions of their spectra, in accordance with the belief that a sensible dispersion in space must produce a want of simultaneity in the respective curves. With this object in view he designed an ingenious modification of the Zöllner type of photometer. By its means the light of the star examined can be compared with an artificial star produced by condensing on a small hole the light of an Osram lamp fed by a constant current. Before entering the eyepiece, the light from both images passes through one of three liquid light filters, and thus the comparison is made in red, green, or blue light as desired. Whatever opinion may be formed of the validity of M. Nordmann's conclusions, it is fair to say that his apparatus has been admirably designed, and that much is to be expected from the systematic application of his method to the study of coloured and variable stars. Finding the atmosphere of Paris unsuitable for delicate researches of this kind, he took his apparatus to Biskra, in Algeria, where he spent several months in 1907-8. Unfortunately, the climate of this station did not fulfil expectations, owing to the prevalence of sand storms, and this fact may account for a certain want of continuity in the observations in a research which demanded continuity as a necessary condition of complete success.

M. Nordmann studied chiefly the stars β Persei and λ Tauri. But before alluding to his results, we may refer to the nearly contemporaneous work of M. Tikhoff, of Pulkowa. M. Tikhoff has conceived more than one ingenious method of attacking the problem of dispersion in space. One of these is in principle the same as that of M. Nordmann, but differs from it in employing photography instead of direct visual estimates. By using bathed plates, the region of the star examined is photographed through certain screens, which are prepared in such a way as to allow only light belonging to restricted ranges in the spectrum to be effective. Thus, an orange screen may be expected to give results comparable with those obtained by visual methods, while a blue screen will give photometric estimates in the ordinary photographic region of the spectrum. By this method M.

Tikhoff studied the variables RT Persei and W Ursæ Majoris. Some years previously he had compared the velocity curves and the light curves of the stars δ Cephei and η Aquilæ, which are well-known spectroscopic binaries and variable stars. Inasmuch as an accepted theory of the physical nature of stars of this type is still wanting, this method must be considered radically unsound. But more recently M. Tikhoff has had the happier idea of comparing the velocity curves as determined from lines in separate regions of the spectrum. Theoretically, this would seem to be the method of all those which have been suggested which is the most free from objection. But it is doubtful whether, among the spectrographic observations already made, even of the highest class, suitable material exists for the successful application of the method. It is certainly possible to criticise on definite and practical grounds MM. Tikhoff and Belopolsky's discussion of the case of β Aurigæ.

The results already obtained may be tabulated thus:—

Star	Range μ	Lag min.	Authority
β Persei	680-450 ...	13 ...	Nordmann
λ Tauri	" ...	30 ...	"
RT Persei	560-430 ...	4 ...	Tikhoff
W Ursæ Majoris.	625-380 ...	10 ...	"
β Aurigæ	450-400 ...	10-20 ...	"

The third column, which alone requires explanation, contains the retardation, expressed in minutes, of some event observed in blue light over what is supposed to be the same event observed in light of greater wave-length. The event in the first four cases is the light minimum of the star, while in the fifth case it is the disappearance of the radial component of the velocity relative to the Sun. Unfortunately, we have no trustworthy determinations of the parallaxes of these stars. Pritchard's values for β Persei and β Aurigæ are near 0.06", and M. Tikhoff himself has found the parallax of RT Persei to be insensible. Thus we can only note the qualitative agreement in the sign of the lag in all cases, which suggests that blue light is transmitted through space at a slower rate than light of longer wave-length. Yet the results are liable, even on this ground, to serious criticism, which has been expressed forcibly by Prof. Lebedew. It is not surprising that close inspection shows that the data in the case of β Aurigæ are not self-consistent. But in the other cases we cannot be certain that the observed event is really synchronous in its origin for different qualities of light. This essential condition may be nullified by the physical character of the star, as, for instance, by a selectively absorbing atmosphere of the occulting body. Prof. Lebedew is entirely right in suggesting these criticisms, but they do not prove that the medium filling space is without dispersive power; and even if this fundamental question is left open, it is to be hoped that researches will be continued on the same lines, for the ingenious methods of MM. Nordmann and Tikhoff bid fair to extend our knowledge of variable stars in a most helpful way.

Meanwhile the line of direct investigation of a possible selective absorption in space has been followed. If two stars the intensities of which are I_1 and I_2 require exposure times T_1 and T_2 in order to register images of equal density on a photographic plate, we may put (after Schwarzschild)

$$I_1 T_1^p = I_2 T_2^p.$$

A priori we might expect the same effect to be produced by the same incident energy, or $p=1$. As a matter of fact, a number of independent researches have suggested that p is much nearer the value 0.8. This deficiency in the value of p has been attributed

to the properties of the photographic plate. But it occurred to Prof. Turner that the fact might have its origin in cosmic causes. He had deduced from the Greenwich astrographic results that "when the time of exposure is prolonged in the ratio of five magnitudes, the photographic gain is four magnitudes." This result, which has been reached by others in more or less the same form, is equivalent to the above statement that $p=0.8$. A number of facts connect with visual and photographic magnitudes could thus be reconciled by supposing that the small particles distributed in space actually produced a selective scattering in accordance with Lord Rayleigh's law.

It seemed as if a crucial test was at hand to try this hypothesis. It was only necessary for M. Tikhoff to apply his light-filters and to see whether the apparent law of photographic action was the same for the blue starlight which affects the ordinary plate, and for the visual rays to which the bathed plate is sensitive. The experiment was immediately made, and the first results seemed to bring a striking confirmation to the hypothesis. M. Tikhoff found that $p=0.6$; to 0.79 for the photographic rays, but that $p=0.91$ to 0.96 for the green-yellow rays. But Mr. Parkhurst of the Yerkes Observatory, who has made a special study of the subject of photographic photometry strikes a note of warning. Under conditions apparently similar, he has obtained $p=0.88$ for the ordinary plate, and $p=0.81$ for the bathed plate with colour filter. These results go in the opposite direction and must be attributed to the different plates (Schleussner and Cramer) and filters employed. Mr. Parkhurst concludes that "if cosmic causes played any part in the matter they would be completely masked by photographic effects."

The inter-relation which has been noticed between the problem of absorption in space and the problem of sidereal structure has naturally engaged the attention of Prof. Kapteyn, who has been the most prominent and assiduous student of the latter question during recent years. He has noticed that the marked deficiency in the numbers of the faintest classes of stars is equally apparent in all directions of the sky. Unless this peculiarity is attributable to the effect of general absorption, we must suppose that the sun is situated at the centre of the universe, although such a thing is perfectly possible, it is not specially probable. Kapteyn prefers to admit a absorption of light, and provisionally estimated the loss required by the hypothesis of nearly constant star-density as 0.016 of a magnitude for stars with parallax of 0.1". More recently he has brought forward an interesting argument of a qualitative kind. Miss Cannon's classification of star spectra distinguishes between two classes which differ only in showing greater or less relative absorption in the violet end of the spectrum. Arcturus is the type of the stars less affected, while α Cassiopeia is the type of those more affected in this way. If the property is not intrinsic in the stars themselves, stars belonging to the Arcturus class should be nearer to us than stars like α Cassiopeia. Hence the former class should on the average, possess greater proper motions. Put to the test, 45 stars of the α Cassiopeia division gave an average centennial proper motion 11.4", and 2 stars of the α Bootis division gave 47.1". Thus the idea is confirmed that the distinction is due to absorption in space. A number of interesting points are involved in this line of argument, and it is to be hoped that it will be further tested by extending its area of application.

Quite lately Prof. Kapteyn has published second and more extended research on the subject. In this he investigates the amount of selective absorp-

tion, and starts from the principle that "the phenomenon must manifest itself in this, that, *ceteris paribus*, the more distant stars will be redder than the nearer ones." As a measure of redness he employs the difference, photographic *minus* visual magnitude, derived from the Draper catalogue and the Harvard revision. It would be profitless to use direct determinations of parallax, for the material at hand is far too scanty and untrustworthy. Hence he derives the measures of distance from his own statistical discussions, which have enabled him to express the average parallax of a star as a function of its magnitude and proper motion. The necessary data have thus been found for 1433 stars, and separate equations have been formed for the different spectral classes and certain ranges of proper motion within each class. It is impossible here to follow the rather complicated discussion in detail, but the result obtained on certain simple assumptions as to the nature of the scattering of light implies a loss of

0.00867 of total light = 0.00945 of mag. for photographic rays
0.00427 " = 0.00465 " visual rays

in the case of a star the parallax of which is 0.1", or the distance of which is 32.6 light-years. Kapteyn considers that these numbers represent lower limits, and finds no difference between galactic and extra-galactic regions of the sky so far as selective absorption is concerned.

Despite the contradictory nature of the evidence, it must be felt that the whole subject is full of interest. It is now receiving the most critical and exhaustive discussion, and the need for fresh material will stimulate original and appropriate observations. It is pleasant to learn from Prof. Kapteyn that the plan of work for the 60-inch reflector on Mount Wilson includes special provision for this line of study. Efforts directed with a serious purpose and pursued with sincerity do not go unrewarded, though the shape of the reward may not always be according to expectation.

H. C. P.

NOTES.

THE list of Birthday Honours was published on Friday last, but, as usual, men of science do not figure largely in it. Among the new Privy Councillors we notice the name of Sir William Mather, who has done much to promote technical education. The honour of Knighthood has been conferred upon Mr. H. Hall, His Majesty's Inspector of Mines for the Liverpool and North Wales district, and Dr. A. Hopkinson, Vice-Chancellor and principal of the Victoria University of Manchester. Colonel F. B. Longe, Surveyor-General of India, and Dr. R. T. Glazebrook, F.R.S., become Companions of the Bath (C.B.). Mr. J. H. Marshall, director-general of archaeology in India, Mr. C. Michie Smith, director of the Kodaikanal and Madras Observatories, and Dr. M. Aurel Stein, superintendent of the Archaeological Survey, Eastern Circle, are appointed Commanders of the Indian Empire (C.I.E.). The order of C.M.G. has been conferred upon Dr. A. D. P. Hodges, principal medical officer of the Uganda Protectorate, in recognition of his services in the suppression of sleeping sickness, and Prof. T. W. Edgeworth David, F.R.S., of the University of Sydney. Mr. C. O. Waterhouse, of the British Museum (Natural History), has been appointed a Companion of the Imperial Service Order.

SIR WILLIAM RAMSAY, K.C.B., F.R.S., has been elected an "Associé Étranger" of the Paris Academy of Sciences, in the place of the late Prof. Alexander Agassiz.

THE Albert medal, of the Royal Society of Arts for the current year has been awarded by the council to Madame

Curie, for the discovery of radium. The discovery, which was the outcome of Prof. Becquerel's researches into the radio-activity of uranium and its compounds, was made jointly by Madame Curie and her husband, Prof. Curie, professor of physics at the Sorbonne, in 1898. Prof. Curie died in April, 1906, and in May of the same year the faculty of sciences paid his widow the distinguished honour of appointing her his successor. She has since continued, on her own account, the researches she commenced in association with her husband. The Davy medal of the Royal Society was awarded to Prof. and Madame Curie in 1903, and the importance of the discovery has been fully recognised by the scientific world.

THE King has consented to become Patron of the Royal Society of Arts in succession to King Edward the Seventh, who became Patron on his accession, after having filled the office of president of the society for thirty-eight years.

THE President of the Board of Trade has appointed a committee to inquire what degree of colour-blindness or defective form-vision in persons holding responsible positions at sea causes them to be incompetent to discharge their duties; and to advise whether any, and, if so, what, alterations are desirable in the Board of Trade sight tests at present in force for persons serving or intending to serve in the merchant service or in fishing vessels, or in the way in which those tests are applied. The committee consists of the Right Hon. A. H. D. Acland (chairman), Lord Rayleigh, O.M., F.R.S., Sir Arthur Rücker, F.R.S., Mr. Raymond Beck, Captain T. Golding, Prof. F. Gotch, F.R.S., Mr. N. Hill, Mr. E. Nettleship, Mr. J. H. Parsons, Prof. J. H. Poynting, F.R.S., and Prof. E. H. Starling, F.R.S. Dr. W. Watson, F.R.S., and Mr. S. G. Tallents will be secretaries to the committee.

WITH reference to Mr. Winston Churchill's statement in the House of Commons on June 16, "that the time has now arrived when a definite effort should be made to break new ground and set up a higher standard" of safety in mines, we learn that a committee, appointed by the council of the Royal Society of Arts, and under the chairmanship of Sir Henry Cunynghame, K.C.B., is now considering the relative merits of a number of life-saving appliances which have been submitted in response to an offer, under the Fothergill Trust, of a gold medal or prize of 20*l.* for the best portable apparatus for enabling men to undertake rescue work in mines or other places where the air is noxious. The committee of the society is in communication with the South Midland Coal Owners Mine Rescue Experimental Committee, which is also conducting exhaustive inquiries with the view of discovering the most suitable apparatus for use in the South Midland coal-fields.

THE King held his second Accession Court for the reception of addresses at St. James's Palace on June 22. Among the addresses presented were eight from universities and a number from learned societies. The King made special replies to the Universities of Oxford, Cambridge, Edinburgh, Dublin, and London. To the representatives of Oxford University his Majesty remarked:—"It is my desire to follow the example of my father and of Queen Victoria in sustaining and in fortifying those seats of learning on whose prosperity and influence the character and repute of our civilisation largely depend. Among them the University of Oxford, with its world-famous traditions of steadfastness and loyalty, will ever hold an honoured place." The reply to Cambridge University included the words:—"Your famous University may count

upon my sincere goodwill, and, like King Edward, I shall watch its progress and expansion with lively interest. I am convinced that you will not fail in the responsibilities with which you are charged, and that the zeal for truth, love of learning, and a high ideal of character and conduct will ever be cherished and fostered in your midst." To the Edinburgh University representatives the King said:—"It gave me great pleasure to listen to the record which you have recited of the growth and increasing prosperity of the University of Edinburgh, since the time when, as Prince of Wales, my dear father matriculated as a student. The work of the universities is of far-reaching importance to the welfare of my people, and I feel confident that every extension of the sphere of their influence will be attended with beneficent results. I shall follow with deep interest and continual good wishes the work which is being done by your university in furthering the advance of sound learning and education." The reply to London University included the words:—"King Edward watched with keen interest the continuing prosperity and progress of the London University. He understood how much the strength and reputation of our country depended upon the moral and intellectual culture of her sons and daughters. He saw with pleasure the distinction and thoroughness with which the London University invested higher education in the capital. You may be assured that the fortunes of your university will ever be near my heart, and that I shall always take a lively interest in your welfare."

QUEEN ALEXANDRA received Captain R. F. Scott at Buckingham Palace on Saturday last, and expressed her deep interest in the forthcoming British Antarctic Expedition. Her Majesty presented Captain Scott with a Union Jack to be carried with the expedition, and to be planted at the most southerly point reached. A telegram from New Zealand announces that the Dominion intends to present the expedition with a quantity of coal and other stores on its arrival at Lyttelton. The *Terra Nova* left Madeira on Sunday for Simonstown, where she is due to arrive on August 1. Captain Scott is to sail from Southampton on July 16, and is due to reach Cape Town on August 2, and to leave there on August 13. The *Terra Nova* should arrive at Lyttelton on October 14, set sail on November 15 for the Antarctic, and reach the base on King Edward VII. Land on December 15.

THE *Times* correspondent in Berlin states that the preliminary expedition to Spitsbergen for the purpose of studying Arctic conditions in connection with the projected Zeppelin airship Polar expedition will leave Kiel on Saturday next in the North German Lloyd steamship *Mainz*, which has been specially fitted up for the purpose. It is said that Prince Henry of Prussia, as well as Count Zeppelin, will take part in the expedition, which is expected to last some eight weeks.

ACCORDING to a Geneva correspondent of the *Times*, an important Swiss scientific expedition left last week to make researches in the Cordilleras basin of the Andes. The expedition is in charge of Prof. O. Fuhrmann, of the University of Neuchâtel, and it will probably be absent two years.

MR. ROBERT NEWSTEAD, lecturer in economic entomology and parasitology at the Liverpool School of Tropical Medicine, and a member of the Entomological Research Committee of the Colonial Office, has gone to Malta to investigate the problem existing there of the menace to health by the sand-fly. The main cost of the expedition will be covered by a special grant from the advisory com-

mittee for the Tropical Diseases Research Fund (Colonial Office).

THE discovery of an immense reef of free-milling gold ore near Stewart, at the head of Portland Canal, British Columbia, is reported. It is stated that the reef has been traced for nearly twenty miles, and naturally there has been a great rush of miners and others to the locality.

It is stated in the *Scientific American* that a fund has been started by Mrs. E. H. Harriman for the collection of complete data on mammals and other animals in the North American continent, and that Dr. C. Hart Merriam, chief of the Biological Survey of the U.S. Department of Agriculture, is about to resign his position to take charge of the work.

A REUTER message from Algiers states that two violent earthquake shocks were felt at that place, and throughout the west of the department, at 1.30 on the afternoon of Friday last. Later telegrams received in Paris on Tuesday state that earthquake shocks continue to take place in the district of Aumale, that Dowar el Enoch suffered particularly, and that twelve lives have been lost.

WE regret to learn of the death, at eighty-one years of age, of Mr. C. Greville Williams, F.R.S., author of many papers in organic chemistry, and for some years assistant to Lord Playfair in the department of chemistry of the University of Edinburgh.

THE *Athenaeum* announces the death, at the age of seventy-five years, of Dr. Julius Weingarten, professor of mathematics in the University of Freiburg im Breisgau.

MR. S. A. STEWART, whose death at the advanced age of eighty-four occurred through an accident at Belfast on June 15, was a distinguished Irish botanist and geologist, and until recently curator of the Museum of the Belfast Natural History and Philosophical Society. Mr. Stewart contributed valuable papers to the Royal Irish Academy and other scientific societies, and wrote in conjunction with the late Mr. T. H. Corry the standard work "A Flora of the North-east of Ireland," brought out in 1888. Although jointly planned, the early death of Mr. Corry a few years before publication left the chief execution of the project to Mr. Stewart. Nearly seven years later a valuable supplement was published by Mr. Stewart in collaboration with Mr. R. L. Praeger in the Proceedings of the Belfast Naturalists' Field Club. Mr. Stewart's contributions to geology were also most original and important. He was an Associate of the Linnean Society, a Fellow of the Botanical Society of Edinburgh, an hon. associate of the Belfast Natural History and Philosophical Society, and one of the founders of the Belfast Naturalists' Field Club.

THE *Times* announces that a memorial to Lieut. Boyd Alexander, the explorer, who was murdered in the French Sudan in April, and his brother, Captain Claud Alexander, who also lost his life in Central Africa while engaged in scientific exploration, has just been completed at Wilsley House, Cranbrook. A sheet of water on the estate has been laid out as an exact reproduction in miniature of Lake Chad from plans by Lieut. Boyd Alexander. On the islands and banks of the lake are reproductions of thatched native huts, and there is preserved on the adjacent lawn one of the boats in which the Alexander-Gosling Expedition made its way down the river Yo to the Nile.

A COMPLIMENTARY banquet to some of the recipients of the Mary Kingsley medal of the Liverpool School of Tropical Medicine was given by the chairman of the

school on Saturday last, when Surgeon-General Sir Alfred Keogh, C.B., who was one of the speakers, said he had endeavoured to help science in the appointment which he had lately vacated. His special mission was to endeavour to bring into the counsels of the War Office a realisation of the fact that medicine was an applied science, and that it was not concerned merely with the treatment of disease, but with its prevention. The problem of making the tropics habitable was easy, and they could make such countries as West and Central Africa as salubrious as Liverpool if they would only take the trouble to think about it and would organise for the purpose. Medical science had also a definite relation to war. He described the work of Sir David Bruce in practically stamping out Malta fever. Thanks to applied medicine, there had been added to the Indian Army for defensive purposes last year the equivalent of two battalions.

THE Cavendish lecture will be delivered to the West London Medico-Chirurgical Society to-morrow by Sir Thomas Oliver, who will take as his subject "Empyema and some Problems Connected Therewith."

THE summer meeting of the Junior Institution of Engineers will be held in Dublin and Belfast from July 16 to 23. The proceedings are to be opened by a reception at Trinity College, Dublin, by the provost and professors of engineering, and afterwards a number of engineering works, &c., will be visited.

THE autumn meeting of the Iron and Steel Institute will take place at Buxton on September 26 to 30.

THE necessity of applying what may be called the "intensive" method of treating some questions of Indian ethnology is enforced by a paper recently read by Sir R. Temple before the Royal Society of Arts on the people of Burma, and by the discussion which followed. The authorities are at issue on the order of the invasions from which the present population resulted. Sir R. Temple thinks that the order of entrance into the peninsula was Mon-Khmer, Tai or Shan, Bama or Burmese. Sir J. G. Scott believes that the Shan, if they migrated at all, formed the third body of newcomers; but he prefers to suppose that the Shan never migrated. Again, as regards religion, Sir R. Temple treats the vast majority of Burman Buddhists as Animists, Animism taking the form of Nat worship. Mr. E. Colston, on the contrary, holds that though Nat worship may be animistic in origin, it is an integral part of Buddhism, analogous to the Deva worship in Ceylon. These two authorities are again hopelessly at issue in their views as to the period when Hindu influence became powerful in the country.

THE iron styles used for writing in India are interesting, because it is through them that the types of the present scripts have been determined, the circular class of alphabets, like the Oriya or Burmese, depending upon the necessity, in order to avoid breaking the material, of moving the style in a curve, not in a straight line, along the fibre of the palm-leaf. Mr. I. H. Burkill in vol. vi., part i., of the *Journal of the Asiatic Society of Bengal* for the current year describes a large collection of these styles. He arranges them in no less than thirty-seven types, beginning with the most simple form, like a porcupine quill, and gradually developing into the most intricate and elaborate shapes.

In the June number of *Man* Mr. T. M. Joyce describes some curious wooden engraved blocks used by the Bushongo of the Belgian Congo for ornamenting their bodies on festal occasions, and for staining palm cloth and

embroidery fibres with a red pigment prepared by bruising the wood of a tree known as *tukula*. They are good examples of the work of this naturally artistic race. It is remarkable that, like our mourning rings, the heir of a dead man, acting as chief mourner, distributes a number of these articles to the immediate friends of the deceased as mementoes.

A good example of the rain-making chiefs, to whom Prof. J. G. Frazer first directed attention, is to be found in a paper on such functionaries in the Gondokoro district, White Nile, contributed to the June issue of *Man* by Mr. W. E. Cole. The rain-maker shows considerable shrewdness in his proceedings. He always builds his village on a hill slope, which he knows attracts the clouds. He smears himself with wood ashes, and wears a number of charms. Then he produces a pot in which he keeps his rain-stones, generally pieces of crystal, aventurine, or amethyst, found on the neighbouring hills. These, in the true spirit of mimetic magic, he covers with water, and, taking in his hand a peeled cane split at the top, he beckons towards him the clouds if his people need rain. Sometimes he maliciously diverts the rain-clouds towards some unfriendly tribe. If by chance his incantations fail, he announces that some hostile chief in the neighbourhood has stolen the rain. This often leads to a raid on the offending village, and to many broken heads.

THE Bulletin of the Johns Hopkins Hospital for May (xxi., No. 230) is devoted to an important article by Drs. Crowe, Cushing, and Homans on the results of removal of the hypophysis cerebri, or pituitary body, a small glandular organ at the base of the brain. Methods were elaborated whereby the organ could be removed without injury to the adjacent brain. In dogs the most striking features following removal are development of a state of obesity, alterations in the sexual organs, and skin, sub-normal body temperature, sugar in the urine, psychic disturbance, and finally death—all of them symptoms which have occasionally been noticed in man in connection with tumours of the pituitary body. The paper makes a very notable addition to our knowledge of the functions of this organ.

THE difficulty of deciding whether butter is genuine or adulterated is illustrated in a paper by Mr. G. Brownlee issued by the Department of Agriculture and Technical Instruction for Ireland. The committee on butter regulations, in their final report, recommended that in the case of any butter giving a Reichert-Wollny number below 24 the presumption should be that the sample is adulterated with foreign fats. As certain Irish butters, known to be genuine, have been found to fall below this limit, an extended set of observations was made. It appears that the chief factor influencing the Reichert-Wollny number is the lactation period of the cows supplying the milk, and that in order to get butter of a more uniform composition the calving of the cows should be distributed more evenly over the year.

THE Department of Agriculture in the Leeward Islands carries out a number of experiments on sugar-cane, the results of which for the past season are now published. Of the varieties examined, some show themselves well suited for cultivation at all the various experimental centres, while others are more limited in their range and are at their best on certain special types of soil. The manurial experiments are mainly on the ordinary lines, but some new ground is broken. Molasses has been tried as a fertiliser with results that justify further investiga-

tion. It is not clear that either nitrogen, potash, or phosphoric acid is present in sufficient quantity to account for the increased crops, and the simplest explanation appears to be that the carbohydrate furnishes additional supplies of energy for the nitrogen-fixing bacteria in the soil, and thus leads to a gain in the soil nitrogen.

THE methods of picking, drying, and packing hops in Kent are described in some detail by Mr. Arthur Amos in the *Journal of the Board of Agriculture* (No. 2). Mr. Amos writes with a complete knowledge of the subject as a hop-grower, and is also a trained botanist; the article is therefore one of considerable interest. Hop production is a highly specialised branch of farming, requiring much more capital per acre than wheat or cattle production, and it includes not only hop growing, but also drying. The oasts, or drying ovens, are familiar objects to all who have travelled across Kent. The drying is managed by a skilled workman, who remains in charge during the whole time of hop-picking, and even sleeps on the spot so that he may be at hand in case of need. A good hop-dryer is a person of distinction in the village community, and rightly so, since he can by his efforts materially influence the value of the product.

THE extraordinary interest shown by the public in poultry production at the present time is discussed in the April number of the *Journal of the National Poultry Organisation Society*. To a certain extent a section of the daily Press is responsible for this outburst, but the popular interest always existed even before it was recognised by the Press. The society is proposing to take as full advantage as possible of the present favourable opportunities for the introduction of cooperative methods in egg production. It will be interesting to see how far cooperation may become a factor in English rural life.

THE *Field* of June 25 contains a summary of an important paper read by Mr. Pocock at the meeting of the Zoological Society on June 21 on the scent-glands of deer and antelopes, and their bearing on the classification of those groups. The author gave reasons for regarding the Indian four-horned antelope as related to the bushbucks rather than to the duikers, while the beira antelope of Somaliland is classed with the dik-diks instead of with the gazelles, and the saiga, the chiru, and the palla are removed from the latter group to independent positions. In the deer it is considered that the form of the antlers does not constitute a trustworthy guide to affinity.

IN the May number of the *National Geographic Magazine* Mr. H. M. Smith, the Deputy Commissioner, tells some of the wonderful results which have been accomplished by the Fisheries Commission in re-stocking the depleted waters of the United States with food-fishes, lobsters, oysters, &c. Nearly forty years ago the Government realised the urgent necessity for measures of this nature, and at the present day the official system of fish-culture is stated to surpass in importance and extent that of all other countries collectively. A few States did not join in the movement, with the result that there has been a shortage in the supply of the eggs of certain species. The obvious remedy for this is the assumption by the Federal Government of supreme power in regard to fisheries. For the first ten years of its existence the energies of the commission were concentrated on the culture of the eight commonest and most valuable food-fishes. Nowadays the list is six times as large, and includes shad, whitefish, Pacific salmon, white perch, yellow perch, cod, various kinds of flat fish, and lobsters.

The hatcheries also rear numerous kinds of fresh-water species. The only permanent marine hatcheries are in Maine and Massachusetts, where, to use the author's own words, such species as cod, pollock, flat-fish, and lobsters are reared and distributed by the billion. Special attention is likewise directed to the diseases of fishes, particularly cancer, for which new laboratories are in course of erection. The article concludes with an account of new fisheries and new methods of fishing discovered by the commission.

IN an article in the June number of the *Zoologist* Mr. F. J. Stubbs endeavours to explain the mechanism by which aquatic birds are enabled to maintain themselves at different levels in the water. Moorhens, it is well known, will not unfrequently maintain themselves at a considerable depth below the surface by grasping plants with their toes, and it is suggested that the same means are sometimes employed by dabchicks. It is obvious, however, that such a method will not hold good for divers, in which grasping power is lacking. The mechanism, in the author's opinion, is afforded by the presence of a layer of air held between the "feather-film"—or mesh of barboles and cilia formed by the outer layer of the plumage—and the skin. "Each of the contour-feathers is provided with a separate apparatus of muscles, whereby it can be held out at right angles or pressed close to the body. In the first case the bird would appear round and fat, in the second very slim, and there would be a corresponding change in the extent of the air-envelope, and consequently of the buoyancy of the bird. By adjusting the thickness of this layer of air between the 'feather-film' and the epidermis the bird can alter its specific gravity." It is further considered that the water-repelling property of the plumage of a duck is due to the feather-film, and not to the natural oiliness of the feathers.

WE have received a series of contributions from the Palaeontological Laboratory of Yale University, reprinted chiefly from the *American Journal of Science*. This department of the Peabody Museum, which became famous through the researches of the late Profs. O. C. Marsh and C. E. Beecher, well maintains its reputation under the direction of Prof. Charles Schuchert. The most important paper is one by Dr. G. R. Wieland describing in detail the remarkable Cretaceous turtle, *Archelon ischyros*, which has now been mounted for exhibition and measures considerably more than three metres in length. A discussion of this and allied Cretaceous fossils seems to show that the curious leathery turtles are the degenerate descendants of ordinary turtles. Baron F. von Huene and Dr. R. S. Lull publish a photograph and sketch of the original specimen of the small Triassic Dinosaur, *Nanosaurus agilis*, showing that it is much less satisfactory than might be supposed from Prof. Marsh's description. Prof. T. D. A. Cockerell and Dr. H. F. Wickham describe many insects and plant-remains from the Miocene of Florissant, Colorado; while Prof. Schuchert himself discusses a series of Silurian fossils from Arisaig, Nova Scotia, carefully collected by Mr. W. H. Twenhofel.

THE "Extracts from Narrative Reports of Officers of the Survey of India," for the season 1907-8, contain an interesting account of precise levelling carried out with the American binocular level. This instrument differs from levels of the ordinary form in several important particulars. It is provided with a second telescope, through which the bubble can be viewed and the scale reading at each end of the bubble observed at the same time as the staff reading is taken. The advantage of this is obvious, as the

change in the position of the observer between the two readings, necessary in the older form of level, is almost certain to cause some shift in the position of the bubble. The staff is graduated on one face only, while the telescope diaphragm carries three horizontal wires instead of the usual single one. The two outside wires are equidistant from the centre one, and in making an observation all three wires are read. The necessity of having a second set of staff graduations on another face with a different zero and in different units is thus obviated, while the three readings form at least as effective a check against errors, and are more rapidly performed than the two required on the older system. The American instrument presents the additional advantage that the interval, as read on the staff, between the wires gives a measure of the distance of the staff from the observer. As an illustration of the precision of which levelling is now capable we may take the Bombay-Madras line. The length of this line is 806 miles, and the closing error was 0.607 foot, or about 1/100 inch per mile. A closely comparable figure could be derived from other lines. Taking another test of precision, viz. the difference in the results of two observers each making a single traverse of the same line, we arrive at a figure of about 1/20 inch per mile.

In our issue of December 23 last we briefly alluded to an interesting paper, by Mr. W. G. Reed, jun., on South American rainfall types, recently read before the Royal Meteorological Society. The author constructed a map of very large size, making use of all published data, and from an inspection of the curves it was seen that (generally speaking) there is a marked division of the rainfall into the following five types:—(1) double maximum, including the region north of the Amazon and west of Dutch Guiana; (2) maximum early in the year, including Guiana and the northern part of Brazil, except the coast region; (3) winter maximum, in the northern coast States of Brazil, also on the west side of the continent south of the equator and west of the Cordillera; (4) summer maximum, extending over central and southern Brazil, Bolivia and Paraguay, and as far south as Buenos Aires; (5) rain at all seasons, embracing the southernmost States of Brazil, Uruguay, south of Buenos Aires, and east of the Cordillera. Small graphs are drawn for stations exhibiting general types of the annual range of rainfall applicable to each of the large divisions. The author also compares his own map of seasonal rainfall with those previously published, preference being given to that by E. L. Voss contained in *Petermann's Mitteilungen*, 1907.

THE University of Wisconsin has issued an account of some instructive experiments on manuring which, while not new in principle, will be of value to agricultural lecturers. The sandy soils of northern Wisconsin are deficient in humus and in nitrogen, both of which could be applied as dung or purchased organic fertilisers. It is, however, much cheaper, and distinctly more effective, to grow a crop of clover on the soil during the previous year, and then to plough it in. The New Mexico Agricultural College has published a bulletin describing the methods of apple culture under irrigation. Apples will grow in a great variety of circumstances, and can be produced in regions lying outside the old apple belt if methods like irrigation are adopted.

THE *Electrician* for June 10 contains a supplement of 160 pages devoted to the applications of electricity to marine work. Already a large proportion of the auxiliary power required on a modern liner or battleship is supplied electrically, but the electrical engineer looks forward to the

near future when electricity will play an important part in the propulsion of vessels. Three possible systems of electro-mechanical propulsion are described in this supplement. In each the prime mover is coupled direct to one or more dynamos, which in turn drive motors on the screw shafts. The great flexibility of the electrical method of transmission makes it possible to vary the speed of the vessel between wide limits without running the machinery at low efficiency. The question of the prime mover of the future is obviously an important one, and several of the writers of the articles expect the oil engine to displace the turbine, just as the turbine has displaced, or rather is displacing, the reciprocating steam engine.

A NEW petrol-electric motor omnibus, constructed by the Daimler Company, is illustrated in the *Engineer* for June 24. Two power units are fitted, one at each side of the frame under the seat line, each capable of developing 12 horse-power. The engines are of the new Daimler type, with crank shafts and frames extended for the dynamotors, by which term is meant an ordinary continuous-current dynamo which is also used as a motor. Each dynamotor is normally rated at 3 kilowatts, but has a give-and-take capacity of three to four times this rating. It is stated that on ordinary greasy roads it is found almost impossible to cause this new omnibus to skid or side-slip to any appreciable degree, and nothing in the nature of a dangerous side-slip has been experienced in 5000 miles' driving. This immunity is attributed to the following factors:—the extreme flexibility of the double-unit system; the better weight distribution obtainable by the construction adopted; the distribution of braking over the front and rear wheels, and the improved methods of braking employed; the improved co-axial pivot steering; and the comparative absence of unsprung weight. The total weight of the vehicle, complete and ready for running, is 3 tons 9 cwt., the regulations allowing 3 tons 10 cwt.

OUR ASTRONOMICAL COLUMN.

METEORITE AT BOMBAY.—Mr. W. F. Denning writes:—"Advices from India mention the fall of a brilliant fireball at Bombay on the afternoon of April 25 last, at 4.15 (standard time). One observer says the meteor flashed out three times in a descent nearly vertical, and the appearance suggested huge drops of fire from a Roman candle. A few minutes later there was a report as loud as one of the harbour guns, only more muffled, and the impression was that a big mine had exploded in the neighbourhood of Khandalla.

"At Lauovli a loud rumbling sound startled the inhabitants, the houses being shaken. Looking upward, people saw a long thin line of smoke rolling from the S.W. to N.E. across the sky. Further reports indicate that the fiery ball shot up from the direction of the sun.

"Other observers at Bombay say that the detonation resembled a blasting operation, heard for many miles around, and lasting nearly a minute. The meteor appeared as a white-hot ball, and it left a long, luminous trail. On striking the surface of the Bombay Harbour it threw up a high column of water with steam.

"At Khandalla a terrific noise was heard proceeding from the direction of Poona.

"It is doubtful whether the object really descended in Bombay Harbour, as one observer says, though it gave that impression, yet it evidently fell far beyond that spot. Directed from the S.E. sky, the radiant was probably in Leo, but the height of the meteor cannot be precisely ascertained from the data available. This is the third brilliant meteor seen in sunshine during the last nine months. Others were reported in England on October 6, 1909, and May 10, 1910.

"The region of Leo seems to be a prominent one for the supply of unusual meteors."

HALLEY'S COMET.—In Circular No. 3 of the Transvaal Observatory Mr. Innes publishes the observations of the tail of Halley's comet recorded by himself, Mr. H. E. Wood, and Mr. W. M. Worssell during May 17-21. Small sketches showing the form of the multiple tail at various times are also reproduced. In addition to the main tail there were two fainter glows separated by some degrees from the main stream near Pegasus, but re-approaching it in the neighbourhood of Aquila. Quite unexpectedly, as recorded by Mr. Payn and other observers, the remnants of the tails persisted in the eastern sky after the comet had passed the earth, and were seen each morning until the moon interfered, after May 21; but it was obvious that they were gradually fading away. On the morning of May 20 the tail was traced to R.A. 19h., dec. 5° S., 150° from the invisible nucleus. In a letter to Mr. Innes, Mr. H. C. Reeve, of Lorentzville, states that at 5 a.m. on May 19 the magnificent main tail extended to the Milky Way, and its attendant shafts were respectively 15° and 20° long, giving the whole the appearance of a huge transparent cone into which the earth was rushing. On the evening of May 19 the whole comet was south of the ecliptic, yet on the morning of May 20 the original, branched tail was still west of the sun and north of the ecliptic.

Mr. Finlay and Prof. Rudge, at Bloemfontein, report having seen a rupture of the tail, near Aquila, take place on the morning of May 18-19, but this was not recorded by any other observers.

Photographs of the comet were taken at the Transvaal Observatory, with the Franklin-Adams star camera, on every possible occasion, and are to be discussed in a subsequent Circular; one of them is reproduced on a plate which accompanies No. 4420 of the *Astronomische Nachrichten*. The chief characteristic of all the photographs is the complicated structure of the tail. Two groups of streamers are seen on either side of the axis, and, in addition, there are several side streamers showing kinks and irregularities; the photographs, in many points, resemble many of those taken of Morehouse's comet in 1908.

The *Astronomische Nachrichten* also contains notes from several Continental observatories generally confirming the results already published.

In the *Comptes rendus* for June 20 (No. 25, p. 1659) M. J. Comas Sola gives a *résumé* of the physical observations of the comet made, visually and photographically, with the 38-cm. refractor of the Fabra Observatory, during the periods of greatest brightness as a morning and as an evening object.

The comet began to be perceptible to the naked eye, at Fabra, on April 15, and the length of the tail whilst near perihelion was about 50 million kilometres (31.2 million miles). There were distinct changes in all parts of the comet after its inferior conjunction with the sun.

Before conjunction the tail was generally bifurcated and made up of numerous long filaments, without knots or sharp bends; M. Sola suggests that this simple straight appearance was the result of the intense repulsive action of the sun while the comet was so near to it. The head was relatively small, although surrounded by very feeble and extensive envelopes; measurements of the photographs generally give 110,000 km. (nearly 70,000 miles) as the diameter of the brightest part. Generally, the envelopes were eccentrically placed in regard to the axis of the tail, a feature which was very marked on May 11. The nucleus was very bright, and its diameter was about 3500 km. (nearly 2200 miles).

After conjunction, the tail was not bifurcated; on May 30 it was like a brush of numerous short hairs, and from May 31 it appeared as an aigrette, which became modified from day to day. The bright part of the head was larger, its diameter being about 160,000 km. (100,000 miles), but the fainter envelopes were reduced. The nucleus at this time was very small, probably not more than 1000 km. (625 miles) in diameter.

Measurements of the photographs of May 30 and 31 indicate that, within two million kilometres of the nucleus, the projected matter travelled at about 23 km. per sec. In a previous note M. Sola referred to projections from the head into the tail, and to the doubling of the nucleus on

June 2; also to the appearance of several rapidly moving condensations on June 4. He now suggests that these appearances were a series of phosphorescent emanations which seemed to commence about May 31, and coincided with the change in the structure of the tail. Not wishing to state definitely the nature of these *ejecta*, he calls them *globes*, and gives some measures of their apparent distances on June 4. Taking a mean, he finds for the velocity with which a *globe* receded from the nucleus, 527 km. per second. All these globes appeared to vanish at a distance of about 25,000 km. from the nucleus.

OBSERVATIONS OF WINNECKE'S COMET (1909d).—In No. 4420 of the *Astronomische Nachrichten* Herr R. Prager gives a number of positions of Winnecke's comet observed with the 24-inch refractor of the Santiago de Chile Observatory between November 2 and December 13, 1909. At all times the comet was very faint, appearing as a circular patch of light 0.7' in diameter, and having no tail or nucleus; after December 13 it was too faint to be seen.

COLOUR OF COMET 1910a DURING ITS PERIHELION PASSAGE.—Observed at the Transvaal Observatory on January 17, the great comet 1910a was near the zenith and therefore practically free from the colour-absorption effects of our atmosphere. Mr. Innes records that, under these conditions, it was identical in colour with, and almost indistinguishable from, the pure snowy-white, alto-cumulus clouds which were passing at the same time (Circular No. 3, p. 21).

THE INTERNATIONAL BOTANICAL CONGRESS AT BRUSSELS.

THERE was a large and representative gathering of botanists in Brussels on the occasion of the International Botanical Congress on May 14-22. The inaugural meeting took place in the large rotunda at the Botanic Gardens, but the serious work of the congress was carried out in the Salle des Fêtes in the grounds of the Exposition. The important subjects of deliberation were further consideration of the rules of systematic nomenclature and a series of propositions on phytogeographical nomenclature. The rules of systematic nomenclature which were drawn up as the result of the deliberations of the Vienna Congress in 1905 left open for future discussion special points in relation to non-vascular cryptogams and palæobotany. A number of sectional committees were appointed, and their recommendations formed the subject of debate at the recent congress. The chief matter for discussion was the starting points for nomenclature in the various groups. Was the date of publication of Linnaeus's "*Species Plantarum*," 1753, which had been adopted as the beginning of nomenclature for seed-plants and ferns, to be the universal starting point throughout the plant kingdom, or would it be preferable to take the date of publication of later systematic works dealing with the various groups of cellular cryptogams?

After some informal discussion among the workers in the groups in question, a series of recommendations was agreed to by the congress. The date 1753 was accepted as the starting point for the Mycetozoa, Algæ (excepting certain groups to be noted below), Characeæ, Sphagnaceæ, Hepaticæ, and Lichens. The exceptions to the general rule for the Algæ were as follows:—Desmids, J. Ralfs, "*British Desmidiæ*," 1848; Oedogoniaceæ, K. E. Hirn, "*Monographie u. Iconographie der Oedogoniaceæ*," 1900; Nostocaceæ, M. Gon'on't, "*Nostocacées homocystées*," 1890, and E. Bornet and Flahault, "*Nostocacées hétérocystées*," 1886-8.

For the Fungi, Fries "*Systema Mycologicum*," 1821-32, was adopted as the point of departure, excepting for the Uredineæ, Ustilagineæ, and Gasteromycetes, which it was agreed should date from Persoon's "*Synopsis*," 1801. For Mosses, Hedwig's "*Species Muscorum*," 1801, was agreed upon. In order to reduce to a minimum changes of names which would result in cases where an early date was adopted as a starting point, special committees were appointed for each of the large groups to draw up lists of *nomina conservanda*, or names of genera which, from long-established use, should be retained, though inadmissible on grounds of strict priority. These lists will be put

before the next congress of 1915; in the meantime, workers are recommended to make as few changes as possible from generally accepted nomenclature. The discussion of a starting point for the nomenclature of Bacteria, and of the Schizophyceæ, excepting the Nostocaceæ, was postponed until the next congress of 1915.

A useful decision was arrived at in connection with the names of pleomorphic fungi, the successive states of which have been described under different names. It was agreed that these should bear one generic and specific name, viz. the earliest given to the state, which it is agreed to call the perfect state, on condition that this name otherwise conforms to the rules. The "perfect state" is that which leads up to the ascus in the Ascomycetes, the basidium in the Basidiomycetes, the teleutospore in the Uredineæ, and the spore in the Ustilagineæ. The addition of figures, including microscopic details, was recommended when describing new genera or species of fungi.

In palæobotany some difficulty has arisen from the use of the same genus name for recent and fossil plants. In order to reduce to a minimum changes of name resulting from this cause, it was agreed to draw up a double list of generic names which are to be retained:—(1) a list of the generic names of living plants, duly published and in general use, which enter into competition with earlier names of fossil genera, such as *Bucklandia*; (2) a similar list of generic names of fossil plants which compete with earlier homonyms of living plants, which have been relegated to synonymy, in order to avoid the future use of such names for the living plant. In the former case the name of the living plant takes precedence, in the latter that of the fossil.

The palæobotanists showed some disinclination to fall into line with workers in descriptive botany generally in making use of a Latin diagnosis when describing new genera or species. It was, however, pointed out that a diagnosis, giving merely the important characters of the fossil in question, was required, and not a complete description; and, further, that such a diagnosis rendered the form in question far more widely intelligible than a description in a vulgar tongue. Those members who were present at Vienna in 1905 called to mind the difficulty experienced when attempting to limit the number and variety of vulgar tongues which should be admissible for the diagnosis of novelties. It was agreed that a Latin diagnosis should be given, with the recommendation to the author to add a full description in a vulgar tongue.

The last matter for discussion was the proposition to add to the list of *nomina conservanda* for seed-plants. The original list, which was agreed to by the Vienna Congress, was admittedly incomplete, but as it had been accepted and used for five years many botanists were disinclined to amend it. A list of additions was proposed which, if accepted, would have upset again changes made since 1905 in conformity with the rules. On the other hand, the new list contained names of large and important genera, such as *Persea*, which could only be retained if included in a list of *nomina conservanda*—on strict grounds of priority they are inadmissible. It was decided to remove from the list those names of genera the inclusion of which would be subversive of changes already made, and with this important alteration the additions to the original list were agreed upon.

Dr. John Briquet, upon whom as Rapporteur-Général has fallen the brunt of the work of the section of systematic nomenclature, was persuaded to continue in office for the next five years until the congress of 1915.

The Vienna Congress had also appointed a commission of eminent plant-geographers to draw up recommendations for phytogeographical nomenclature. The reporters of the commission, Profs. Flahault and Schroeter, drew up a report embodying their own views and those of other workers upon various aspects of the question, and also a series of recommendations based on the consideration of the views and suggestions put forward. These recommendations were accepted by a large majority of the commission, and formed the subject of debate at the congress. It was recognised that the congress should not attempt to pass laws or rules, but merely recommendations supported by reasoned annotations. It became evident, however, that a general agreement on the recommendations as a whole

was not likely to be reached, and the reporters therefore decided to put before the congress only those recommendations upon which there appeared to be substantial agreement. The substance of these was as follows:—

(1) That every author should explain exactly what he understands by the terms he uses.

(2) That the popular names of units of vegetation in the various languages should be retained.

(3) That the principle of priority in phytogeographical terminology is inadmissible.

(4) That a polygot synonymic dictionary of phytogeographical terminology with bibliographical references should be compiled by a special commission.

(5) That the colour scheme suggested by Prof. Engler for maps of tropical vegetation be recommended for adoption.

(6) That ecological phytogeography may be defined as the study of the relationships of plants and plant-communities with their environment.

These recommendations were carried *nem. con.* As regards the somewhat contentious question as to the meaning and definition of the two terms *plant-association* and *plant-formation* which have come into use to designate the most important units of vegetation, Prof. Flahault stated that there appeared to be general agreement in considering the *association* as a unit of definite floristic composition and the *formation* as something different from the association.

Though it has not resulted in the establishment of a uniform system, the work of the commission has been of the greatest use in forcing workers to think about the concepts and terms they employ and in promoting international exchange of views; the promised synonymic dictionary will be invaluable.

An invitation to the congress to meet in London in 1915 was accepted.

At the conclusion of the congress many of the members went on to Berlin to visit the new Royal Botanic Garden and Museum, at the invitation of the director, Prof. Adolf Engler. The spacious new gardens, with the commodious plant-houses, museum, and herbarium, which have been arranged by Dr. Engler at Dahlem, fifteen minutes by rail from Berlin, have replaced the older, smaller, and less convenient institution in the Grunwaldstrasse, Berlin. A special interest attaches to the gardens and museum at Dahlem. Starting *de novo* with the advantage as object-lessons of the great botanical institutions throughout the world, Dr. Engler has organised a garden and museum on thoroughly scientific lines, and embodying the ideas of a great systematist and plant-geographer. It was a great privilege to be conducted through the grounds and buildings by Dr. Engler, with the help of Prof. Urban, the assistant-director, and other members of the staff, and in the glorious summer weather which prevailed at the end of May the gardens showed to the best advantage. The arrangement is strictly scientific and educational, a small space only being devoted to mere ornamental gardening. A large portion is arranged on the lines of plant-geography. Here we find a representation of typical German forest-land and other Central European formations, and, so far as space and climatic conditions permit, illustrations of the vegetation of widely different areas both in the Old and New Worlds. A most striking feature is the Alpine section, or Alpium. Miniature mountain ranges have been thrown up, as far as possible to scale, and formed of the natural stone, and planted with the characteristic species and plant associations of the mountain area in question; an attempt has also been made to indicate altitudinal distribution. The student is thus able to make himself acquainted by an object-lesson, to some extent, at any rate, with the flora of the Swiss Alps, the mountains of the Caucasus, or the Himalayas. Miniature streams and waterfalls add to the effect.

Another section is devoted to biology and morphology, while another forms a systematic teaching collection, with facilities to enable the student to work at the plants on the spot. Medicinal and economic plants have also their section. A great part of the area is devoted to the arboretum, a fine collection, though still young, as work on the gardens was only begun about fourteen years ago. The plant-houses include a fine tropical house illustrating

a tropical landscape, with a wonderful lawn of *Selaginella Kraussiana*, and forming the main feature in a four-sided series of smaller houses devoted especially to aroids, tropical dicotyledons, tropical orchids, other tropical monocotyledons, tropical ferns, various succulents, Cactaceae—these last two forming a particularly fine collection—tropical economic plants, tropical water and marsh plants, Cape plants, subtropical Australian plants, and others; also a large temperature house and numerous culture houses. The museum contains a spacious herbarium and a number of fine exhibition galleries, including sections devoted to biology, systematic botany, palaeobotany, plant-geography, and economic botany, also a section illustrating the products of the various German colonies. In addition there is a large lecture theatre, a laboratory, and a number of work-rooms. The whole forms a magnificent example of botanical organisation and enterprise.

On the following day opportunity was given for visiting the State School of Horticulture and the Biological Institute for Agriculture and Forestry, both adjoining the Botanic Garden.

An interesting and enjoyable meeting closed with a pleasant excursion on the Wannsee to Potsdam, arranged by the Union of Systematists and Plant-geographers. This included a visit to Sans-Souci and the Royal Park and Gardens under the guidance of Director Fintelmann.

A. B. R.

AN ENGLISH PHILOSOPHICAL CONGRESS.

ON Friday and Saturday last, June 24 and 25, joint meetings of the Aristotelian Society, the British Psychological Society, and the Mind Association were held at 22 Albemarle Street, London, at which subjects of wide philosophical and psychological importance were discussed before large and interested audiences. The discussions were based upon papers previously printed and circulated among the members of the several societies. On Friday afternoon the problem of "Instinct and Intelligence" was considered on the basis of papers by Messrs. C. S. Myers, C. Lloyd Morgan, H. Wildon Carr, G. F. Stout, and Wm. McDougall; Saturday morning was devoted to the discussion of the question, "Are Secondary Qualities Independent of Perception?" on the basis of papers by Messrs. T. Percy Nunn and F. C. S. Schiller; and the congress was brought to a close on Saturday afternoon with papers on the nature and development of attention, by Mr. G. Dawes Hicks; the "faculty" doctrine: outline of some experiments on school children in relation to this doctrine, by Mr. W. H. Winch; and some observations on the aesthetic appreciation of colour combinations, by Mr. E. Bullough.

I.—Instinct and Intelligence.

Dr. C. S. Myers maintained the view that instinct and intelligence are inseparable in all forms of mental activity, animal and human alike; that they are respectively the objective and subjective aspects of the same thing, viz. mental process in general and in its various particular manifestations; and that instinctive behaviour, while characterised by mechanism in its objective aspect, is from the point of view of the experiencing subject characterised by finalism. He criticised the two assumptions commonly made with regard to instinct as a form of mental process distinct from intelligence, viz. that in instinctive behaviour as such there is no awareness in the individual's consciousness of the end to be achieved, and that such behaviour is fixed and from the beginning perfect. He pointed out that an instinct is to be distinguished from a mere reflex or chain of reflexes by (1) a feeling of activity, and (2) a vague awareness of the result of the instinctive action before the action is actually performed, both characteristics being present in the very first manifestation of the instinct. These rudiments of conation and meaning are essential constituents of any activity deserving the characterisation "instinctive." Observations of instinctive activities in insects and other animals do not justify the view that such activities are "perfect the very first time," or that they

exhibit undeviating uniformity; "even ants are capable of learning from their elders," and this power is generally regarded as a sign of intelligence. The common view that man has few instincts compared with the lower animals is partly accountable for by the fact that "he is never aware that he is acting instinctively." His inner or subjective acquaintance with those activities pronounces them to be of the nature of intelligence.

Lastly, from the more general points of view of evolution and philosophy, the finalistic interpretation of the evolution of mind, and indeed of the entire universe, is the necessary complement and essential correlative of the mechanical interpretation, if our thought is to be saved from that pure abstraction—purposeless mechanism.

In conclusion, neither are instincts identifiable with reflexes, nor do they form a third class in addition to those of reflexes and intelligence. Summing up in Dr. Myers's own words:—"According to my view and my use of the words, instinct regarded from within becomes intelligence; intelligence regarded from without becomes instinct."

Prof. Lloyd Morgan agreed with Dr. Myers so far as to admit that the two factors, instinct and intelligence, "are present in the most intimate relationship throughout very nearly the whole range of animal behaviour as exhibited by those organisms in which the central nervous system has reached a sufficiently high level of development and differentiation to justify the use of the words 'instinctive' and 'intelligent.'" In his view, "the instinctive factors depend entirely on how the nervous system has been built up through heredity under that mode of racial preparation which we call evolution; intelligent behaviour depends also on how the nervous system has been modified and moulded in the course of that individual preparation which we call the acquisition of experience." (Dr. Myers suggested in the course of the discussion that this was genetic rather than psychological analysis.)

Prof. Lloyd Morgan illustrated his views by means of a somewhat detailed account of the experience of a young moorhen chick, and gave as a brief definition of instinctive behaviour, behaviour which is "practically serviceable on the occasion of its first performance," thus including within its scope reflex action so far as this is accompanied by consciousness. He also referred to the behaviour of the Yucca moth, and to the stinging of prey by the solitary wasps, as instances of instincts performed once only in the lifetime of the individual, where learning by imitation, &c., was impossible. He considered that the element of intelligence supervened in originally instinctive behaviour by the introduction of "meaning" through "factors of revival," though he emphasised the fact that "this is every whit as much the outcome of the innate potentiality of the moorhen as the originally instinctive performance." If instinct be identified with innate potentiality, all intelligent behaviour involves an instinctive element.

Mr. H. Wildon Carr considered the problem from the philosophical standpoint, and gave a detailed exposition of Bergson's views, which he supported by arguments for the most part metaphysical. He refused to identify natural dispositions or tendencies with instinct, and for this reason found himself unable to agree with Dr. Myers's view. He emphasised the contrast between the very complicated instinctive activities of ants, bees, &c., many of which cannot by any possibility have been learnt by individual experience, and the more pronounced cases of intelligence in man, and, reminding his audience that "instinct and intelligence are not observable facts, but interpretations," proceeded to show how the two terms represent two distinct lines of evolution of animal life, along each of which there is to be found no tendency towards evolution in the direction of the other. Along one, instinct evolves at the expense of intelligence; along the other, intelligence evolves at the expense of instinct. "The fundamental difference is one of kind, and lies in the mode of apprehension of reality, and the kind of knowledge that serves the activity of each. It is this essential difference that accounts for the degree of consciousness or unconsciousness, plasticity or fixity that characterises each, and not *vice versa*. . . . It is not a scientific but a metaphysical distinction, which rests on a criticism of the nature and limitations of intel-

lectual and instinctive knowledge." Intelligence is a knowledge of the relations of things, instinct is a direct insight into their inner nature. Bergson has employed the word "sympathy," in its technical sense, to represent this kind of knowledge. In Mr. Carr's view, mechanism and finalism are mutual contradictions, resulting from the limitations of merely intellectual knowledge.

Prof. G. F. Stout agreed with Dr. Myers, as against Prof. Lloyd Morgan, that every instinctive action as such is determined by intelligence, for the reason that the very first performance of an instinctive action involves intelligence. Adopting provisionally Prof. Morgan's own criterion of intelligence as "learning by experience," he showed that the learning must take place on the first occasion and not on the second (where the second is the presentation of a situation similar to that of the first, but to which the animal reacts in a different way owing to its previous experience). "On the second occasion the lesson is utilised; but in order to be utilised it must already have been learned." Unless there is mental reference beyond the immediate present there can be no intelligence, but such reference cannot be furnished by mere revival of past experience itself lacking reference. Conation, or the felt tendency towards an end, which, equally with the cognitive aspect, is present in the first performance of an instinctive act, forms the basis of attention and initiative which contributes to the "future reference" above-mentioned, and also definitely marks off instinctive action from merely reflex action.

Prof. Stout rejected Mr. Carr's view that instinct is a peculiar way of knowing, distinct from intelligence, his reason being that he could "find nothing in the instinctive behaviour of animals which cannot be accounted for by the combination of certain purely biological adaptations with psychical processes marked by intelligence fundamentally akin in nature to all other intelligence." He sided with Prof. Morgan against Dr. Myers in thinking that use of the term instinct should not be extended to cover all cases of inherited nervous organisation conditioning the development of intelligence, but that the word should be used "to mark off a distinct kind of connate endowment," viz. congenitally definite modes of behaviour; but he supplemented Prof. Morgan's criterion of definiteness (definite enough to be "practically serviceable on the occasion of its first performance") by saying that the congenital definiteness referred to was "a definiteness such as would require to be explained as the result of learning by experience or conscious contrivance, if it were not directly provided for by inherited constitution of the nervous system, as determined by the course of biological development." What non-instinctive congenital endowment provides for is "a special capacity for acquiring skill and knowledge," itself dependent on interest and retentiveness. It is marked endowment in this direction which distinguishes genius from ordinary ability.

In Stout's view, instinct "is mainly confined to animal life, and in the life of animals it has a two-fold function. On the one hand, it is a substitute for learning by experience. On the other, it has an educative value as a condition of learning by experience; it has this value inasmuch as it provides an animal with the experiences which are useful to it, and thus enables it to learn just what it requires to learn. In the case of human beings, this function of instinct is, in the main, superseded by instruction. All that either instinct or instruction can do is to supply appropriate experiences. How this material will be utilised depends on other factors."

Mr. William McDougall found himself for the most part in close agreement with Dr. Myers and Prof. Stout. He regarded instinctive processes and intelligent processes as of essentially similar nature, as involving the same fundamental modes of mental activity, but considered that "we can properly and usefully distinguish between mental processes that are conditioned wholly or mainly by innate dispositions on the one hand, and on the other hand such as are conditioned by dispositions that have been largely built up through the experience of the individual," and that "the words instinctive and intelligent may properly be used to mark this distinction." He objected to Stout's use of the designation intelligent for every process which is capable of producing modification of innately determined

modes of behaviour, even when such modification is not, as a fact, brought about. Intelligence is only operative when a modification is effected. Thus the Yucca moth, laying its eggs in the Yucca flower on a single occasion in its life, may be said to perform an act which is purely instinctive, having no admixture of intelligence. Prof. Bergson's view of instinct, presented by Mr. Carr, is not supported by the facts. The work of Dr. and Mrs. Peckham on solitary wasps has shown that instinctive activities are far from being perfect and invariable in nature, and that they may be combined with a (seemingly) high degree of intelligence. In *Ammophila* the capacity for acquiring and acting upon detailed knowledge of locality is found developed to an extraordinary degree. This development of intellect is all the more remarkable when we consider at what a disadvantage the higher insects are placed compared with the higher mammals in being deprived of all the advantages for training of the intelligence given by a period of youth (play, &c.).

Bergson's use of the term sympathy does not seem very appropriate or helpful in many actual cases of instinctive activity, e.g. that of the paralysing wasp.

Lloyd Morgan's view that the strictly mechanical interpretation of natural processes is the only one permissible to science forces him to the identification of instinctive action with compound reflex action, and causes him to ignore the extremely important conative character exhibited by the process.

The criterion of being "practically serviceable on the occasion of its first performance" is not sufficient to mark off instinctive activity from reflex action on the one hand, and from intelligent behaviour on the other.

The small part assigned by most psychologists to instincts in the development and functioning of the human mind is surprising and difficult to understand. Especially is this the case with regard to Prof. Stout's system of psychology, and its explanation would seem to be that Stout limits the application of the term instinct to forms of mental process expressed through innately coordinated motor mechanisms. "Now all our mental processes manifest themselves through the agency of preformed motor coordinations, innate or acquired. For Stout, then, as for me (McDougall), instinctive process can be marked off from other modes of behaviour only by reference to the origin of some part of its conditioning factors in the innate constitution of the organism. For Stout the innate factors by which it is marked off are the motor mechanisms only by which the mental process manifests itself in bodily movement; for me they are also and chiefly the innate disposition by which the whole instinctive mental process is conditioned." The specific conative tendency exhibited by each instinctive process is a far more important and characteristic feature of the process than the operation of innate motor coordinations. The only reason why Stout selects the latter rather than the former as the differentia of instinctive process is "because the more essential feature, the specific conative tendency, continues to reveal itself at all levels of mental development and throughout the life of the human mind, while the innate motor factor comes clearly into view only in instinctive processes that are relatively pure."

Another characteristic of purely instinctive activity which Stout has failed to note is the existence of an unmodified innate perceptual disposition which conditions the perception evoking the instinctive reaction. Such innate perceptual dispositions continue to be active in the adult human mind, though undoubtedly modified and differentiated through experience.

McDougall summarised his view of instinct as follows:—"A typical example of a purely instinctive action implies the existence in the creature's innate constitution of, first, a specialised perceptual disposition; secondly, a specific conative tendency that is excited when this perceptual disposition is played upon by the appropriate sense-impression; and, thirdly, some coordinated system of motor channels through which the conative tendency works towards its satisfaction. The three things belong together; each implies the other two; each can subserve the life of the organism or of the species only in conjunction with the other two; all three together constitute a functional unit which is transmitted as such from generation to

generation; and to such a functional unit of the innate constitution only, and to no part of it alone, and to no other fact or feature of the organic world, can, I submit, the name instinct be properly applied."

II.—Are Secondary Qualities Independent of Perception?

Dr. T. Percy Nunn maintained in his paper " (1) that both primary and secondary qualities of material bodies 'are really in them, whether anyone's senses perceive them or no'; (2) that they exist as they are perceived; and (3) that sensations, as mental entities exercising a representative function, need not, therefore, be postulated." He attacked the view that there are elements in experience (e.g. tooth-ache) whose being consists "only in being experienced," and these are therefore psychical in nature, showing how the (false) belief in their psychical nature arose. In place of this view he advocated a form of the theory of realism which he considered to be more consonant with the facts of science and immediate experience, and which involved the theses above-mentioned. He devoted much space to the consideration of the problems of error and illusion as they appeared from this point of view.

Dr. F. C. S. Schiller criticised Dr. Nunn's theory of realism from the point of view of pragmatism, and endeavoured to show that all his arguments were based upon pragmatist postulates. He also considered critically the senses in which the words *independent*, *extramental*, *reality*, had been used in the paper, and to what extent the theory advocated could be regarded as a metaphysical one.

III.—Psychological Papers.

Prof. G. Dawes Hicks criticised the views of attention which made it either, on the one hand, "a unique faculty" or "mode of mental energy" having presentations for its objects, or, on the other hand, a property of the presentations themselves regarded as independent and interacting with one another. He advocated the treatment of the problem of attention from the genetic point of view, and urged that the attempt should be made to form some conception of the conditions under which attention became possible in the primitive mind. After a consideration of the various factors influencing the attention process, such as feeling-tone, intensity of stimulus, &c., he traced the gradual growth of voluntary attention and indicated the relation of attention to willing and to the consciousness of self.

Mr. W. H. Winch discussed the value of the "faculty doctrine" in the light of experimental results obtained in the investigation of different forms of memory, accuracy, &c. The results of investigations into the transfer of practice effects, in which the method of "equal groups" was employed, were given, and were shown to prove slight transfer in the domain of memory, but none in that of accuracy, the improvement in the allied function being so small, even in the former case, compared with the improvement in the medium of training itself, as to make the balance of evidence against the "faculty doctrine."

Mr. E. Bullough described a series of observations made on a large number of individuals as to their preferences for colours, when seen in pairs, and the reasons given by the subjects themselves for such preferences. The two methods of (A) appreciation and (B) production were employed, and the material used was coloured silks. The subjects were found to belong to the following "perceptive types":—(a) objective type; (b) "physiological" type; (c) "character" type; (d) associative type. Definite relations were shown to exist between these perceptive types and the various criteria of preference or rejection of pairs of colours, such as "balance," "unification and dissociation," "consonance and dissonance," &c.

The societies dined together at the Criterion Restaurant on Friday evening, Prof. W. R. Sorley being in the chair. In the course of the after-dinner speeches the important suggestion was made by Prof. S. Alexander, and accepted with acclamation by the company, that the Aristotelian Society should strive to become the representative society of English philosophers, much as the Chemical Society, the Physical Society, &c., represent English science in those subjects.

WILLIAM BROWN.

THE MOTION OF THE MOON.

THE *American Journal of Science* for June contains an interesting article in which Prof. E. W. Brown discusses possible causes for the want of agreement between the moon's observed motion and theory. In his second section Prof. Brown gives a summary of these outstanding discordances:—(1) a secular acceleration $2''$ greater than that due to the change of the eccentricity of the earth's orbit round the sun; (2) a term of 300 years' period and coefficient $15''$; (3) a term of 60 years' period and coefficient $2''$.

The secular acceleration is usually ascribed to tidal friction. Prof. Brown considers certain hypotheses as to the origin of the three-hundred-year term. He takes no further notice of the sixty-year term. It is quite possible, however, that the secret will be ultimately revealed by the term of shorter period, for if we assume that the forces required for the two terms vary as the coefficients and inversely as the square of the periods, it appears that the force required for the smaller term is the larger; moreover, the period of the sixty-year term is already known with a smaller percentage of error, and the next few years' observations will accentuate this consideration in its favour.

The fourth section of the paper lays down the fundamental rule which controls this detective problem. Any hypothetical cause must be dismissed from consideration that would produce a motion in either perigee or node above thirty seconds of arc in a century. Here Prof. Brown is at least as cautious as there is any need to be; he might have said fifteen seconds instead of thirty.

The sixth section dismisses from consideration the figure of Jupiter, the cumulative effect of the asteroids, and light pressure. Imperfections in the calculated theory seem to Prof. Brown inconceivable, and those who have followed his work will agree with him.

The seventh section raises the hypothesis of an equatorial ellipticity in the sun's figure. There is no direct evidence of such an ellipticity, and, moreover, it becomes necessary to assume that the period of rotation of the sun must be of a length that can be specified to its hundred-thousandth part. It is true that this period lies between the extreme values that have been determined from observation of the photosphere, and these values differ by six parts in a thousand; but it is clearly a large assumption to take 1.00000 (five zeroes) as the true value of a quantity of which all we are entitled to say is that it probably lies between 1 ± 0.003 .

The eighth section deals with magnetic hypotheses. The discordance between theory and observation in the moon's motion is not due to the secular motion of the magnetic axis of the earth, but it is possible to frame hypotheses as to the moon's magnetism that cannot be dismissed as impossible.

The conclusions of the ninth section, dealing with the moon's libration, are very similar in character to those of the preceding section. Some hypotheses can be ruled out, for they involve librations that would have been already detected by observation, but other hypotheses remain tenable for the present, in particular a long-period libration of fifty seconds.

THE TRAINING OF ENGINEERS IN FRANCE.¹

IN a lecture published in the *Revue générale des Sciences* for April, M. André Pelletan compares the training of engineers in France with the similar training given in the United States, England, and Germany. He devotes himself more particularly to the courses of study provided for those intended to occupy the highest engineering posts.

In so far as the lecture deals with the courses elsewhere than in France, there is, naturally, little that is new in his paper, but his statement in regard to the training given in the *Ecole polytechnique* will cause surprise to those not well acquainted with the work of that important institution.

It appears that students enter about the age of seventeen, as soon as they have passed the French equivalent for an English matriculation examination (the *baccalauréat*).

¹ "La Formation des Ingénieurs en France et à l'Etranger." By André Pelletan.

They then commence the preparatory course, which occupies, on the average, not less than three sessions, for, although 22 per cent. of the students complete preparatory courses in two sessions, 45 per cent. take three sessions, 27 per cent. four sessions, and 4 per cent. five sessions. This preparatory course comprises mathematics, chemistry, mechanics, and physics, as well as modern languages; it extends over about seven months in each year, and the course is repeated year by year. M. Pelletan thinks that to make a student follow the same course for an average of three years must frequently tend to make him rather stupid. According to him, the course in mathematics is much too theoretical in its character; the students spend too much time on analytical geometry; they deal too much with abstractions and too little with problems involving realities and actual numbers; as a result, their attempts to apply the mathematics they have learned lead to results, not only false, but actually absurd.

When the student has completed his preparatory course he spends two years on the more advanced courses, making a total of five years' study. A very large part of his time is devoted to higher mathematics, as is shown by the fact that about 36 per cent. of the marks awarded for purposes of classification are given to this subject, while mechanics and machinery receive about 26 per cent., physics about 21 per cent., chemistry about 20 per cent., astronomy (!) about 9 per cent., architecture about 2 per cent., history and literature about 4 per cent., German about 4 per cent., drawing about 5 per cent., and military subjects about 5 per cent. According to M. Pelletan, a large part of the mathematical course is simply a repetition of the work done before.

The amount of time spent on practical work is absurdly small; none is mentioned in the case of mechanics and machinery; only six lessons are given in physics and eleven in chemistry; on the other hand, the physical welfare of the students is treated more seriously, for they receive eighty lessons in horsemanship, sixty-four in gymnastics, forty in fencing, and sixteen in boxing.

Students are allowed little liberty; they are under military discipline, have little leisure, and are required to spend a considerable time in drill, &c.

According to M. Pelletan, the result of this is that the most mediocre students, provided they are gifted with a good memory, come out first in the list and receive the best positions; in all that concerns "red tape" they are perfect, but they lack initiative, for they have never been allowed to think or do for themselves.

It is not for a foreigner to criticise French methods, many of which, as the writer well knows, are admirable, but if the premier engineering school of France is conducted on the principles set forth in this paper, there is certainly ample room for that reform which the author demands. The present writer has ventured to suggest to the director of the Ecole polytechnique that a reply should be made to this indictment of his institution.

J. WERTHEIMER.

REFRIGERATION.¹

A SHORT account of the first International Congress on Refrigeration appeared in NATURE of October 2, 1908, and served to indicate the important position which refrigeration has taken in the fields of technics and commerce.

The bulky volumes before us, in which communications appear in their original French, English, German, or Italian, fully confirm that view. The subjects discussed range from magneto-optic investigations on liquid hydrogen, through the preparation of cooling agents to the law of the transport of chilled food; from the use of liquid air in mining to its use for increasing the efflorescence of bulbs.

These 200 communications vary very much in character. Some are *résumés* of well-known work at low temperatures, others compilations by authors who appear to have been ignorant of the work of others in the field, and to have thought it necessary to fill their papers with elementary transcriptions from text-books.

¹ Premier Congrès international du Froid, Paris, Octobre 5-12, 1908. Tome I., Comptes rendus, pp. iv+700. Tomes II. and III., Rapports et Communications. Vol. II., pp. iv+1009+ii; Vol. III., pp. iv+653+ii; illustrated. (Paris: Secrétariat-Général de l'Association du Froid; London: 3 Oxford Court, Cannon Street, n.d.) Price, 3 vols., 25s.

The vast majority, however, are new and valuable additions to the subject. Many are the results of prolonged and careful experimental research on questions such as the industrial separation of oxygen and nitrogen from the air, the specific heat of certain salt solutions, the conductivity of insulators under experimental and under practical conditions, and both relatively and absolutely. Naturally much attention was paid to the preservation of food of all kinds, both on land and at sea. In this connection the particularly complete investigations from America on the physiological effect of cold storage for varying times and at varying temperatures on poultry are specially noticeable. This paper is accompanied by really beautiful photographs of sections, and quite disposes of the notion that cold storage has any bad effect on nutritive values if maintained at the proper temperature and followed by careful thawing in dry air. Many other communications discuss the same question less exhaustively with regard to other food materials. In this connection it is noticeable that, on the whole, the standard of the English papers was below that reached by those from the other great countries. Happily, this defect was to a large extent made up by the colonial communications; but this does not fully atone for the want of any official notice of the congress by the Boards of Trade and Agriculture. The difference is particularly marked with reference to America, and is only an indication of the want of interest these departments take in the fields which they are supposed to represent. Another question which appears in several communications in various forms is that of suitable units for the refrigerating industry. It is extremely desirable that some agreement should be arrived at which would be internationally acceptable. As a result of these deliberations an international bureau has been formed, which has come to some agreement, and which will submit recommendations to the next congress at Vienna in October, 1910.

FRANCIS HYNDMAN.

UNIVERSITIES AND TECHNICAL TRAINING.¹

PERHAPS the most noteworthy educational event of modern times was the origin and development of the Universities of Berlin and Bonn. After the Battle of Jena and the humiliating Treaty of Tilsit, after the closing of the University of Halle by Napoleon, at a time when Prussia had sunk under the heel of Bonaparte to the rank of scarcely a third-rate Power, the King, influenced chiefly by the brothers Wilhelm and Alexander von Humboldt, determined to look to higher education as a means of retrieving his country's fortunes. Such was, and still is, the faith across the Rhine in the practical value of education to the State. Napoleon got his Treaty of Tilsit, but there were men by the side of the Prussian King with great ideas, men who with stern and far-seeing determination forged weapons which, during the hundred years which have passed since then, in the field, in the laboratory, and in the Seminar, have made Prussia, have made Germany, what they are to-day.

The mediæval university as it developed in England held residence, in the sense of actual living together in seclusion, as an essential condition of study. The modern university, following the almost universal practice, required residence indeed, but residence only in the sense of working and thinking together, in science in the laboratory, in literature and philosophy in the Seminar. The faculties of the mediæval university were retained—theology, law, medicine, and philosophy—music and other technical subjects were left outside to the care of special schools. The mediæval university, as we have seen, had behind it the accumulated prestige of centuries; the modern university had no such individual advantage; it built upon the common educational history of mankind, and adapted itself with the greatest freedom to the requirements of the time. There is much wisdom in the saying that a university is born old. The mediæval university was a centre of dogmatic teaching; research, if not explicitly discouraged, was practically discouraged by the fact that general culture, the training of the judgment, was aimed at, not specialised learning; a recent Cambridge writer puts the object as "not how to keep our trade, but how to keep our souls

¹ From a lecture delivered before the Royal Dublin Society on March 9 by Prof. A. Senior.

alive." The modern university broke away from this entirely, its ideal being research, with absolute freedom. Paulsen, in his well-known work on "German Education," says:—"Scientific research cannot possibly be regulated by decrees of the ruling powers, but can only thrive in full liberty: to find aims and objects, means and ways of speculation and research, must be left to individual initiative." The teaching of sufficient preparatory knowledge, chiefly in languages and mathematics, was left to the secondary schools, these having long attained to a very high degree of efficiency in Germany. Thus the modern university became a research university, the object of study, according to Paulsen, being "the ability to think scientifically, that is to say, the ability to comprehend and test scientific researches, and to conduct them; and in the second place, to solve practical problems on the basis of scientific knowledge." This ideal, which includes both the pursuit of pure science and its technical applications, was realised to the greatest degree in the philosophical faculty. The results were sometimes great and sometimes small, but were always honest attempts to do something toward the advancement of knowledge.

To be successful in research it is necessary to confine the attention to special departments of the subject of study, to specialise, and to become acquainted, at first hand, with the work of previous investigators, their difficulties and failures, as well as their final results, obtained in the original records published in the scientific journals of their respective countries—not from inhuman text-books or mechanical indexes. Every large research laboratory consists of a little army of specialists who consult one another in the subjects in which each has special knowledge, just as in ordinary life one consults the physician, the lawyer, or the engineer. Next, success depends largely on imaginative capacity. This should be strengthened by every available means. Many find strength in poetry, fairy-tales, the Arabian Nights, in music—for by the scientific method, conjectures, hypotheses, have to be invented, to be subjected to rigorous experimental or other testing, and to be abandoned, modified, or established as they are found to conform, or not to conform, to nature. Again, everything should be done to awaken and to cultivate natural curiosity respecting the unknown: the leader, the teacher, should never miss an opportunity to direct attention to possible new developments. Prof. Appell, of the Sorbonne, recently defining a man of science, said he did not mean "the man who knows," but the man who "combines with his knowledge scientific activity, that is to say, a curiosity always alert, indefatigable patience, and, above all, initiative and again initiative."

In the foregoing paragraphs I have endeavoured to indicate the conditions essential to the success of research, to the success of a research university—conditions from without, contributed by the community, by the State, a suitable environment; and conditions from within, properly trained leaders and students to follow them, afterwards to carry on the leadership. Thus, as to the first condition, Wilhelm von Humboldt in a State paper, in 1810, says:—"The State should not treat the universities as if they were higher classical schools or schools of special sciences. On the whole, the State should not look to them at all for anything that directly concerns its own interests, but should rather cherish a conviction that, in fulfilling their real destination, they will not only serve its own purposes, but serve them on an infinitely higher plane, commanding a much wider field of operation, and affording room to set in motion much more efficient springs and forces than are at the disposal of the State itself." As to the second condition, in the selection of leaders, of professors, Paulsen tells us that "proficiency in some branch of scientific research was regarded from the first as the principal requirement, aptitude for teaching coming into consideration only in the second place, although it would be more correct to say it was taken for granted that a prominent scholar who had distinguished himself in scientific research was always likely to make the best and—in the last and highest resort—the most efficient teacher." Professors and students gathered in the Prussian capital, the work of the laboratories and the *Seminare* began—men like Fichte, Schleiermacher, and Wolf; Mitscherlich and Rose; later, Hegel, Böckh, the brothers Grimm, Scherer, Bopp,

Niebuhr, Ranke, Savigny, and Eichhorn; Mommsen, Virchow, Helmholtz, and Hofmann, and so many others, did therein their life's work. The work of these men, their glorious example, is felt to-day, either directly or through their students, throughout the world of learning. There is scarcely a university or college now in existence in which, not one, but many workers look back directly or indirectly to Friedrich Wilhelm's university in Berlin with gratitude and with affection.

To trace the effects of the research university, which after Berlin and Bonn became universal throughout German countries, though of absorbing interest, cannot be undertaken here, even in outline; but the result in two directions must not be passed over altogether—first, the effect of habits of research on our general views of education; and, secondly, the extraordinary rise of chemistry in the nineteenth century, directly ascribable to it. As to the first point, it has gradually come to be recognised that work in research has an educational value to the worker, quite apart from its value in other respects, as awakening and strengthening what is noblest and of greatest utility in man, which places it at least on an equality with the older studies peculiar to the mediæval university. The thoughtful student can hardly enter a research laboratory without feeling that he is entering a place sacred to the wondrous mysteries of nature—a place where, when he has attained the requisite knowledge and dexterity, he will be permitted to put questions to nature, and, it may be, see something of those mysteries revealed. An explorer famous for his achievements will take him by the hand, and will in the friendliest manner direct him, will tell him what to do and where to go. He will lead him at first along some short and well-worn paths; he will then allow him to venture on longer ones, but still worn with footsteps, which he will recognise as those of former students, who subsequently became great explorers; then little by little he will be encouraged to go out alone into paths less known, until in time he will wish to push on, to extend his wanderings into unknown regions, a little at first, but afterwards more and more, to seek his own way, into regions of wondrous and, to his imagination, of unlimited possibilities; and the reception by the old explorer and the others, on his return, is a pleasure so exquisite that it exceeds any possible description. In most of this wandering he is associated with his fellow-explorers, who have like aims and like aspirations—men whom to know and to work with is the highest form of education.

The second point to which I wish to allude, as a direct result of the establishment of research universities, is the great development of the science of chemistry during the last century. Just before and about the beginning of the century there were three centres of notable activity in chemistry; one was in England, another in France, and the third in Sweden. The work of these served to lay the foundations of the science: in England, by Priestley, Black, Cavendish, Dalton, and Davy; in France, by Lavoisier, Berthelot, and Gay-Lussac; in Sweden, by Bergmann, Scheele, and Berzelius. With some important exceptions, the work of these chemists was isolated; they did not train students or found schools of after-workers; they owed little, almost nothing, to universities—the research university had not arisen. But the exceptional students were indeed important—men of genius who in any circumstances would have forced their way: Faraday, the student of Davy; Wöhler, the student of Berzelius; and Dumas, and, above all, Liebig, the students of Gay-Lussac. Dumas in Paris and Faraday in London worked practically by themselves, and their great discoveries were well known: they were generals of the highest genius, but without an army; but it was reserved for Liebig, and his great collaborator Wöhler, who both returned to Germany, there, with the splendid environment of the new research universities, to be instrumental in founding organic chemistry, and raising the science generally to the high position it attained. A further example of the indebtedness of the world to the brothers von Humboldt is the interesting fact that Alexander von Humboldt was the discoverer of both the French Dumas and the German Liebig: his influence it was that induced Dumas to leave the apothecary's shop in Geneva to go to Paris to Gay-Lussac; and it was by his interest, too, that the German

student Liebig was brought to the notice of the great Frenchman. At Giessen Liebig founded the first chemical laboratory—indeed, the first science laboratory—open regularly to students; there, and afterwards at Munich, he conducted his great researches, and trained the research students who continued his work, and who themselves or their successors still continue it in all countries. Without the research university all this would have been impossible.

A few words must be devoted to Napoleon's experiment in founding a university centralised in Paris, and doing no teaching or research of any kind. One of the effects of the Revolution was the abolition in 1793 by the Convention of the ancient universities of France. The effect on education was disastrous. To remedy this, Napoleon, in 1806 and 1808, determined to establish an examination university for the whole of France; and this university, once established, continued until our own time, and has only recently been abandoned in favour of the German type. The University of London, founded in 1825, was of the Napoleonic type, for well-known reasons; and the Royal University of Ireland followed on the same lines. All this has now happily been changed, in Paris, in London, and in Dublin; and they must be few who would urge to-day that education by examination can lead to anything but failure to literature, to science, or to the State.

Realising with Carlyle that "the end of man is an action, not a thought," the research university has always recognised that the end of learning is not itself, but the benefit that it confers on its own votaries and on mankind. Thus Liebig was alert to the applications of his scientific discoveries and to the possession on the part of his students of the special talent necessary, the aptitude, for making such applications efficiently. Liebig's first inquiry, on fulminates, led to the modern manufacture of those substances and generally to the explosives industry. Similarly other researches either originated or improved almost every industry of the last century into which chemistry enters. His concern throughout his life for the requirements of medicine, of agriculture, of our food supply, and the enormous advances to which his discoveries led, need not be recapitulated. Hofmann himself, who perhaps more than any of Liebig's students realised his master's ideal, and became, after Liebig, the greatest scientific teacher of his day, came to England in 1845 to take charge of the newly founded Royal College of Chemistry. For twenty years he worked in London with well-known results to science and manufactures and to the training of research chemists and teachers. It was the time of the Great Exhibition, and it seemed as if chemistry was transferred to England. But the environment was not congenial. We had no research universities. Humboldt's universities were too great an attraction. Palaces for research were built for him, first at Bonn and finally at Berlin; and, naturally, the great research teacher re-crossed the Rhine. The industries which otherwise might have been ours followed him, and, directly or indirectly, the great rise of chemical industries in Germany, of which we hear so much at the present day, is to be ascribed largely to the work of this wonderful man and the surroundings of the research university. Hofmann continued the practice of Liebig in entrusting to those of his students who gave evidence of having the requisite capacity the application of his scientific discoveries. At least one of the large colour works in Germany was thus indirectly connected with the university laboratories in Berlin. This was a labour of love on the part of his students; but it led eventually to the enrichment alike of master and pupil, to a degree that professors in these lands can only envy. Thus the research university, splendid as were its achievements in pure science, never lost touch with technology; and there can be no question that this was to the advantage of science itself, quickening it by contact with the concrete conditions of real life, and justifying it by a worthy object.

But it gradually became apparent that there was an important field of research between the discoveries of pure science and their actual use in manufacturing processes. This was recognised as a field of work somewhat different in its point of view from that of pure science, but, like

the latter, requiring the highest degree of knowledge and skill. It has been conveniently termed technical research. For example, there are many more coloured compounds known than dyes; but some of these might be converted into dyes if the requisite conditions could be discovered by which changes could be effected in their molecular structure in accordance with well-known laws. Again, the synthetic formation of indigo, of the structure which chemists imagine to represent its molecule, though long known as a laboratory experiment, was until recently economically impossible as a manufacturing operation. To overcome this difficulty, with a faith akin to that of the Humboldts in the success of their universities, one of the large industrial undertakings in Germany set to work with its little army of technical research chemists, and after years of patient labour, and the expenditure of three-quarters of a million sterling, the reward has been success. The demand for this technical research work has grown in Germany as it has in no other country. The large industrial undertakings have their own laboratories devoted to it, and, in addition, the practice has become general of retaining, at substantial salaries, the interest of the university professors, for the advantage of particular manufacturers. German professors of chemistry are now princes indeed compared with their position in the time of Liebig. But all this has not been sufficient to meet the demand for technical research work and for trained workers; and there has arisen a new class of high school, the technical research university, of which that at Charlottenburg may be taken as a type. These new institutions, by the standard required for entrance, and by the quality of the work they do, are entitled to take, and do take, rank equal to the university, and they confer a doctorate in engineering.

We have now considered four types of institutions for the advancement and diffusion of learning and of its applications to society—institutions of acknowledged university rank: of the mediæval or residential college university, exemplified by Oxford; the research university, as seen at Berlin; the examination university, first known in Napoleon's University of Paris; and the technical research university, as seen at Charlottenburg. In England, where numerous new universities have been established in recent years, the type adopted has been a combination of the German research university and the German technical research university, the one or the other type predominating according to local needs, and the whole adapted to its surroundings, particularly to the conditions of secondary education. Whatever view may be held respecting the German practice of separating these two types, as adapted to German conditions, it will, I think, be generally agreed that, for the conditions which prevail in these islands, the combination of the two in the new universities is a wise arrangement. Our two new universities in Ireland are also of this combined type, and are to be adapted to Irish educational conditions and the needs of the country.

Two advantages the German university has which are not found in this country: the one is the *Seminar*, the other the coordination between the secondary school and the university, which relieves the university of all work except research and preparation for research. In science the influence of Liebig, through his students, was so great that science laboratories, after the model of Giessen, have become the recognised attribute of science professorships throughout the world; but the corresponding laboratories for literature and philosophy are with us entirely wanting. No doubt the work is done here in a less organised and different way, but the institution of organised and properly equipped *Seminars* would be an important advantage to the literary, philosophical, and other departments of our universities. The second advantage referred to possessed by the German university is the character of the leaving examination of the secondary school. It corresponds to our matriculation examination, with the added knowledge acquired by about two years' university study in arts, and its acceptance by the university as evidence of sufficient knowledge for matriculation relieves the university of that most unfortunate practice, so common here, of giving the student an examination as his first experience on entering. The student in "Faust" who said, "Zwar weiss ich viel, doch möchte ich Alles wissen," would have been surprised

had his first experience been an examination. The higher matriculation standard in Germany, and the fact that the German student is older—the average age is twenty to twenty-five years—on entering the university, must be borne in mind when comparisons are made as to the proper time for specialisation and research to commence.

If we desire to rival the work of the German universities, we should seriously attempt the better organisation and coordination of our entire educational system. One might imagine a trunk railway with stopping-places and branches. The trunk line might represent pure science, literature, and philosophy, and be always extending itself further; the stopping-places to where the scholars or students branch off to apply their training to livelihood occupations. Where exactly these stopping-places should be placed should be fixed after careful deliberation. Most would branch off for the arts and crafts from the primary school; most of the remainder would branch off after the secondary school; a small proportion would enter the university, branching off for the professions at places decided upon. Encouragement to enter the university should only be given after careful consideration. Far too many men nowadays are painfully struggling against nature in the university, to the detriment of the occupations for which nature really equipped them. Even in the German Empire only 13 out of every 1000 of the male population enter the university.

The *Times*, in a recent leading article, says:—"Germany has built up a chemical industry, worth tens of millions of pounds annually, through the agency of research chemists, methodically trained in her numerous technical schools." This is quite true; but there is one further requirement that must be mentioned: German manufacturers know the value, in dividends, of the services of trained research chemists; Irish and English manufacturers do not; and no matter how many and how well trained our university students become, the effect on the country's industries will be small unless they find suitable fields of operation. This is a serious and fundamental question which might well be taken up by industrial improvement movements and by anyone who has the ear of the public.

RECENT DEVELOPMENTS IN TELEGRAPHY AND TELEPHONY.¹

FOR many years the simple form of Morse apparatus or its equivalents served the requirements of most countries, but as the telegraph service grew and the traffic rendered it imperative to erect long lines directly connecting distant cities, the problem of obtaining a greater revenue from the large capital expenditure involved became pressing, and progress was made broadly on three distinct lines of development. In the first, means were designed for the transmission of several messages simultaneously over the same conductor; in the second, by the use of suitable mechanical and electrical devices, the actual speed of transmission was raised in overhead wires to ten or twelve times that possible by manual operating, and, finally, type printing and writing systems were invented with varying degrees of success.

A method which in theory admits of sending as many as twelve simultaneous messages in one direction, or double that number if duplexed, depends on the superposition of musical vibrations on a telegraphic circuit at one end of a line. To effect this result, a number of electrically driven tuning-forks, arranged to vibrate at different frequencies, are connected through telegraphic keys to a line wire, so that on depressing any one key a series of electrical vibrations, of the frequency of its companion tuning-fork, are sent through the line. At the far end the receivers are of a type that will respond to musical vibrations only, and each receiver is constructed or adjusted to respond to the vibrations of one of the distant tuning-forks alone, and to no others. If any one key is depressed a simple musical oscillation traverses the line, and the receiver in tune responds. If two or more keys, however, are depressed simultaneously, a series of compound curves is transmitted, and those receivers that are in tune with the various components of the curves respond, and all the

others remain unaffected. This system originated in America, but it has been developed and improved by Mercardier in France, where it is said to have given good results recently. In the modern apparatus the receivers consist of so-called mono-telephones, each of which is so made and adjusted as to respond to only one frequency.

The second method of increasing the output of telegraphic wires is the automatic or machine-transmitting instrument, which is typified by the Wheatstone apparatus adopted and perfected by the Post Office in Great Britain. In all instruments of this character a long paper ribbon is perforated by a suitable machine in an arbitrary manner, and the transmitting and receiving apparatus is so designed as to transcribe these perforations, at the distant end, into Morse signals, into similar perforations, into type-printed messages, or even into written characters.

This Wheatstone system has been very fully developed in the United Kingdom. It is capable of dealing with traffic at a maximum rate of 450 words per minute, and it is invaluable for the transmission of news. Thus, in the central office in London, items of news may have to be transmitted to fifty or more towns simultaneously. Circuits are made up for news transmission, each providing for a number of towns, some of the circuits being of a permanent character and some formed temporarily to meet special requirements. As many as eight Wheatstone-slips can be punched simultaneously in one operation, and each length of slip is run through the necessary transmitters at the highest speed considered judicious. When long Press messages are received they are divided into sections, and each section handed to a separate telegraphist for perforating, so that the transmitting apparatus can be kept to its maximum capacity. Without this useful and adaptable apparatus, it would be almost impossible to deal satisfactorily with the vast amount of news traffic which is sent daily to every town in the country.

For ordinary public message traffic on lines of moderate length, where each individual message is short, the Wheatstone has certain disadvantages, namely, the initial delay in perforating the slip, its distribution, and, finally, the re-distribution of the received slip amongst the writing telegraphists, for it is obvious that at the high speed at which Wheatstone is worked, several operators are required at each end of the line to keep pace with the apparatus. In practice in this country, for circuits of moderate length it is generally considered preferable to provide direct Morse apparatus worked simplex, duplex, or quadruplex, as circumstances may dictate.

With overhead lines the limit of speed in automatic working is that imposed by the receiving apparatus, which, owing to its self-induction, obstructs the reception of Morse signals at a higher speed than that named. This difficulty has been overcome by substituting a chemical for an electromagnet receiver. In this form the current at the received end passes through a long paper ribbon saturated with a solution which is decomposed by a positive current. The Morse signals appear in blue lines on the received slip.

It is said that with this method a maximum speed of 1000 to 1200 words is possible under favourable conditions, but the difficulty in working at such high speeds, where characters are received in Morse code and have to be transcribed manually, is the division and distribution of the slips amongst the large number of writers necessary to keep abreast of the work, the precautions needed to avoid loss of messages, the injurious effect of brief contacts caused by workmen, which result in the loss of several words, and last, but not least, the difficulty and delay in obtaining repetitions where errors, false signals, or missing words render this necessary.

All the foregoing methods increase the carrying capacity of the wires; in other words, they reduce the capital expenditure per message, but none of these increase the output per operator, nor do they diminish the working cost in the instrument-room; in fact, with high-speed automatic transmission this cost may be higher than with other methods described. The messages have to be prepared by the perforation of the punched slip, telegraphists have to control the sending and receiving apparatus, and the Morse slips, as they are reeled off the receiving apparatus, have to be divided and distributed amongst a number of operators for transcription. The initial pre-

¹ From the "James Forrest" Lecture, delivered before the Institution of Civil Engineers on June 22 by Sir John Gavey, C.B.

paration of the transmitting slip will always, of course, be necessary in all automatic systems, but inventors have turned their attention to increasing the speed and reducing the cost of transcription at the received end, in the case of manual as well as automatic sending, by the substitution of typing apparatus worked mechanically or electrically for the manual transcription. A very considerable number of instruments has been designed to achieve this end, but one of the earliest, which has met with permanent success, and by means of which a very large proportion of the work in Europe and nearly the whole of the Transcontinental work is dealt with, is the well-known Hughes's type-printing instrument.

The Hughes method of transmission has many advantages. It provides a clearly typed message for delivery instead of a written one, it removes a possible source of error in transcription, and it increases the speed of working as compared with Morse by about 25 per cent. It can be duplexed, and it is used by the Post Office on all its Continental wires. It has, however, the disadvantage that a considerable interval of time elapses between the transmission of two consecutive signals owing to the revolving arm having to traverse all the intervening letters. Baudot has obviated this waste of time by adopting the multiple system of telegraphy. He entirely abandons the Hughes method of transmission, and he forms an arbitrary signal code which, by means of five consecutive currents, some plus, some minus, in combination, he represents each letter of the alphabet, figures, or other signals. By his method he can provide four or six channels simultaneously on one wire, each being worked manually.

The Baudot system admits of the transmission of a much larger number of messages over each wire than the Hughes. It is also more flexible, inasmuch as the various channels it provides can be divided amongst an equal number of towns; thus Paris can use two channels to Lyons and two to Marseilles over a Paris-Lyons circuit extended from Marseilles, and so on. It is largely used in France, and has been introduced into this country.

It will have been observed from the foregoing that there are three distinct methods of telegraphic transmission with which we are mainly concerned to-night, although others might be mentioned. In the first, an arbitrary code of signals is repeated in similar arbitrary signals by which the alphabet is artificially represented, and the message is read by a skilled operator; in the second, what may be termed the dial type of apparatus is used, where two type-wheels, either moved mechanically or electrically, revolve isochronously, and they may either show fleeting letters or print them in permanent characters; and in the third, an arbitrary set of electrical signals is devised which actuates specially designed apparatus which may reproduce the message in legible characters, printed, or even written. The third method has been utilised by various inventors and applied to automatic transmission, so as to dispense with manual transcription at the receiving station.

In all cases a paper ribbon or slip is perforated by punches generally actuated by a specially designed type-writer keyboard, in which the depression of any key causes a series of perforators representing the arbitrary combination of the corresponding letter to appear on the slip. This is passed through an automatic transmitter; the electrical currents corresponding with the perforators are transmitted over the circuit, and the distant apparatus actuated.

Murray has devised a system which has undergone lengthy trials both at home and abroad. His slip has one row of perforations which gears into the moving mechanism of the transmitter, and below this a second series of perforations which represent his artificial signalling code, which is of the Baudot type. At the receiving apparatus an exact counterpart of the transmitted slip with its perforations is reproduced, and this perforated slip is passed through and actuates an automatic type-writer, which prints the message.

Creed has worked in the same direction, but he uses the ordinary Wheatstone alphabet already described, and, of course, the Wheatstone transmitter. At the receiving end a perforated Wheatstone slip is reproduced by a punching machine, which, controlled by the reverse currents from

the transmitter, and, using compressed air as a motive-power, perforates the received slip at considerable speed. This slip is then passed through an automatic type-writer adapted to work with the Wheatstone alphabet, which types the message on a long slip, to be gummed on the telegraph form. In both these cases the received slip can be inserted in a second automatic transmitter and the message sent on to another town—an advantage in the transmission of news, which frequently has to be redistributed from large provincial centres to other towns having no direct communication with London. Both these systems are in use in the British Post Office.

Siemens and Halske in Berlin have devised an automatic system in which, by means of suitable apparatus, the message is printed by the receiving apparatus direct by photographic methods.

Writing telegraphs, based on the fact that two ordinates at right angles to one another can be made to describe any curve, have been designed. The telewriter, in which the pen is connected to two arms which follow the movements of the writer, and which in doing so pass over varying resistances and transmit to line currents of varying strength, is well known. At the receiving end two pivoted electromagnets, placed in a very powerful magnetic field, are deflected over arcs dependent on the strength of the current circulating at any moment. Two arms at right angles to one another are connected to the transcribing pen, one arm being pivoted to each magnet, and the writer's movements are reproduced.

There is only time to refer briefly to the beautiful writing apparatus designed by Pollak and Virag. In this a slip is perforated by suitable means with nine rows of holes of varying sizes; suitable flexible brushes make contact through these holes between batteries and the line wires, and thus cause currents of different electromotive forces and duration to circulate over the line, and to act on two telephone receivers at right angles to one another. Rays of light are reflected from one to the other and on to a photographic slip, and the written messages, which can be transmitted at 600 to 1000 words a minute, appear developed and fixed on the sensitised paper which emerges from the dark closet of the apparatus.

Submarine telegraphy is not susceptible of the many developments that have been possible with land-lines. The high electrostatic capacity, varying from 0.3 to 0.4 microfarad per mile, and the very long lengths that are necessary to connect the great continents of the world, rendering the use of any but the most delicate apparatus impossible on long cables. The receiving instruments originally invented by the late Lord Kelvin; then Sir William Thomson, are still the only apparatus available for the reception of messages on long Transcontinental cables, and so far it has not been found possible to increase materially the speed of working except, of course, by increasing the dimensions and cost proportionately.

In ordinary telegraphy, when transmitting through an overhead line, the frequency of the current alternations is only 180 per second for 450 words per minute, and the current has actuated the apparatus at the further end before the battery connection has ceased. Another condition, however, is introduced when a conductor is used for telephonic speech in which a maximum frequency of 1800 to 2000 vibrations per second has to be dealt with. In these cases the transmission from the telephone assumes complex wave-forms, and the effect of even a moderate capacity becomes far more marked than in the case of telegraphic transmission. If a simple wave impulse were emitted in a circuit containing neither capacity nor inductance it would maintain its form, and it would only lose in amplitude owing to the waste of energy in heating the conductor. With much capacity in the circuit, however, the wave tends to elongate, and if the capacity be sufficiently great and the line sufficiently long, the following wave overtakes the lagging tail of the previous one; they blend more or less together, and having lost their distinctive character they fail to impress on the receiving telephone the distinct character of the sound from which they emanate.

The loss of the overtones means diminution of the timbre of the voice; in other words, through speech may still be possible, but the voice ultimately becomes less recognisable until, when a certain limit is passed, if the

resistance of the conductor be not too great, it may degenerate into a low-toned imitation of speech, or with the smaller conductors which are used for city work the attenuation rapidly lowers the volume of sound until it becomes unrecognisable. Self-induction is the analogue of inertia in mechanics; therefore, if it were possible to endow the circuit in which a wave was in movement with sufficient self-induction to prevent the tailing and consequent distortion of its form, the limit of speech would be materially increased, as the attenuation due to resistance alone would have to be provided for. Now it is possible to achieve this result to a certain extent by adding artificially to the self-induction of telephone cables, technically termed loading. The ideal method would be to increase the self-induction uniformly throughout, and attempts have been made to effect this by lapping a copper conductor with thin iron wire or tape of a high magnetic permeability. Another method consists in distributing magnetic coils at uniform distances of a mile or two apart throughout the length of the line. Under these conditions the distance over which speech is possible has been increased from two and a half to three and a half times.

The British Post Office has recently laid a cable with distributed inductance between England and France which will increase the range of speech about four times as compared with a similar type of unloaded cable.

The rapid and enormous development of the telephone service that has taken place throughout the world within the last few years is a remarkable achievement of the electrical engineer. The principle of the microphone, which converts sound vibrations into electrical vibrations, and of the telephone, which re-converts the electrical into sound vibrations, are so well known that I need not dwell further on the subject than to point out that Graham Bell's telephone, as it left his hands in 1876, is essentially the same instrument, slightly improved in mechanical construction, as he gave it to the world, but all the other adjuncts of a complete telephone service have been profoundly modified, and we are not yet in sight of finality.

In the period during which the ordinary telephone equipment has undergone modifications, inventors have turned their attention to the design and perfection of an automatic telephone in which each subscriber, by a simple method of manipulation, may without the intervention of an operator at the exchange obtain direct access to any other subscriber connected with the service. One of the earliest systems of this type was known as the Strowger. Each subscriber's line terminates on a line switch which forms part of a group of 100 switches. This switch is connected by ten circuits, the equivalent of the plugs and cords in a manual board, with a series of selectors each accommodating 100 junction lines. According to the size of the exchange, there may be two or three sets of selectors connected similarly by means of junction circuits, and, finally, there is a connector, a somewhat similar instrument, which makes the connection between the two subscribers.

Each telephone has a dial with finger holes and numbers. On removing the telephone from the hook the procedure is as follows. If, say, No. 4852 is wanted, the caller inserts his finger in hole 4 and revolves the dial up to the limiting stop. This actuates the line switch, which causes a connecting plug to enter the springs of the first disengaged junction leading to the selector group of 4000. The same action follows in sequence with 8, 5, and 2, the final movement of the connector making the connection if the required subscriber is disengaged. If he be through to another a busy back signal (a vibratory current) is given. When the connection is made and the conversation is complete, the hanging up of the telephones restores the connections to the normal. This method has had considerable development amongst the independent telephone companies in America.

On the subject of the future development of telegraphs and telephones, few of those acquainted with the subject would venture to dogmatise, but certain statistics I have prepared will convey to you possibilities far more pregnant than any amount of speculation. The following figures, for the years 1902 and 1907 respectively, have been gathered from authentic returns, and they embrace information from every country of importance throughout the world:—

Telegraph and Telephone Statistics—Wire Mileage.

Telegraphs		1902	1907	Increase
Land wires	...	3,659,659	5,038,981	1,379,322
Submarine cables	...	212,894	259,000	46,106=21.6%
Telephones				
Wire	...	7,467,417	10,839,537	12,372,120
Subscribers' stations	...	3,534,036	8,406,336	4,873,300

Large figures frequently fail to impress the mind, but when it is stated that this mileage of wire will soon, if it has not by this time, equal one-third the distance from the earth to the sun, the remarkable activity of the modern telegraph and telephone service will perhaps be more forcibly realised.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The engineering department is losing the services of Mr. F. H. Hummel, lecturer in civil engineering, who has accepted the chair of engineering at Belfast, and of Dr. J. D. Coales, lecturer in electrical engineering, who has been appointed principal of the Wolverhampton Technical School.

CAMBRIDGE.—The observatory syndicate, in a report to the Senate on the Huggins dome and the astrophysical building, state that the buildings now erected may be regarded as consisting of two parts, though for the sake of economy in construction they are structurally blended. The first part consists of a dome 23½ feet in diameter, together with a small room for accessory apparatus and a room for any observer who may be making use of the Huggins instruments installed in the dome. These are to be called the Huggins dome and the Huggins observer's room. The second part—the astrophysical building—comprises a computing room, which also serves as a library, and a small room appropriated to the use of the head of the department. The Huggins instruments are now ready for adjustment and use.

The Goldsmiths' Company have given 700*l.* for the equipment of the metallurgical department of the chemical laboratory.

The prize of 50*l.* out of the Gordon Wigan fund for a research in chemistry has been awarded to Mr. J. Thomas, Trinity, for experimental investigations on "The Isolation of the Aromatic Sulphinic Acids" and "The Resolution of Externally Compensated Quinoline Derivatives containing Two Asymmetric Carbon Atoms."

Mr. W. F. Penée, of the Indian Forestry Service, will deliver a course of lectures on Indian forestry during the Michaelmas term of 1910.

OXFORD.—The next award for the Radcliffe prize will be made in March, 1911. The prize, which is of the value of 50*l.*, is awarded by the master and fellows of University College every second year for research in any branch of medical science comprised under the following heads:—human anatomy, physiology, pharmacology, pathology, medicine, surgery, obstetrics, gynaecology, forensic medicine, hygiene. The prize is open to all graduates of the University who shall have proceeded or shall be proceeding to a medical degree in the University. Candidates must not have exceeded twelve years from the date of passing the last examination for the degree of B.A., and must not, at the date of application, be fellows on the foundation of Dr. John Radcliffe. The memoirs must be sent to the University Registry on or before December 1.

The Rolleston memorial prize, the value of which is 60*l.*, will be awarded in Easter or Trinity term, 1912. The prize is open to such members of the Universities of Oxford and Cambridge as will not have exceeded ten years from the date of their matriculation on March 31, 1912, and is to be awarded for original research in any subject comprised under the following heads:—animal and vegetable morphology, physiology and pathology, and anthropology, to be selected by the candidates themselves. Candidates wishing to compete should forward their memoirs to the registrar of the University before March 31, 1912. The memoirs should be inscribed "Rolleston Memorial Essay," and should each bear the name and address of the author. They may be printed or in manuscript, memoirs already published being admitted to the competition.

The electors have appointed Mr. Raphael Meldola, F.R.S., professor of chemistry in Finsbury Technical College, City and Guilds of London Institute, to deliver the Herbert Spencer lecture in the course of next Michaelmas term. No more appropriate selection could have been made than that of Prof. Meldola, whose wide range of scientific knowledge and interest, extending far beyond the bounds of his special subject, and whose well-known sympathy with everything which can tend to further the progress and popularise the results of physical and biological research, justify the expectation that his lecture will be of exceptional interest and value. The subject and date of the lecture will be announced later.

Mr. Selwyn Image, who has recently been elected to the Slade professorship of fine art, is well known to naturalists as a keen student and collector of the British Lepidoptera. He is a Fellow of the Entomological Society of London, and is at present serving on the council of that society.

The delegates of the common university fund propose shortly to appoint a reader in social anthropology.

At the tercentenary festival of Wadham College, held on June 23, allusion was made both by Lord Curzon and by Sir Archibald Geikie to the connection of the college with the early history of the Royal Society. The latter speaker gave it as his opinion that but for Dr. John Wilkins, the warden of Wadham, under whose auspices the Oxford meetings of "the association of certain worthy persons inquisitive in Natural Philosophy" (Walter) began about 1648 or 1649, the Royal Society might never have come into existence.

SHEFFIELD.—Dr. J. Robinson has been appointed junior lecturer and demonstrator in physics, and Mr. J. Miller assistant in the architectural department.

MR. H. S. JACKSON, research assistant in plant pathology at the Oregon Agricultural Experiment Station, has been appointed professor of botany and plant pathology in the Oregon Agricultural College.

THE Speech Day of the Merchant Venturers' Technical College, Bristol, will be Friday, July 22, when Colonel F. C. Ord, C.B., the master of the Society of Merchant Venturers, will distribute the prizes.

DR. H. S. JENNINGS, hitherto professor of experimental zoology at the Johns Hopkins University, has been appointed professor of zoology and director of the biological laboratory of the same University, in succession to the late Prof. W. K. Brooks.

THE Cleveland College of Physicians, now the medical department of Ohio Wesleyan University, is to be consolidated with the medical department of Western Reserve University at the close of the present college year. Mr. H. M. Hanna has given the sum of 50,000*l.* as an additional endowment fund for the medical department.

It is announced in *Science* that two more industrial fellowships for the investigation of the diseases of plants (making four in all) have been established in the New York State College of Agriculture. They are to be known respectively as the Herman Frasch fellowship and the John Davey fellowship. The first-named provides for the investigation of the use of dry sulphur as a fungicide both to the plants and in the soil, and the second provides for the investigation of heart-rot of trees.

A NEW University for Natal is, says the *Westminster Gazette*, to be opened formally in August next. It is anticipated that a large number of students will be enrolled at once. Under the South Africa Act of Union the University will come under the jurisdiction of the Union Government, while education, other than higher education, will be vested in the Provincial Council for a period of at least five years. The Act establishing the University provides that instruction shall be given in classics, literature, law, science and art, and other studies. Designs for a handsome building have been approved by the Natal Government. Already Mr. W. N. Roseveare has been appointed professor of mathematics and Mr. Bews professor of botany and geology.

THE Rural Education Conference, which has been constituted by the Presidents of the Board of Agriculture and

Fisheries and the Board of Education, for the discussion of all questions connected with education in rural districts, and for the periodical exchange of views between representative agriculturists and the two departments, will be composed as follows:—Lord Moreton, Lord Barnard, the Right Hon. Lord Belper, the Right Hon. Lord Reay, G.C.S.I., G.C.I.E., the Right Hon. A. H. Dyke Acland, the Right Hon. H. Hobhouse, Sir Francis A. Channing, Bart., M.P., Sir A. K. Rollit, Major P. G. Craigie, C.B., Mr. Graham Balfour, Mr. C. Bathurst, M.P., Mr. G. A. Bellwood, Mr. J. F. Blackshaw, Mr. W. F. Brockholes, Mr. G. G. Butler, Mr. A. W. Chapman, Mr. F. J. Chittenden, Mr. S. H. Cowper-Coles, Mr. D. Davies, M.P., Major J. W. Dent, Mr. H. J. Elwes, F.R.S., Prof. W. R. Fisher, Mr. P. Hedworth Foulkes, Mr. W. J. Grant, Mr. A. D. Hall, F.R.S., Mr. W. A. Haviland, Prof. C. Bryner Jones, Mr. T. Latham, Mr. J. L. Luddington, Mr. H. Martin, Mr. E. Mathews, Rev. R. Meyer, Mr. W. Parlour, Mr. C. N. P. Phipps, Mr. J. H. Sabin, Mr. A. F. Somerville, Prof. W. Somerville, Mr. A. E. Bromehead-Soulby, Mr. C. Turnor, Mr. F. Verney, M.P., Prof. T. Winter, and Prof. T. B. Wood. The Right Hon. H. Hobhouse will act as chairman of the conference, and Mr. E. G. Howarth, of the Board of Education, and Mr. H. L. French, of the Board of Agriculture and Fisheries, will act as joint secretaries.

ON May 28, at the Regent Street Polytechnic, London, Mr. Blair (education officer to the London County Council) gave an address on "The Newer Education" to the members of the Federated Associations of London Non-primary Teachers. Mr. Blair said that the adverse criticisms sometimes passed on the results of modern elementary education arise from ignorance of the progress that has really been made in this direction during the last fifty years. There is now hardly an illiterate person in the country, and, moreover, the facts that crime has decreased, that sanitary conditions have improved, that the death-rate has fallen, and that the funds of savings banks and provident societies show a steady increase, must all be attributed indirectly to the work done in elementary schools. We were in this respect far ahead of Germany. An important part of the recent work of the London County Council has been the institution of its scheme of scholarships for children fit to pass from the elementary to the secondary schools. The full development of this scheme is yet to come, for there is a distinct need that the child, leaving the secondary school at the age of sixteen and not wishing to take up elementary-school teaching, shall have some course of definite technical training. So far as wage-earning capacity is concerned, boys and girls leaving secondary schools at this age are in no better position than children leaving the elementary schools at the age of fourteen. After reading certain examiners' reports referring to the unsatisfactory work in some secondary schools, Mr. Blair stated that there is still a tendency for this work to be too academic in character, and he urged that secondary-school teachers must strive to correlate their teaching with the facts of life, and remember that upon them falls a large part of the responsibility for training the child for its future duties as a citizen of the Empire. Some statesmen consider that before long we may be called upon to meet a serious national emergency, and the way in which we shall do this will depend on the work of the teachers both in the elementary and in the secondary schools.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 23.—Mr. A. B. Kempe, vice-president and treasurer, in the chair.—A. Mallock: Damping of sound by frothy liquids. The object of the note is (1) to explain the well-known fact that a vessel which, when empty or filled with a homogeneous liquid, gives a musical note when struck, ceases to do so when the liquid contains bubbles of gas; (2) to direct attention to the fundamental difference between the damping of waves propagated through a gas containing spheres of liquid (e.g. rain or fog), and that which occurs in a liquid containing bubbles of gas. The damping of sound waves by fog has received considerable attention, and it has been shown that although

presence of liquid particles does cause a certain amount of dissipation, loss of energy is small, and this agrees with observation. On the other hand, with a liquid containing bubbles, damping of vibration is excessive, practically the whole of the wave energy being dissipated in a few wavelengths or periods. When spheres of liquids are disseminated in a gas, compressions and dilations take place in the latter much as if only the gas were present, and the increased dissipation is due to slight modification in the motion of the gas, brought about by the liquid spheres. In the converse case, when bubbles of gas are disseminated through a liquid, variation of volume consequent on the passage of a wave takes place almost entirely in the gas, and distortion of the liquid about the bubbles of whose volume is the variable introduces a rate of dissipation of a different and larger order. It is pointed out that in a mixture of liquid and gas (in the form of bubbles) the velocity of wave propagation is less than that in either constituent alone, and has a minimum when the proportion of gas to liquid has a certain value. If the mixture consists of air and water, minimum velocity of propagation is reached when the volumes of air and water are nearly equal, and is then about one-fourteenth the velocity of sound in air. When the volume ratio of gas to liquid exceeds a certain limit, depending on the order in which the bubbles are arranged, the latter cannot remain spherical, and the mixture then becomes a froth, or collection of air cells separated by thin liquid walls. It is shown by experiment that such froth is a very effective agent in damping vibrations.—Prof. P. V. **Bovan**: The dispersion of light by potassium vapour. The work described in this paper was an attempt to measure quantitatively the amount of dispersion in the vapour of potassium. Dispersion takes place in the vapour chiefly on account of the red absorption lines, but is also to a smaller extent due to other lines of the principal series. Measurements were made showing dispersion affected by the first six pairs of lines of the principal series, and an effect could just be detected at the next pair of lines. The dispersion was found to fit a Sellmeier formula, and values for four of the constants for this formula were obtained. On theoretical grounds we can conclude, from the relative values of the constants of the dispersion formula, that the number of atoms taking part in the absorption of the light after the first pair of lines must be only a small fraction of the total number present in the vapour, and that this fraction decreases with the number of lines in the series. It is suggested that the explanation of series lines must therefore be looked for in systems which are not the atom pure and simple, but probably atoms to which a corpuscle or more than one corpuscle become attached. Several types of quasi compounds may thus be formed in a way suggested by Sir J. J. Thomson, and the periods commonly associated with the atoms may be the periods of these systems. Our conception of the atom may be thus considerably simplified, as the number of degrees of freedom for each individual atom may be diminished very largely if this view be the true one.—J. W. **Gifford**: Additional refractive indices of quartz, vitreous silica, calcite, and fluorite.—J. Ivon **Graham**: The absorption spectra of sulphur vapour at different temperatures and pressures, and their relation to the molecular complexity of this element. The absorption spectra were photographed at temperatures varying from 530° C. up to 900° C., at atmospheric pressure, and at constant temperatures, under pressures between atmospheric and 10 mm. of mercury. The photographs at constant pressure with the above variation of temperature show the presence of two distinct absorption spectra; these are attributed to the intramolecular vibrations of the S_8 and S_2 complexes respectively, the former producing a series of absorption bands between $n(=\lambda^{-1})$ 2000 and n 2600, with mean position of maximum absorption about n 2500, whilst the relatively lighter S_2 molecular system, by taking up vibrations of greater frequencies, produces a series of bands lying between n 2900 and n 3820, with mean position of maximum absorption about n 3750. Since only two distinct spectra are evident, it is concluded that the equation $S_8=4S_2$ represents the sole reaction that occurs in the dissociation of sulphur vapour on heating from its boiling point up to 900° C. The interpretation of the photographs of the absorption spectra of the vapour at different (con-

stant) temperatures, but with reduction of pressure, indicates that above 580° C. the dissociation of the molecule S_8 is simple, that is, there is direct dissociation into S_2 complexes, but at or below 520° C. the dissociation takes place with the formation of molecules intermediate in complexity between the above two aggregates. The position of maximum absorption of each band is towards the more refrangible edge, whilst the individual bands of each series appear to become stronger, also in the more refrangible direction. The two series of bands are shown mapped in oscillation frequencies, the similarity between the series being much more evident when illustrated in this manner. Reproductions of photographs also accompany the paper.—Dr. T. H. **Havelock**: The wave-making resistance of ships: a study of certain series of model experiments. In a previous paper (Proceedings, A, vol. lxxxii., p. 276, 1909) the author discussed the variation of the wave-making resistance of a ship with its speed, and a formula was obtained by specifying the action of a ship in terms of a simple equivalent pressure distribution travelling over the surface. The present investigation is a more systematic study of some of the coefficients of the formula, the experimental data being taken from published records of tank experiments with models. The discussion is limited to types for which the resistance-velocity curve shows clearly the humps and hollows which are usually ascribed to interference of wave systems originating at the bow and stern; the tabulated results form a numerical study of the latter theory, and exhibit the variation of the coefficients of the simple equivalent pressure system with the displacement of the model, the proportion of parallel middle body, and various coefficients of fineness. Without attempting to express the coefficients by empirical formulae, sufficient information is available to allow of an approximate estimate of their values in similar models; this is illustrated by the *Turbinia*, and the result is discussed in relation to the published record of trials of that vessel. The characteristic interference effect mentioned above appears to occur specially in rather full-ended models, with fairly high cylindrical coefficients; in this case it is permissible to regard the equivalent pressure system as having two parts associated with the bow and the stern respectively. An examination of models with finer ends suggests that this simple interference theory is inadequate in certain cases; the study of a modified type of pressure distribution is indicated.—Dr. Georges **Droyer** and W. **Ray**: The blood volume of mammals as determined by experiments upon rabbits, guinea-pigs, and mice, and its relationship to the body weight and to the surface area expressed in a formula. The blood volume of animals has for many years been the subject of numerous investigations. This is but natural considering its great importance for the study of disease. As, however, the results obtained are very discordant, the authors have determined the blood volumes of rabbits, guinea-pigs, and mice by Welcker's method, by washing out the circulatory system and by following the percentage fall of hæmoglobin after bleeding. The experiments of the authors have given the following results:—(1) The blood volume of living mammals can be determined very accurately by bleeding the animal (about 20 per cent. of its original blood volume) and determining the percentage fall of hæmoglobin at the moment when equilibrium is reached. This method gives results remarkably concordant with those obtained by washing out the circulatory system. In employing this method it is absolutely essential that the animals should not have been bled before. (2) In normal healthy mammals (rabbit, guinea-pig, and mouse) the blood volume is satisfactorily expressed by the following formula, $B=W^{1/k}$, where B is the blood volume in cubic centimetres, W the weight of the individual in grams, and k a constant to be ascertained for each particular species of animal. This formula indicates that the smaller animals of any given species, which have a relatively greater body surface than heavier ones, have also a relatively greater blood volume. That is to say, the blood volume can be expressed as a function of the surface area. It is therefore misleading to express the blood volume as percentage of the body weight, as has hitherto been invariably done. (3) The constant k , by means of which the blood volume in cubic centimetres can be calculated from the formula $B=W^{1/k}$ when the weight of the animal in grams is known, is approximately,

for rabbit, 1.58; guinea-pig, 3.30; mouse, 6.70.—**E. C. Hort:** Autotoxæmia and infection. The object of this communication is to show that fever, loss of weight, and changes in the antitryptic values of the blood serum, three phenomena common to bacterial and protozoan infection in man, can be reproduced in animals by the subcutaneous injection of small quantities of distilled water. Elaborate controls were set up throughout, and absence of sepsis repeatedly proved by autopsy and by microscopical sections. **Fever.**—Sixty guinea-pigs received single injections of boiled distilled water in quantities varying from 1 to 10 c.cm. Fever resulted in fifty. Thirty guinea-pigs received multiple injections, always followed by fever except when the injections were too closely crowded, or too large, when subnormal temperatures resulted. Twelve rabbits received single injections varying from 10 to 60 c.cm. Fever followed in all. Ten rabbits received multiple injections. All showed fever. Fever after each injection was always rapid in onset, abrupt and fugitive in both guinea-pig and rabbit. By appropriate spacing of injections continuous fever can be produced, ceasing with the injections. Hypersensitisation was frequently observed. Establishment of a constant between weight of injection, animal injected, and degree of fever induced has been so far impossible. **Weight.**—The effect of small single injections was inconclusive. Multiple injections always produced marked loss, recovery ensuing on discontinuance of injections if few in number. **Antitryptic values.**—Multiple injections produced marked rise in values, strikingly parallel in gross effect to the rise produced in the same species of animal by single injections of diphtheria toxin, or of emulsions of living bacteria. From these experiments it would appear that however great the share taken by bacteria and protozoa in initiating the disease-complex of infection, the net result is, perhaps to a large extent, a state of true auto-intoxication. The results obtained suggest that such auto-intoxication is in part directly due to absorption of derivatives of the infected cells themselves, and only indirectly to the absorption of bacterial products.

Physical Society, June 10.—**Prof. H. L. Callendar**, F.R.S., president, in the chair.—**Dr. W. E. Sumner** and **W. C. S. Phillips:** A galvanometer for alternating current circuits. The galvanometer described is the result of an attempt to construct a measuring instrument by means of which inductances and capacities can be compared by bridge methods as accurately as it is possible to compare resistances. The instrument is like a moving coil galvanometer in almost every respect, except that its field is due to a specially constructed electromagnet excited by an alternating voltage.—**A. E. Garrett:** Positive electrification due to heating aluminium phosphate. Many of the results obtained, in particular (a) with varying pressures and constant temperatures, (b) at atmospheric pressure in which after removal of all free ions by a field sufficient to produce a saturation current, a current of equal values for ions of both signs was found at an electrode placed behind that on which the saturation voltage acted, and (c) the loss of charge of a Faraday cylinder when screened from the action of free ions, indicate that one of the products due to heating aluminium phosphate is in the form of neutral pairs or doublets which afterwards split up into negative and positive ions.

Royal Anthropological Institute, June 14.—**Prof. Gowland**, past-president, in the chair.—**P. A. Talbot:** The Ekoi of southern Nigeria. The Ekoi dwell by the border of the German Kamerun. Their land, between its maze of rivers, is one stretch of dense "bush," which reaches even to the summit of the hills, of which the greater part of the country consists. The whole existence of the race mirrors the twilight and mystery of the bush, peopled to the native's fancy by strange, half-human shapes, such as were leopards and the genii of trees and rocks. Magic is the keynote on which the lives of the Ekoi turn. Idiong, the practice of divination, is much resorted to, and is clearly connected with ancestor worship, the dominant factor in the religion of the race. The great festival of the year is that of Eja, held at the time of the new yams. Investigations have proved that these rites are almost identical with many of the darker traits of the old Adonis-Attis-Osiris worship. Many beliefs and customs of the Ekoi have come down from remotest

antiquity. They have a marvellous folklore, which at times shows poetic feeling, at others a keen sense of humour. There are legends to explain all customs and beliefs. The land is full of societies, secret and otherwise, the chief of which is the Egbo Club, which ruled the country before the coming of the white man. Though a polygamous people, the chief wife, not the husband, is the head of the house, and women's rights as to property and the custody of children are most strictly safeguarded by native law.

Zoological Society, June 14.—**Dr. S. F. Harmer**, F.R.S., vice-president, in the chair.—**R. I. Pocock:** The cutaneous scent-glands of ruminants. The author pointed out that the structure of the feet, whether furnished with special glands or not, supplied valuable data for classifying the genera of antelopes and deer, and showed that with some modifications, such as the removal of *Tetraceros* from the *Cephalophinae* to the *Tragelophinae*, of *Dorcotragus* from the *Antilopinae* to the *Neotraginae*, and of *Pantholops*, *Saiga*, and *Æpyceros* from the *Antilopinae*, the subfamilies usually admitted were valid groups. In the case of the deer, it was interesting to note that *Rucervus*, *Panolia*, *Elaphurus*, and *Sika* were closely allied to *Cervus*, *Dama* being a totally distinct type. *Axis* and *Hyelaphus* belonged to another group, while *Rangifer*, *Alces*, and *Capreolus*, as Sir Victor Brooke claimed, belonged to the section typified by *Dorcclaphus*, *Mazama*, and other American deer.—**R. Lydekker:** A wapiti and a muntjac. The author described two wapiti antlers from Tibet as *Cervus canadensis wardi*, and a muntjac from An-wei, China, as *Cervulus bridgmani*. The latter was characterised by its dark blackish-olive colour, the black ears of the female and the yellow ones of the male, coupled with the relatively wide divergence of the antler-pedicles.—**R. Lydekker:** Three African buffaloes.—**Dr. A. Cabrera:** Two new antelopes. The author described a new species of *Damaliscus* from British East Africa and a new chamois from north Spain.—**Dr. E. A. Wilson:** Changes of plumage in the red grouse (*Lagopus scoticus*) in health and disease.

PARIS.

Academy of Sciences, June 20.—**M. Émile Picard** in the chair.—**H. Deslandres**, **L. d'Azambuja**, and **V. Euron:** An extraordinary solar filament. A detailed account, with reproductions from photographs, of a filament which appeared on April 11. It had the peculiarity of having large radial velocities, mostly ascending, which at certain points exceeded 100 kilometres per second. The solar disturbance of April 11 was not apparently accompanied with terrestrial magnetic disturbances.—**J. Boussinesq:** The principles of mechanics and their applicability to phenomena which appear to contradict them.—**E. Bouty:** A new measurement of the dielectric cohesion of argon. The determination of the dielectric cohesion of argon is attended with difficulties which do not arise in the case of the other rare gases. For a fixed pressure, for no apparent cause, there are progressive variations in the minimum difference of potential capable of causing the discharge. By making two consecutive measurements rapidly at widely different pressures this difficulty is partly got over. The cohesion of argon was finally found to be practically double that of helium, the gas immediately preceding it in the periodic table.—**A. Chauveau** and **M. Contejean:** The elimination of nitrogenous waste in the act of renal secretion, the subject having been deprived of food. The relation between this elimination and that of water, the vehicle of the urinary excreta. The reciprocal independence of the two phenomena. The amounts of water and urinary nitrogen excreted in the young subject are independent, and hence variations in the quantity of urine secreted, in the course of a series of experimental periods, introduce no difficulties in the significance of the nitrogenous excreta carried away by the urine.—**M. Gouy:** The mutual action of two kathodes in the magnetic field. In high vacua, when the negative charges are connected by the lines of magnetic force, they produce an action of unknown nature, which is shown by a marked lowering of the explosive potential and by the production of the inter-kathodic light.—**M. Nicolau:** The variation in the motion of the moon.—**Edmond Bauer** and **Marcel Moulin:** The luminosity of

the sun and the solar constant. A description of a new method of determining the constant in Stefan's law.—**J. Comas Solá**: A résumé of physical observations made on Halley's comet.—**E. Vessiot**: The integration of complete systems.—**M. Hadamard**: Some properties of Green's function.—**Paul Renard**: A method of causing an aéroplane to pursue a rectilinear path with a minimum expenditure of total work.—**B. Szilard**: An action at a distance on the coherer produced by metallic contacts. Instead of putting one extremity of the coherer to earth, as usual, it is connected with one pole of an alternating current, the other pole being earthed. In this way the sensibility of the coherer is greatly increased, and some applications of the modified coherer are described.—**F. Croze**: The prolongation of the band spectra of carbon gases in the extreme red and infra-red. For carbon monoxide photographs in the infra-red show several bands resembling the bands already known in their structure, and occupying very closely the place predicted according to the known law of distribution. The results with cyanogen were similar.—**Ch. Fabry and H. Buisson**: Some electrical and spectroscopic properties of the arc between metals.—**G. Sagnac**: An interferometer with superposed inverse light rays giving in polarised white light a narrow central fringe and narrow coloured fringes with white interspaces.—**Louis Dunoyer**: A method of measuring a magnetic field in magnitude, direction, and sense.—**L. Houlevigie**: The formation of cathodic deposits. The walls upon which the metallic deposit forms are those possessing a positive charge, allowing the electrical neutralisation of the cathode granules.—**A. Perot**: Some peculiarities of the mercury arc in a vacuum. A study of the distribution of the fall of potential in the arc, together with the demonstration of the existence of an extra pressure at the anode.—**E. Baud and L. Gay**: The temperature of crystallisation of binary mixtures. On the basis of certain assumptions, the lowering of the freezing point is shown to be proportional to the logarithm of the molecular concentration and to the absolute temperature of crystallisation. For very dilute solutions this is equivalent to Raoult's formula. Experimental proofs of the logarithmic formula are given.—**Daniel Berthelot and Henry Gaudechon**: The photochemical synthesis of carbohydrates at the expense of the elements of carbon dioxide and water vapour in the absence of chlorophyll. The photochemical synthesis of quaternary compounds. Various gaseous mixtures were exposed to the action of the rays from a mercury vapour lamp. Carbon dioxide was obtained at the ordinary temperature from a mixture of oxygen and carbon monoxide. Carbon dioxide and hydrogen gave a little CO and formaldehyde; no trace of acid was formed in this reaction. Formamide was produced in the same way from ammonia and carbon monoxide.—**G. Austerweil and G. Cochin**: Some relations between molecular constitution and smell.—**E. Léger**: Crystallised aloinose and its identity with *d*-arabinose.—**H. Arsandaux**: A new contribution to the study of the laterites.—**Raoul Combes**: The best illumination for the development of plants.—**V. Pachon and Em. Perrot**: The cardio-vascular action of green coffee compared with that of corresponding doses of caffeine. The action noted is due to some other agent than caffeine.—**A. Magran**: The influence of the alimentary régime on the intestine in birds.—**G. Seliber**: The coloration of the pigment in two fungi.—**A. Étard and A. Vila**: The analysis of protoplasmic materials. A discussion of the various group reagents which may be used for the separation of the substances present in the liquids resulting from the hydrolysis of protoplasmic materials.—**M. Noel**: The infiltrations on the massif of Zaghouan (Tunis).

DIARY OF SOCIETIES.

THURSDAY, JUNE 30.

ROYAL SOCIETY, at 4.30.—A New Method for the Quantitative Estimation of Hydrocyanic Acid in Vegetable and Animal Tissues: Dr. A. D. Waller, F.R.S.—On the Structure, Development, and Morphological Interpretation of the Pineal Organs and Adjacent Parts of the Brain in the Tuatara (*Sphenodon punctatus*): Prof. A. Dendy, F.R.S.—On the Scattering of Homogeneous β -Rays, and the Number of Electrons contained in the Atom: J. A. Crowther.—On the Spontaneous Crystallisation and the Melting and Freezing Point Curves of Mixtures of Two Substances which form Mixed Crystals and possess a Minimum or Eutectic Freezing Point. Mixtures of Azobenzene and Diphenylamine:

Miss F. Isaac.—On the Determination of the Chief Correlations between Collaterals in the Case of a Simple Mendelian Population Mating at Random: E. C. Snow.—The Propagation of Sound in a Fog: C. J. T. Sewell.—A Determination of the Ratio of Mass to Weight for a Radio-active Substance: L. Southern.—The Relative Atomic Weights of Nitrogen and Sulphur: F. P. Durt and F. L. Usher.—The Relation of Light Perception to Colour Perception: Dr. F. W. Edridge-Green.—The Anatomy and Morphology of the Leaves and Inflorescences of *Welwitschia mirabilis*: Miss M. G. Sykes.—And other papers.

FRIDAY, JULY 1.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology of West Yorkshire, with Special Reference to the District to be Visited during the Long Excursion: Prof. P. F. Kendall.

FRIDAY, JULY 8.

PHYSICAL SOCIETY, at 5.—A Thermo-electric Balance for the Absolute Measurement of Radiation: Prof. H. L. Callendar, F.R.S.—The Convection of Heat from a Body cooled by a Stream of Fluid: Dr. Alexander Russell.—On Hysteresis Loops and Lissajous' Figures, and on the Energy wasted in a Hysteresis Loop: Prof. S. P. Thompson, F.R.S.—The Energy Relations of certain Detectors used in Wireless Telegraphy: Dr. W. H. Eccles.
